1) mostly research instruments with differing ranges, sensitivities and reproducibility
2) strongly depending on capabilities of standard electrical instrumentation

strumentation is not less demanding. The difficulties involved require a careful interpretation of the results.

Table 10.1 gives an overview of the measuring methods described in the subsequent chapters. The techniques are classified according their main application for hard or soft magnetic materials, although some of them may also be applicable in the other group.

Table 10.2 compares the capabilities of various methods. Of course, it can only cover typical configurations and applications and give rough in-

dications. In many cases, the measuring conditions may be adjusted to meet special demands. The magnitude of the quantities, which limit the measuring ranges, can either be determined by the instrumentation or by the requirements resulting from the specimen properties.

The tables can certainly not give a complete survey of all requested quantities and methods that are used today. The selected techniques are common in industrial and scientific research or in quality control.

Some basic methods in magnetic measurement are taken as known. Fluxmeters are used in many measuring set ups to integrate voltages that are induced in measuring coils to obtain the magnetic flux. Today various analog or digital integration methods are used. A discussion of them would exceed the scope of this chapter.

The same applies for field-strength meters that use the Hall effect. These instruments, usually called Gauss- or Teslameters, are widespread. A description of their working principle is given in many educational books.

In many cases it is impossible to determine the material properties of components in a shape that is defined by the production conditions or application. In these cases, relative measuring methods are often applied. These usually compare measurable properties or combinations of properties with those of a reference sample.

Sections 10.2.2 and 10.2.3 focus on methods that provide directly material properties, allow traceable calibrations and are widespread in application. The information is selected to allow an evaluation of the methods. More details are given where errors are liable to be introduced.

Section 10.2.3 is completed by a short description of measuring methods for magnetostriction and, provided by R. Grössinger, nonstandard testing methods for soft magnetic materials that are used in scientific research laboratories.

10.2.2 Properties of Hard Magnetic Materials

Hysteresisgraph for Hard Magnetic Materials

A very important instrument for the characterization of bulk permanent magnets is the hysteresisgraph [S-10-9, S-10-22]. It is mainly used to record the second-quadrant hysteresis loop. From this, material parameters such as the remanence B_r , the maximum energy product $(BH)_{\max}$ and the coercive field strengths (coercivities) H_{cJ} and H_{cB} , can be determined. A measurement of recoil loops allows the calculation of the recoil permeability μ_{rec} .

Main components use an electromagnet to magnetize and demagnetize the specimen, measuring coils for the field strength H and the polarization J and two electronic integrators (fluxmeters) to integrate the voltages induced in the coils. A typical configuration of a computer-controlled hysteresisgraph is shown in Fig. 10.1.

An electromagnet with a vertical magnetic-field direction is used. The magnet specimen is placed on the

Fig. 10.1 Hysteresisgraph for hard magnetic materials. The cabinet contains two fluxmeters for H and J measurement and the electromagnet power supply. The specimen and surrounding coil are placed between the poles of the electromagnet (Permagraph® C Magnet-Physik Dr. Steingroever GmbH, Köln)

pole cap of the lower pole. The upper pole can be lowered to close the magnetic circuit.

While recording the hysteresis loop, high flux densities are only required for relatively short time periods. Therefore it is possible to avoid active cooling of the electromagnet coils up to a peak electric power of approximately 3 kW. If the electromagnet is designed carefully, maximum flux densities of 1500–2400 kA/m can be achieved for specimen heights of several millimeters. Beyond this point, the steel parts of the electromagnet frame become saturated. For a further increase of the field strength significantly higher electric power and water cooling become necessary.

The measuring principle is based on the fact that the poles of the electromagnet form faces of equal magnetic potential. It is only under this condition that the specimen is homogeneously magnetized and the field strength that is measured next to the magnet is equal to its inner field strength. The pole materials (soft magnetic steel or iron-cobalt alloy) and the polarizations of permanent-magnet specimens limit the measuring range of the method to about $H < 800$ kA/m in the first quadrant and $|H| < 2400$ kA/m in the second quadrant of the hysteresis loop.

As it is impossible to saturate rare-earth permanent magnets (Sm-Co, Nd-Fe-B) in an electromagnet, it is necessary to saturate them in a pulsed magnetic field prior to the measurement. Depending on the recoil permeability, the polarization will be lower than the remanence after the specimen has been inserted into the electromagnet and the magnetic circuit has been closed. However, a magnetization in the electromagnet allows full remanence to be achieved again.

Measuring Coils. Two types of measuring coils are used: the J -compensated surrounding coil and the pole-coil measuring system.

The J -compensated surrounding coil (Fig. 10.2) is suitable for all kinds of permanent-magnet materials. For the measurement it is placed around the specimen. It consists of the following windings.

One winding with area-turns of $N_1 A_1$ encloses the inner hole of the coil that accepts the specimen during the measurement. This senses the magnetic flux penetrating the magnet specimen,

$$\Phi_M = B_M N_1 A_M, \quad (10.1)$$

where B_M is the flux density and A_M is the cross-sectional area of the magnet specimen. If the coil is not completely filled by the specimen, the air flux between the specimen and the winding,

$$\Phi_{A1} = \mu_0 H N_1 (A_1 - A_M), \quad (10.2)$$

is also detected, where H is the field strength in air next to the specimen.

A second coil with area-turns $N_2 A_2$ also surrounds the specimen but does not enclose it. This senses only

the air flux,

$$\Phi_{A2} = \mu_0 H N_2 A_2. \quad (10.3)$$

The area-turns of the two coils are adjusted to be equal

$$N_1 A_1 = N_2 A_2. \quad (10.4)$$

Both coils are connected in series opposition to a fluxmeter integrator. If the inner of the first coil is partially filled by a specimen, the magnetic flux measured is

$$\begin{aligned} \Phi &= \Phi_M + \Phi_{A1} - \Phi_{A2} = (B_M - \mu_0 H) N_1 A_M \\ &= J N_1 A_M, \end{aligned} \quad (10.5)$$

where J is the polarization of the specimen, which is connected to the magnetization M by $J = \mu_0 M$. In the absence of a specimen the resulting flux Φ is zero.

Usually the surrounding coil system contains a third coil that senses the magnetic field strength H . It is connected to a second fluxmeter integrator. In this way the $J(H)$ hysteresis loop can be measured directly using one combined-coil system that can be made 1 mm thin. The $B(H)$ hysteresis loop can be derived from the $J(H)$ loop. Figure 10.3 shows the demagnetization curves of different permanent-magnet materials measured using surrounding coils.

Instead of the field measuring coil a Hall probe can also be placed next to the specimen to sense H . This requires additional space for the probe and an additional measuring instrument. Because of the linearity error and the temperature dependence of the sensitivity of a Hall sensor, suitable corrections are necessary. Additional errors can arise from the facts that the Hall probe always

38/10 permanent
magnets

has to be aligned truly perpendicular to the magnetic-field direction and that it is, due to the small active area, more sensitive to local field-strength variations.

The second coil system that is used in hysteresis-graphs is the pole-coil measuring system [10.4]. It is used mainly for hard ferrite magnets. The pole-coil system consists of two coils that are embedded into one pole of the electromagnet (Fig. 10.4). One coil is completely covered by the specimen. The other coil remains free.

The first coil senses the flux density B at the surface of the specimen. The second coil measures the magnetic field strength H . Both coils are connected in series opposition. In this way the polarization, $J = B - \mu_0 H$, is obtained directly. This compensation also cancels out the residual field of the poles before the specimen is inserted.

The surrounding coil measures the whole magnetic flux penetrating the specimen. The pole-coil system only senses the flux in a small area (typically with a diameter of 3–6 mm) on the surface. Therefore it is suitable for the detection of nonhomogeneities in different regions. Especially for anisotropic ferrite magnets it is usual to carry out measurements on both sides of a magnet to quantify differences caused by the production process.

Pole-coil systems are also made arc-shaped for measurements on segment magnets for motor applications. They must be machined to match the radii of the segments exactly. Both the upper and the lower pole contain a pair of pole coils.

Measurements at Elevated Temperatures. For measurements at temperatures up to 200 °C pole caps with built-in heating (Fig. 10.6) can be used [S-10-39]. A hole in the pole cap accepts a thermocouple for temperature measurement and control. Prior to the measurement the specimen must remain between the poles for a sufficient time to reach the desired temperature. The surrounding coil needs to be temperature-proof. Hysteresis measurement is carried out in the same way as at room temperature.

Measurements on Powders. Powder samples can be measured in the same way as solid magnets if the powder is filled into a nonmagnetic container, for example a brass ring that is sealed with a thin adhesive foil at the bottom. As the measured polarization depends on the apparent density, it may be more feasible to regard the specific polarization. The coercivity H_{cJ} however can be measured directly.

Fig. 10.5 Segment poles with pole coils

Vibrating-Sample Magnetometer (VSM)

The **VSM** is used to measure the magnetic moment m and the magnetic dipole moment $j = \mu_0 m$ in the presence of a static or slowly changing external magnetic field [10.5]. As the measurement is carried out in an open magnetic circuit the demagnetization factor of the specimen must be considered.

Most instruments use stationary pick-up coils and a vibrating specimen but arrangements with vibrating coils and rigidly mounted specimens have also been proposed. The drive is either carried out by an electric motor or by a transducer similar to a loudspeaker system.

The specimen is suspended between the poles of the electromagnet and oscillates vertically to the field direction; it must be carefully centered between the pick-up coils.

In the pick-up coils a signal at the vibration frequency is induced. This signal is proportional to the

Fig. 10.6 Heating poles for measurements at elevated temperatures

magnetic dipole moment of the specimen but also to vibration amplitude and frequency. The coil design ensures that it is independent of variations in the field generated by the electromagnet.

The amplitude and frequency can be measured separately, for example using

- a capacitor with one set of fixed plates and one set of movable plates (Fig. 10.7),
- a pick-up coil and a permanent magnet,
- an electro-optical sensing system.

The signals are fed to a differential amplifier, so that changes of oscillation amplitude and frequency can be compensated. A synchronous detector (lock-in amplifier) followed by a low-pass filter produces a direct-current (DC) output signal that only depends on the magnetic moment.

For the generation of the outer magnetic field a strong electromagnet is required; the field direction is horizontal. Water-cooled magnets are mostly used but superconducting magnets are also common. The power required is even higher than for a hysteresisgraph as the

volume between the pole caps is quite large. The specimen rod must be able to oscillate, and sufficient space for a pick-up coil system is required between the specimen holder and the pole caps.

Usually a distance that is sufficient for an optional oven or a cryostat to heat or cool the specimen is chosen. Ovens, LN₂ or helium cryostats that are shaped to fit between electromagnet poles are available. Care must be taken to avoid errors due to magnetic components or electrical supply lines. In this way the determination of Curie temperatures and the observation of other phase transitions become possible.

Figure 10.8 shows measurements on nanocrystalline specimens. Measurement below room temperature was carried out using an LN₂ cryostat. Above room temperature a tubular oven was used; it had a water-cooled outer wall to avoid heating of the pick-up coils and electromagnet poles. The oven can be evacuated or filled by an inert gas to avoid specimen oxidation.

For practical purposes and to separate the mechanical system from building oscillations it is usually mounted onto the electromagnet. This offers a stable

Fig. 10.7 Vibrating-sample magnetometer, 1: oscillator, 2: transducer, 3: capacitor for frequency and amplitude measurement, 4: differential amplifier, 5: synchronous detector, 6: pick-up coils, 7: specimen, 8: H field sensor, e.g. Hall probe, 9: electromagnet poles and coils (frame not shown)

base due to its large mass. For high sensitivity the transfer of oscillations from the drive to the pick-up coils through the electromagnet should be avoided; a mechanical resonator can achieve this. In this case the drive frequency must be matched to the resonant frequency.

A **VSM** is mostly used for measurements on magnetically hard or semi-hard materials. Specimen forms include small bulk samples, powders, melt-spun ribbons and thin films. The **VSM** can also be used for measurements on soft magnetic materials. In this case the electromagnet can be replaced by a Helmholtz-coil system.

VSMs are very sensitive instruments. Commercial systems offer measuring capabilities down to approximately 10^{-9} Am^2 . A system that used a **SQUID** sensor instead of pick-up coils achieved a resolution of 10^{-12} Am^2 [10.6].

Closely related to the **VSM** is the alternating gradient field magnetometer (**AGM**). As it is typically used for measurements on thin films, it is discussed in Sect. 10.4.

Torque Magnetometer

If the magnetization energy of a freely rotating specimen depends on direction, the specimen aligns with its axis of easy magnetization parallel to a magnetic field. The axis of easy magnetization is determined by the magnetocrystalline anisotropy energy E_a if the specimen has rotational symmetry.

If the magnetic field is rotated out of the preferred direction by an angle α , the vector of polarization J_s will point in the direction of H , if the field strength is sufficiently large to saturate the specimen. If H is smaller, the direction of J_s is rotated only by an angle $\varphi < \alpha$.

For a material showing uniaxial anisotropy, the anisotropy energy is assumed to be

$$E_a = K_1 \sin^2 \varphi, \quad (10.6)$$

where K_1 is the uniaxial anisotropy constant. The magnetizing energy is

$$E_H = HJ_s \cos(\alpha - \varphi), \quad (10.7)$$

which leads to the torque:

$$L = -\frac{d(E_a + E_H)}{d\varphi} = -K_1 \sin 2\varphi - HJ_s \sin(\alpha - \varphi). \quad (10.8)$$

Therefore the determination of anisotropy constants requires high field strengths or suitable extrapolation. A broad discussion of the anisotropy energy for different crystal symmetries can be found in [10.7], Chap. 5.

Fig. 10.8 VSM measurement of the temperature dependence of the magnetization M of nanocrystalline melt-spun samples. The curve shows the spin orientation temperature T_s of $\text{Nd}_2\text{Fe}_{14}\text{B}$ and the Curie temperatures of the comprised phases (heating curves, $dT/dt = 45 \text{ K/min}$)

Fig. 10.9 Torque magnetometer, 1: torsion wire, 2: light beam, 3: specimen rod with mirror attached, 4: specimen, 5: electromagnet on rotating base

The specimen is attached to a rod that is suspended between torsion wires, and is located between the poles

of an electromagnet. The electromagnet is mounted to a base plate that can be rotated by 360° . The rotation angle can be measured and recorded.

The excitation of the specimen is measured by the deflection of a light beam from a mirror that is attached to the specimen rod.

Automated systems use an electrodynamic compensation of the torsion, which is measured by an optical system consisting of a mirror attached to the specimen rod, a light beam and photosensors to detect the excitation. The excitation is compensated by an electromagnetic system that is located outside the stray field of the electromagnet. The current in the compensating coil is proportional to the torque.

The main application of the torque magnetometer is the determination of anisotropy field constants of hard magnetic materials, including small particles and thin films. Other applications are the determination of texture on grain-oriented electrical sheet and tape and the determination of the anisotropy of susceptibility of paramagnetic materials with noncubic structure.

Moment-Measuring Coils

Helmholtz-coil configurations [10.8] [S-10-37] are very common for the measurement of the magnetic dipole moment of permanent magnets. They provide a large region with uniform sensitivity that can be easily accessed from all sides. Long solenoids can also be used (Fig. 10.10). The installation of the coil must be carried out with care. No magnetic or magnetizable parts are allowed in the vicinity of the coil as they would affect the measurement result.

The measuring coil is connected to a fluxmeter. The magnet specimen is placed in the center of the coil so that the vector of polarization is aligned with the coil axis. The fluxmeter is set to zero and the magnet is withdrawn

from the coil as long as the reading of the fluxmeter changes. Alternatively the magnet can be rotated by 180° so that the vector of polarization points in the opposite direction. If the rotation method is used, the fluxmeter reading must be divided by 2.

The magnetic dipole moment j of the specimen is proportional to the measured magnetic flux Φ ,

$$j = k\Phi. \quad (10.9)$$

The measuring constant k can be calculated from the dimensions and the number of turns n of the coil. For a Helmholtz coil, k is approximately $1.4r/n$, where r is the coil radius. In practice, k is obtained by calibration.

From the dipole moment, the magnetic polarization J in the working point of a magnet with the volume V can be calculated using

$$J = j/V. \quad (10.10)$$

This allows the determination of the working point if the demagnetization curve of the material is known.

For an anisotropic magnet, the polarization in the working point is typically only 1–3% lower than the remanence B_r . This fact is used in the main application of the method: a fast and repeatable test for B_r . This makes it popular in industrial quality control if a measurement of the demagnetization curve is too time-consuming or expensive.

The method can also be used for radially anisotropic, arc-shaped magnets that are common in motor applications (Fig. 10.11). As the coil only detects the magnetic moment parallel to the coil axis, a correction must be applied.

The measured magnetic dipole moment is

$$j' = 2JA r \int_0^\beta \cos \beta \, d\beta. \quad (10.11)$$

Here A is the cross-sectional area of the specimen. The volume of the magnet,

$$V = 2Ar\beta, \quad (10.12)$$

Fig. 10.10a,b Moment-measuring coils: solenoid (a) and Helmholtz coil. (b) The dashed line in the Helmholtz coil marks the cross section of the measuring space for 1% accuracy

Fig. 10.11 Measurement of the magnetic dipole moment of a radially anisotropic segment magnet

leads to the polarization

$$J = \frac{j'}{V} \frac{\beta}{\sin \beta} . \quad (10.13)$$

Another application is the determination of the anisotropy direction of block magnets. The magnetic dipole moment is measured in the direction of one mechanical symmetry axis (j_x) and in two perpendicular directions (j_y, j_z).

The angle α between the mechanical symmetry axis and the axis of anisotropy is

$$\alpha = \arccos \frac{j_x}{\sqrt{j_x^2 + j_y^2 + j_z^2}} . \quad (10.14)$$

10.2.3 Properties of Soft Magnetic Materials

DC Hysteresisgraph – Ring Method

The basic method for the measurement of quasistatic hysteresis loops mostly uses ring-shaped specimens. Other specimen shapes providing a closed magnetic circuit with constant cross section may also be appropriate. The specimen is equipped with a primary winding and a secondary winding [S-10-31].

Usually the bipolar current source is computer-controlled and the fluxmeter and ammeter are also integrated into a data-acquisition system.

The magnetizing current I is applied to the primary winding. The magnetic field strength H is calculated from

$$H = \frac{N_1 I}{l_m} , \quad (10.15)$$

where N_1 is the number of turns of the primary winding. The mean magnetic path length l_m is usually obtained from

$$l_m = \pi \frac{D+d}{2} , \quad (10.16)$$

where D is the outside diameter and d is the inside diameter of the ring.

The radial variation of H must be kept small. Therefore the ratio between the outer diameter and inner diameter should not exceed 1.1. A ratio up to 1.4 is permitted for sintered specimens as thinner rings are often impracticable. If these conditions cannot be met for any reason, l_m can better be calculated with respect to the average field strength,

$$l_m = \pi \frac{D-d}{\ln \left(\frac{D}{d} \right)} . \quad (10.17)$$

The voltage that is induced into the secondary winding must be integrated to obtain the magnetic flux Φ . Therefore a fluxmeter is used. From the flux Φ , the flux density B is calculated as

$$B = \frac{\Phi}{N_2 A} . \quad (10.18)$$

Here N_2 is the number of turns of the secondary winding and A is the cross-sectional area of the specimen. For a massive ring of rectangular cross section and height h , the area is calculated from

$$A = \frac{D-d}{2} \cdot h . \quad (10.19)$$

If the ring consists of stacked sheets or wound ribbons, the area must be calculated from

$$A = \frac{2m}{\rho \pi (d+D)} , \quad (10.20)$$

where m is the mass and ρ is the density of the specimen material.

Prior to the measurement the specimen is demagnetized. An alternating current with decreasing amplitude is applied to the primary winding. The frequency and decay rate of this current can be preset. The measurement can then be started with the initial magnetization curve. The hysteresis loop is either excited up to the maximum current provided by the current source or to a preset limit of H or B .

Often the measuring speed is controlled so that a constant rate of change of the flux density with time, dB/dt , is achieved. This allows the steep parts of the loop to be passed slowly to avoid errors due to eddy currents. The flat parts of the curves can be passed faster as eddy currents do not affect the magnetization. However, the instrument must also have the possibility to run curves at constant speed, for instance in the case that control is not possible, e.g. for a Z loop. The typical time to trace a hysteresis loop is of the order 1 min.

Quasistatic measurement allows one to obtain magnetic material properties independently of the influence of eddy currents. In this way the hysteresis loss can be obtained directly by integrating the area of the hysteresis loop

$$P = \oint B dH . \quad (10.21)$$

Coercivities of soft magnetic ring specimens range from less than 0.1 A/m for ring cores made of wound ribbons of amorphous alloys up to several 100 A/m for rings made of solid steel or sintered material. Depending

Fig. 10.12a–c Hysteresis loops of ring specimens measured by the DC ring method, (a) Fe–Si alloy with round (R-)hysteresis loop, (b) Fe–Ni alloy with high squareness (Z-)loop, (c) amorphous cobalt alloy with flat (F-)loop

on the ring dimensions, current and number of primary turns, typically maximum field strengths up to approximately 10 kA/m can be achieved.

The permeability curve $\mu_r(H)$ can be created by dividing the corresponding values of B and $\mu_0 H$, which are usually taken from the initial magnetization curve. The highest point of the $\mu_r(H)$ curve, the maximum permeability μ_{\max} , is typically stated in measurement reports.

Figure 10.12 shows some sample measurements on different materials. The field-strength excitation is 5 kA/m for the Fe–Si and 60 A/m for the Fe–Ni specimen.

Winding a Ring Specimen. In schematic drawings such as Fig. 10.13 primary and secondary windings are usually shown on opposite sides of the ring. This configuration produces a high stray field if the permeability decreases while approaching saturation. Therefore, both windings are often equally distributed around the circumference if the number of turns is sufficiently large. To avoid air flux between the ring and the secondary winding, this winding is wound directly onto the ring. The primary winding is wound onto the secondary winding.

Fig. 10.13 Circuit of the ring method

Each of the equally distributed windings produces an effective circular turn with a diameter equal to the mean diameter of the ring. In this way the primary winding produces a magnetic field in the direction of the ring axis. This can be avoided by winding the turns in pairs of layers that are wound alternating clockwise and counterclockwise around the ring.

This also reduces the error arising from the effective mutually inductive coupling between the two windings in the axial direction. To minimize this error, the wire of the secondary winding can also be led back along the mean diameter of the ring.

After winding, the specimen should be checked for short circuits between the windings and core.

Specimens for ring-core testing include wound ribbons of amorphous alloys and iron–nickel alloys. If the magnetic properties can easily be altered by mechanical stress, the windings cannot be applied to the cores directly. The cores can be coated or placed in plastic core boxes that are wound afterwards. Prefabricated windings with multipole connectors are also used.

Depending on the field-strength range, the air flux between the measuring winding and specimen must be considered. The flux density must then be calculated from

$$B = \frac{\Phi}{N_2 A} - \mu_0 H \cdot \frac{A_2 - A}{A}, \quad (10.22)$$

where A_2 is the cross-sectional area of the secondary winding and A is the area of the specimen.

DC Hysteresisgraph – Yoke Methods

The DC hysteresisgraph or permeameter is used for quasistatic hysteresis measurements on soft magnetic materials. The specimen can either be a bar with round or rectangular cross section or a strip of flat mater-

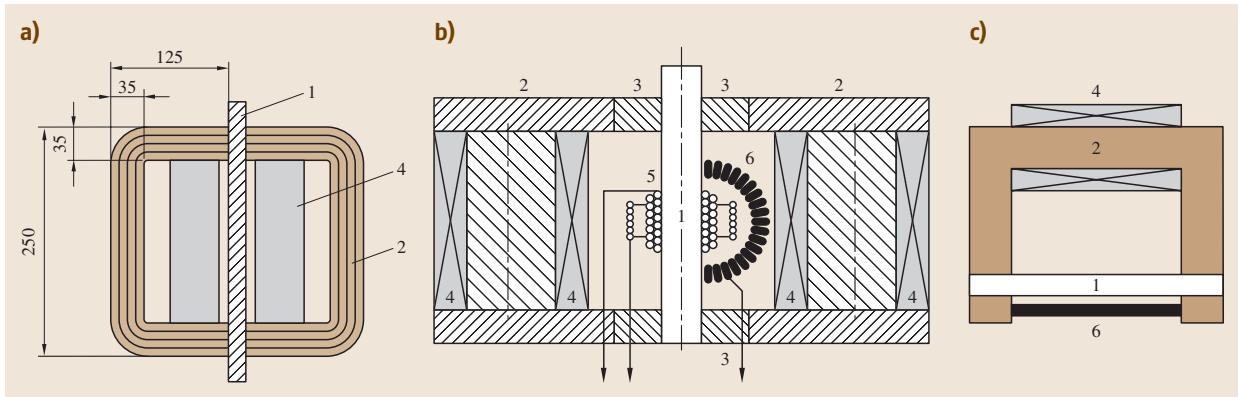

Fig. 10.14a–c Permeameters: IEC Type A (a), IEC Type B (b), Fahy Simplex (c) 1: specimen, 2: yoke frame, 3: exchangeable pole pieces, 4: field-generating coils, 5: surrounding coil for B or J , 6: sensor for H

ial. The choice of the method depends on the shape and magnetic properties of the specimen. Yoke methods are generally used instead of the ring method if the coercivity of the specimen material is larger than 50–100 A/m. Maximum field strengths range from 50–200 kA/m.

The most widespread yoke configurations today are the permeameter yokes type A and type B according to [S-10-31] and the Fahy permeameter [10.9] (Fig. 10.14). Many other, often similar, configurations have been designed. A larger collection can be found in [10.10].

For the measurement of the flux density B , a coil that is directly wound onto the specimen can be used. In everyday use J -compensated coils are often preferred. They can be made more sturdy and can be used for specimens with various diameters and shapes.

The measurement of the field strength H can be carried out by a Hall probe or a field-measuring coil (search coil) next to the specimen. Due to the restricted space, this approach is used with the type A permeameter. Another way is a c-shaped potential-measuring coil, as shown in Fig. 10.14b for the type B permeameter. It is placed directly onto the specimen surface and senses the magnetic potential difference P between its ends. The magnetic field strength is obtained by $H = P/s$, where s is the distance between the ends of the potential coil. A straight potential-measuring coil can be used with the Fahy permeameter.

In the type A permeameter, the specimen is surrounded by the magnetizing coil. This configuration generates relatively high field strengths. However, specimen and field strength sensor are heated directly by the power dissipation in the coil. If the field strength is

increased above approximately 50 kA/m, air or even water cooling becomes necessary. The minimum specimen length for the type A permeameter is 250 mm.

The type B permeameter uses specimens that are only 90 mm long, but the maximum field strength is limited to 50–60 kA/m.

Like in the DC ring method, the measuring speed is often controlled to $dB/dt = \text{const.}$ to minimize the influence of eddy currents on the measurement results.

Coercimeter. The size and shape of soft magnetic components often makes it impossible to measure the complete hysteresis loop. In this case a coercimeter can be used to determine the coercivity H_{cJ} . As this quantity depends sensitively on the microstructure, it is a good indicator of successful material heat treatment. The measurement is carried out in an open magnetic circuit [S-10-32].

A solenoid is used to magnetize and demagnetize the specimen. The maximum field strength must be sufficient to achieve technical saturation, beyond which the coercivity would remain constant if the magnetizing field strength were further increased. This can be tested by a series of measurements with increasing magnetizing field strengths. The required field strength depends on the specimen material and shape. Commercial solenoids provide up to 100–200 kA/m. Sometimes an additional higher-field pulse is used for saturation.

After the specimen has been saturated and the polarity is reversed, the field strength must be increased slowly to avoid errors due to eddy currents in the specimen. A field sensor detects the stray field. For a homogeneously magnetized specimen the stray

Fig.10.15 Coercimeter, 1: specimen, 2: field-generating solenoid, 3: field sensors, 4: zero detector

field vanishes at H_{cJ} . Fluxgate probes, Hall probes or compensated coils can be used as zero-field-strength detectors. The arrangement of the sensors in Fig. 10.15 ensures that only the stray field of the specimen and not the field generated by the solenoid is measured.

Formerly it was usual to align the instrument with respect to the Earth’s magnetic field. Today shielded systems are preferred as they are easier to install and also dynamic noise fields are suppressed.

It is often claimed that coercimeters allow measurement of the coercivity independently of the specimen shape. For machined components such as parts of relays the coercivity is not uniform due to mechanical or heat treatment. Complex-shaped parts are not uniformly magnetized. In these cases the coercimeter provides only an integral value given by the vanishing stray field at the sensor position.

AC Hysteresisgraph. An AC hysteresisgraph is mainly used for ring specimens but also sometimes with fixtures that allow measurements of stripes. In these cases the feedback yoke, e.g. a C-core, must be laminated to avoid eddy currents. The permeability should be high compared with the permeability of the specimen.

For the winding of the ring specimen the same considerations as for the DC ring method apply.

The simplest version of an AC hysteresisgraph uses an oscilloscope. The secondary induced voltage is integrated using a resistor–capacitor (RC) circuit. The output is displayed as a function of the primary current. Today this method is mainly used for demonstration purposes. For material testing, digital data-acquisition systems are more suitable [S-10-17].

Figure 10.16 shows the operating principle. A programmable function generator controls a power amplifier that supplies a current I to the primary winding of the specimen. The current is measured using a shunt with negligible inductance. From the current and the magnetic path length l_m the field strength H can be calculated. The secondary induced voltage is digitized and integrated to obtain the flux density B .

The measuring conditions have to be defined to achieve comparable results. Programmable function generators allow the waveform of B to be defined as sinusoidal [10.11]. A sinusoidal H can be easier achieved using a current output amplifier. Systems with digital control for B are available up to frequencies of several kHz, while uncontrolled systems can reach several 100 kHz.

Due to an increase of applications for soft magnetic materials using pulse-width modulation (PWM), the interest in measuring systems that allow measurements in the presence of higher harmonics is growing [10.12]. Function generators with arbitrarily programmable waveforms can meet these requirements.

Prior to a measurement, the specimen is demagnetized by applying an alternating current with decreasing amplitude. After $U_1(t)$ and $U_2(t)$ have been recorded, various evaluations can be carried out. The hysteresis loop or $\mu(H)$ curves can be calculated.

The AC hysteresisgraph can also measure the curve of normal magnetization. Therefore the amplitude of the magnetizing current is successively increased and corresponding peak values of the field strength and flux density, \hat{H} and \hat{B} , are plotted.

Epstein Frame. The Epstein frame is mainly used by producers and users of electrical sheet and tape. Many consignments in industry are based on Epstein values,

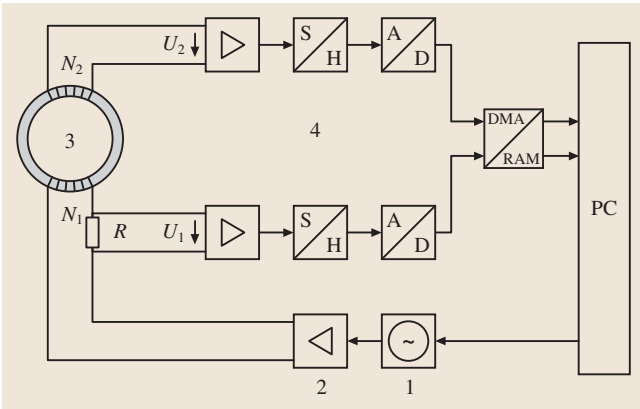

Fig.10.16 AC hysteresisgraph, 1: programmable frequency generator, 2: power amplifier, 3: specimen, 4: transient recorder with preamplifier and analog-to-digital conversion

Fig. 10.17 25 cm Epstein frame, 1: specimen, 2: magnetizing and measuring coils

but the importance of the Epstein frame is decreasing. This is mainly caused by the demanding specimen preparation and the large quantity of specimen material. The classical Epstein frame had a width of 50 cm and required about 10-kg specimen mass. It has been nearly completely replaced by the 25-cm frame (Fig. 10.17) [S-10-25, S-10-4].

Four coil sets form the frame. Each of them contains two windings: an inner flux measuring winding and an outer winding to magnetize specimen. The specimen must be cut into stripes that are between 280 mm and 320 mm long and $30 \text{ mm} \pm 0.2 \text{ mm}$ wide. These are stacked into the frame so that they overlap alternately in the corners.

For non-oriented material, one half of the stripes is cut in the rolling direction and the other half perpendicular to it. The stripes cut perpendicular to the rolling direction must be placed at opposite sides.

Measurements are mainly carried out at power-line frequencies (50 Hz to 400 Hz). Rarely the Epstein frame is also used for quasistatic measurements or up to the kHz range. Normally the measurements are carried out under the condition of sinusoidal flux density B . The excitation is typically limited to $\hat{B} = 1.5 \text{ T}$ for non-oriented and $\hat{B} = 1.8 \text{ T}$ for oriented material. At higher excitations, digital or analog feedback control becomes necessary.

To calculate the magnetic field strength H from the magnetizing current I , the magnetic path length l_m is required (10.11). Due to the overlapping edges, l_m cannot

be determined exactly. Therefore it is set by definition to 94 cm for the 25 cm frame.

To obtain the polarization J , the air flux that is generated in the measuring coils must be compensated. A mutual inductor is the conventional solution (Fig. 10.18). It is adjusted so that the output of the measuring winding is canceled out if no specimen is inserted in the frame.

Today the Epstein frame is mostly connected to a data-acquisition system, as shown in Fig. 10.16 for the AC hysteresisgraph. Then the air-flux correction can also be carried out by calculating the difference between a measurement with an empty frame and the measurement on the specimen.

The Epstein frame is not always used to measure the complete hysteresis loop. If only loss or permeability data are required, the wattmeter method or the voltmeter–ammeter method can be applied to the Epstein frame.

Single-Sheet Tester. The single-sheet tester (SST) uses a yoke to close the magnetic circuit (Fig. 10.19). The specimen is placed between the two halves of the yoke inside a set of coils that consists of an inner measuring coil and an outer coil that applies the magnetizing field.

The standardized SST yoke is 500 mm long and wide [S-10-28]. It is designed for sheets with a minimum length of 500 mm. A square specimen allows measurement in and perpendicular to the rolling direction. Narrower specimens can also be measured. For a sufficient measuring signal, they should cover at least 60% of the yoke width. In practice down-scaled frames for smaller specimen sizes are also used.

To minimize the influence of eddy currents, the frame must be made of strip-wound cut cores or stacked isolated sheets. The magnetic losses of the yoke must be much smaller than the losses of the specimen. Therefore high-quality electrical steel or iron–nickel alloy is used.

The main advantages compared to the Epstein frame are lower specimen mass and easier specimen prepara-

Fig. 10.18 Air-flux compensation using an adjustable mutual inductor, 1: Epstein frame, 2: mutual inductor

Fig. 10.19 Single-sheet tester, 1: specimen, 2: yoke frame, 3: magnetizing and measuring coils

tion and installation. The SST allows the measurement of the same quantities and curves as the Epstein frame. The electronic part of the instrumentation is principally the same.

The Epstein frame is increasingly being replaced by the SST. Therefore it was essential to explore the relationship between the two methods [10.13]. The results of an extended comparison for grain-oriented steel are compiled in [10.14].

Normally the field strength is calculated from the magnetizing current. In this case the magnetic losses of the yoke and in the gaps to the specimen must be minimized. An uncertainty also exists in the determination of the magnetic path length. To overcome these difficulties, a measurement of the field strength has been proposed [10.15].

Wattmeter Method. The wattmeter method is used to measure the specific total loss (power loss) on ring specimens at a given alternating-current (AC) excitation [S-10-17, S-10-6]. The measurement is carried out under condition of sinusoidal magnetic flux density. For some specimens this may require digital control of the magnetizing current waveform or an analog feedback control of the power amplifier.

The circuit of the wattmeter method is shown in Fig. 10.20. Three instruments are necessary: a voltmeter V_1 displaying the average rectified value (sometimes scaled to 1.111 times the rectified value), a voltmeter V_2 displaying the root mean square (r.m.s.) voltage and a wattmeter. All instruments must have high input impedances and the wattmeter must have a low power factor.

Prior to a measurement the specimen must be demagnetized. Therefore the amplitude of the magnetizing alternating current is slowly reduced from its maximum

value to zero. The current is then increased to generate the desired flux density \hat{B} in the specimen. This is determined via the average rectified voltage

$$|\overline{U_1}| = 4fN_2A\hat{B}. \quad (10.23)$$

The form factor of the secondary waveform must be verified to ensure a sinusoidal flux density. This is determined by the ratio of the r.m.s. voltage U_2 to the average rectified voltage U_1 . Additionally an oscilloscope can be used to monitor the waveform.

For the calculation of the total loss of the specimen, the power P_1 consumed by the instruments connected to the secondary winding must be taken into account. As the voltage shall be sinusoidal it is, to a first approximation, equal to

$$P_1 = \frac{(1.111 \cdot |\overline{U_2}|)^2}{R_i}, \quad (10.24)$$

where R_i is the combined input resistance of all the instruments connected to the secondary winding. The total loss P of the specimen is calculated from the reading P_m of the wattmeter using

$$P = \frac{N_1}{N_2} P_m - P_1. \quad (10.25)$$

The specific total loss is obtained by dividing P by the mass of the specimen.

Voltmeter–Ammeter Method. The voltmeter–ammeter method allows the determination of the normal magnetization curve and the amplitude permeability [S-10-17]. The circuit of the method is shown in Fig. 10.21. The instruments needed are an average-type voltmeter, a root-mean-square-type (r.m.s.) voltmeter and an r.m.s. or peak-reading ammeter or a noninductive resistor and

Fig. 10.20 Circuit diagram of the wattmeter method. V_1 is an average-type voltmeter, V_2 is an r.m.s. voltmeter

Fig. 10.21 Circuit diagram of the voltmeter–ammeter method. V_1 is an average-type voltmeter, V_2 is an r.m.s. voltmeter

Fig. 10.22 Saturation coil, 1, 2: windings of a Helmholtz coil, 3, 4: permanent magnet material, 5: fluxmeter, 6: specimen; the dashed line (7) marks the limit for 1% accuracy

appropriate voltmeter. The voltmeters must have high input impedances. An oscilloscope can be helpful to monitor the secondary induced waveform.

If comparable results are desired, either the waveform of the primary current or of the secondary voltage must be kept sinusoidal. Depending on the excitation and the shape of the hysteresis loop control can be necessary. A sinusoidal H waveform can be achieved by a current-controlled power amplifier or by a feedback using a noninductive resistor in the primary circuit. This can be the resistor used for current measurement. A sinusoidal secondary voltage can be achieved by analog or digital control. The form factor can be determined by the ratio of the r.m.s. voltage to the average rectified voltage.

The excitation field strength \hat{H} is calculated from the current I using (10.15). If I is sinusoidal it can be measured by multiplying the r.m.s. value by the square root of 2. If the primary waveform is significantly non-sinusoidal a peak-reading instrument would be required. In practice this is often ignored and an effective excitation field strength that is lower than the real field strength is used instead.

Prior to the measurement the specimen is demagnetized. Then I is successively increased and the average rectified value of the secondary voltage is measured. The flux density \hat{B} is calculated from (10.23). The normal magnetization curve can be obtained by plotting corresponding values of \hat{H} and \hat{B} .

The relative amplitude permeability μ_a can be calculated from

$$\mu_a = \frac{\hat{B}}{\mu_0 \hat{H}} \quad (10.26)$$

and the r.m.s. amplitude permeability from

$$\mu_{a,r.m.s.} = \frac{\hat{B}}{\mu_0 \sqrt{2} \tilde{H}}, \quad (10.27)$$

where \tilde{H} is the r.m.s. value of the field strength.

Saturation Coil. The saturation coil, sometimes also called J_s -coil or saturation magnetometer, combines the moment-measuring coil with a permanent-magnet system that magnetizes soft magnetic specimens [10.16], [S-10-37]. The measuring coil, usually a Helmholtz coil, is connected to a fluxmeter.

When a specimen with volume V is inserted into the coil, it is magnetized and the magnetic dipole moment j can be obtained from the flux measurement using (10.9). If the field strength is sufficiently high, the saturation polarization can be determined through

$$J_s = \frac{j}{V}. \quad (10.28)$$

Of course the specimen can also be withdrawn from the coil for measurement, but the rotation method, which is frequently used with the moment-measuring coil, cannot be used.

For lower field strength the relative permeability can be calculated using

$$\mu_r = 1 + \frac{J}{H_i}. \quad (10.29)$$

The inner field strength H_i of the specimen must be determined from the magnetizing field strength, taking into account the demagnetization factor.

The main applications of the method are the determination of the saturation polarization of specimens made

Fig. 10.23 (a) Faraday method and (b) Gouy method, 1: specimen, 2: electromagnet poles, 3: balance

of nickel or nickel alloys and the determination of the cobalt content in hard metal specimens.

Magnetic Scales. Magnetic scales or balances measure the force that acts on a magnetic specimen in a nonhomogeneous field [10.17]. From this force the following quantities can be determined:

- magnetic moment m and magnetic dipole moment $j = \mu_0 m$,
- magnetic permeability μ and magnetic susceptibility $\chi = \mu - 1$.

As the specimens can be easily heated or cooled, the methods can also be used to measure the temperature dependencies of the properties. This includes the determination of Curie and Néel temperatures and the observation of other phase transitions.

Faraday Method. The force acting on a small specimen with volume V in a magnetic field with gradient dH/dy is

$$F = j \frac{dH}{dy} = V \chi H \frac{dH}{dy}. \quad (10.30)$$

The specimen is suspended from the scale so that it is located between the poles of an electromagnet. The pole caps are shaped such that the product $H(dH/dy)$ is constant over the whole volume (gradient pole caps), so that the force is proportional to the susceptibility χ . The Faraday method is suitable for all kind materials, especially ferro- and ferrimagnetic specimens. It allows the determination of the saturation polarization J_s for soft magnetic materials if the specimen shape is appropriate.

Gouy Method. A long bar-shaped specimen is suspended from the scale so that one end is located between the poles of an electromagnet generating a field strength H . The other end outside the poles is only affected by the stray field strength $H_s \ll H$. The force acting on the whole sample is

$$F = \frac{1}{2} A \chi (H^2 - H_s^2) \approx \frac{1}{2} A \chi H^2, \quad (10.31)$$

where A is the cross-sectional area of the specimen. The Gouy method is mainly used for para- and diamagnetic materials including liquids and gases.

Impedance Bridges. If an alternating current is supplied to a coil that contains a ferromagnetic core, a phase shift between magnetic field strength and flux density occurs. The magnetic material can be characterized by

Fig. 10.24
Maxwell–Wien
bridge

the complex permeability

$$\underline{\mu} = \mu' - i\mu'' . \quad (10.32)$$

The impedance of the filled coil is

$$\underline{Z} = R + i\omega L = \omega\mu'' L_0 + i\omega\mu' L_0 \quad (10.33)$$

if losses and additional phase shifts that are not caused by the core material are neglected. L_0 is the inductance of the measuring winding without the magnetic core. For a cylindrical specimen, it can be calculated as

$$L_0 = \frac{\mu_0}{2\pi} \ln \left(\frac{D}{d} \right) h N^2, \quad (10.34)$$

where D is the outer diameter, d is the inner diameter and h the height of the coil, and N is the number of turns of the winding.

The loss angle δ and the Q -factor can be determined from

$$\tan \delta = \frac{R}{\omega L} = \frac{1}{Q} = \frac{\mu''}{\mu'} . \quad (10.35)$$

For the determination of \underline{Z} , various impedance bridges are available from electrical measuring techniques; they differ in sensitivity and frequency range. For the characterization of magnetic components, suitable circuits are used in a frequency range of approximately 1 Hz to 100 MHz. A basic circuit is the Maxwell–Wien bridge shown in Fig. 10.24. It can be used from about 50 Hz to 100 kHz.

The specimen, a ring core that is uniformly wound with a single winding, is defined by its equivalent circuit diagram consisting of R_x and L_x . The bridge is balanced if

$$R_x = \frac{R_1 R_2}{R_v} \quad (10.36)$$

and

$$L_x = R_1 R_2 C_v . \quad (10.37)$$

R_x consists of the loss R caused by the magnetic core and the loss in the winding:

$$R_x = R + R_0 . \quad (10.38)$$

The loss in the winding R_0 is basically the DC resistance if the frequency is not too high, and can be obtained from a resistance measurement.

The inductance L_x is composed of the leakage inductance L_σ and the inductance of the specimen L

$$L_x = L_\sigma + L = L_\sigma + \mu' L_0 . \quad (10.39)$$

For large permeabilities the leakage inductance L_σ can be neglected and μ' can be calculated to

$$\mu' = \frac{L}{L_0} \approx \frac{L_x}{L_0} . \quad (10.40)$$

Otherwise the real inductance L'_0 of the winding should be considered. L'_0 can be measured on an air-core coil: a winding that is wound on a nonmagnetic core and that has the same dimensions as the measuring winding. It can be assumed for small permeabilities that the stray field would be the same, regardless whether there is a core or not. With

$$L'_0 \approx L_\sigma + L_0 , \quad (10.41)$$

it follows that

$$\mu' \approx 1 + \frac{L_x - L'_0}{L_0} . \quad (10.42)$$

At higher frequencies the resistance of the winding differs from the DC resistance due to the skin effect. In this case mutual inductance bridges provide more accurate results, as in these circuits the resistance of the wire does not enter the measuring result. The specimens must be equipped with two windings. Suitable circuits are the Wilde [10.18] and Hartshorn bridges. Further methods are compiled in [10.19].

Measurement of Magnetostriction. Magnetostriction comprises all dimensional changes of a specimen that are caused by changes in magnetization. For both the volume-invariant shape effect and the volume magnetostriction, a measurement of a change of the specimen length in one or more dimensions can be carried out.

The specimen is placed in the center of a solenoid, which generates the magnetic field required. The change in length is transferred via a rod to a displacement transducer that is located outside the stray field of the

Fig. 10.25 Magnetostriction measurement, 1: solenoid, 2: specimen, 3: specimen rod, 4: displacement transducer

solenoid. The material of the rod must be properly chosen to keep the outer force acting on the specimen as small as possible and to avoid errors due to temperature-induced changes in length. Capacitive, inductive or optical sensors are used to measure the displacement.

Another method uses strain gauges that are directly attached to the specimen. To cancel out errors due to the magnetic and thermal properties of the strain-sensing element, a second element of the same type can be attached to a substrate that shows no magnetostriction but is exposed to the same environment. The two sensing elements can be connected to opposite paths of a bridge circuit.

A third method uses a single-mode optical fiber attached to the specimen. The fiber is part of an interferometer. The change in length is detected as a phase shift in the electromagnetic wave propagating in the fiber [10.20].

The volume magnetostriction can also be measured by the conventional measuring method for volumetric content. The specimen, immersed in a liquid, is exposed to the magnetic field.

Measurement of the Hysteresis Loop of Amorphous or Nanocrystalline Ribbons

Sample shape. In the case of soft magnetic ribbons the hysteresis loop can be measured on

1. open ribbons, in which case the demagnetizing factor has to be considered,
2. toroids.

The temperature the loop is measured is also important. In the case of low- or high-temperature measurements the system has to withstand the desired temperature.

In principle, magnetic measurements should always be carried out on a toroid instead of open ribbons be-

cause only then is a closed magnetic circuit realized. For ribbons this method has the disadvantage that the material is not in a stress-free state – there is a tensile stress on the outer surface and compressive stress on the inner surface. Another possibility is to use a single straight ribbon but then the demagnetizing field has to be considered.

Hysteresis Loop on a Single Ribbon. When hysteresis is measured on a single open ribbon a well-defined external stress can be applied. Temperature-dependent measurements are possible, although technically more complex. The facilities necessary for measuring the hysteresis loop are field coils, a compensated pick-up coil, a current source, an ammeter and an integrator (fluxmeter). For the measurement of coercivity a Helmholtz coil is mainly used, and for the measurement of saturation magnetization the field is applied by a cylindrical coil producing a sufficient high field. The coils are energized by a computer-controlled power supply.

The devices are connected and controlled by a data-acquisition and control unit, forming a full automatic hysteresis-loop system. Figure 10.26 shows as an example a set up for such a hysteresis measurement on single strip ribbons.

In this case a compensated pick-up system has to be used. When the pick-up and the compensation coils are connected, so that the induction signals due to the field are subtracted, the remaining signal will be proportional to the magnetization M

$$u_{\text{ind}} = u_{\text{pick}} - u_{\text{comp}} = -N_{\text{pick}}\mu_0 A_{\text{rib}} \frac{dM}{dt} \quad (10.43)$$

Magnetostriction. Magnetostriction on thin ribbons can be measured by direct and indirect methods. Direct methods are, for example, measurements with strain gauges, capacitance transducers or interferometers. All these methods have the disadvantage that sample preparation is difficult. Strain gauges are limited in sensitivity ($\Delta\lambda/\lambda_0 = \pm 1 \times 10^{-6}$). Additionally the saturation magnetostriction constant has to be determined from measurements parallel and perpendicular to the external field.

Indirect methods are the Becker–Kersten method [10.21] and the small-angle magnetization-rotation (SAMR) method [10.22]. With the Becker–Kersten method the magnetostriction is determined from the stress dependence of the hysteresis loop. The SAMR method was developed by Narita et al., especially for ribbon shaped materials with a small magnetostriction constant.

The SAMR method. First of all a DC field is applied in the ribbon axis. This field should magnetically saturate the sample. Then a smaller AC field (with frequency f) is applied perpendicular to the ribbon axis. This causes a small rotation (small angle) of the magnetization vector out of the ribbon axis. A small induction signal with double the frequency of the AC field is now detected by a pick-up coil (Fig. 10.27a) and measured by a lock-in amplifier. Applying an external stress to the ribbon causes, for ribbons with positive magnetostriction, a decrease in the deflection angle, whereas for samples with negative magnetostriction the angle increases (Fig. 10.27b). Now the DC field H_{DC} is changed in such a way that the deflection angle and therefore also the induction signal go back to their initial value (Fig. 10.27c).

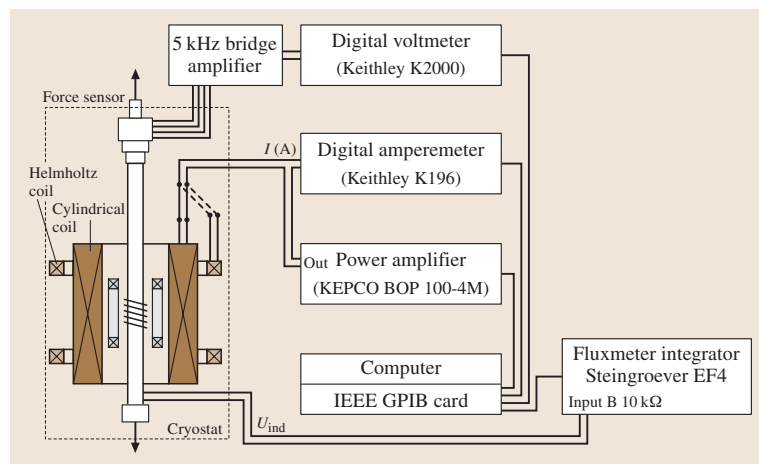

Fig. 10.26 Hysteresisgraph for a quasistatic hysteresis measurements and devices for force measurement for single ribbons

Fig. 10.27 Magnetostriction measurement by the SAMR method

The variation of the DC field ΔH_{DC} and the variation of the external stress $\Delta \sigma$ determine the magnetostriction constant. To get an accurate value this procedure has to be repeated step by step with increasing stress. From the balance of the magnetic and the magnetoelastic energy one can calculate the saturation magnetostriction as

$$\lambda_s = -\frac{1}{3} J_s \left(\frac{\Delta H_{DC}}{\Delta \sigma} \right) \bigg|_f = -\frac{1}{3} \frac{\Phi_{sat}}{A_{rib}} \left(\frac{\Delta H_{DC}}{\Delta F/A_{rib}} \right) = -\frac{1}{3} \Phi_{sat} \left(\frac{\Delta H_{DC}}{\Delta F} \right), \quad (10.44)$$

where J_s is the saturation polarization of the ribbon at a certain temperature. The polarization J_s is proportional to α/A_{rib} , where α is the output value of the fluxmeter and A_{rib} is the cross section of the sam-

ple. The value of $\Delta \sigma$ is given by $\Delta F/A_{rib}$. According to the equation above the magnetostriction then becomes completely independent of the cross section. The magnetostriction then depends only on the exact measurement of the magnetic flux (saturation value Φ_{sat}), on the measurement of the force ($\Delta F = F_1 - F_2$, by the force-sensor bridge) and on the measurement of the magnetic field H_{DC} ($\Delta H_{DC} = H_{DC1} - H_{DC2}$). Figure 10.28 shows as an example a possible set up for magnetostriction measurements using the SAMR method.

This method was used successfully to determine the magnetostriction of many amorphous materials [10.23]. It delivers comparable results and achieves a sensitivity in the magnetostriction constant of up to 10^{-9} [10.24].

Magnetoimpedance. Relevant information about transversal magnetization processes in magnetic materials can be obtained from the field H and frequency f dependence of the complex impedance ($Z = R + iX$). In soft magnetic high-permeability materials, large variations of Z (for current frequencies larger than 100 kHz) have been observed upon the application of relatively small magnetic fields, the so-called giant magnetoimpedance effect (GMI) [10.25–27]. Generally magnetoimpedance is based on the application of an AC field caused by an inhomogeneous field distribution in a conducting material with a high permeability. This effects depends therefore on the frequency, and on the applied field, but also on material parameters such as the conductivity as well as the permeability – which depends additionally on the applied DC field – of the material. Additionally the sample geometry (ribbons, wires) as well as

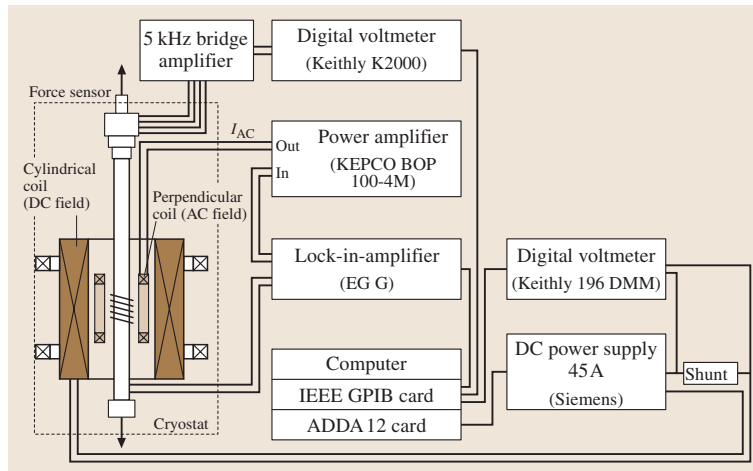

Fig. 10.28 Experimental set up for magnetostriction measurement by SAMR method

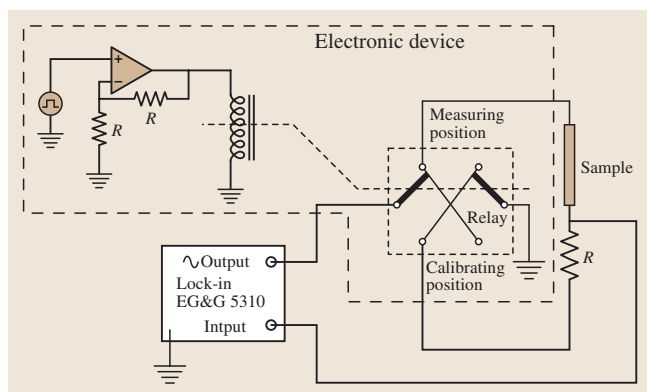

Fig. 10.29 Schematic diagram of the electric necessary to measure the magneto-impedance

local fluctuations of material parameters have to be considered.

For these measurements one needs: a digital lock-in amplifier working over a broad frequency range, a power supply, a dynamic signal analyzer, some form of digital multimeter, and a computer with an interface for the data acquisition. The lock-in amplifier supplies the AC signal and is also employed to read the real and imaginary voltage drop across the sample. In **GMI** measurements, a constant-current source supplies a constant AC current flowing along the sample in order to assure a constant circular magnetic field. As the generator of the lock-in works generally as a constant-voltage source, either one uses an external constant-current source or one measures the AC voltage drop across a resistor R , which determines the actual current through the sample as shown in

Fig. 10.4. In this experiment not only the AC current has to be controlled but also the phase signal. In order to do this a two-position relay controlled by a computer can be used; the two positions correspond to calibration and measurement. In the calibration position (Fig. 10.29), the signal is applied to the sample, which is in series with a grounded resistor and the lock-in measures the voltage across the resistor, which can be controlled to maintain a constant intensity value. In the measurement position (Fig. 10.29), the relay inverts the ground and signal position so that the signal is applied to the resistor, and the sample is grounded. The lock-in thus measures the sample's signal. The voltage over the sample is measured in a four-probe configuration and the contacts with the sample are made using silver conducting ink.

The magnetic **DC** field, which is applied along the sample's length, is supplied by a pair of Helmholtz coils connected to a power supply, which operates as a current source. The current passing through the coils is measured by a multimeter. With this equipment the magnetoimpedance as a function of frequency and external **DC** field can be measured. Furthermore, the experimental set up can be completed by a dynamic signal analyzer, which allows one to follow the time dependence of the impedance after a sudden rearrangement of the domain configuration [10.28]. After the magnetic field is switched off ($t = 0$), it is possible to measure both R and X from t_0 up to t_1 by connecting the **DC** output of the lock-in to one of the inputs of the signal analyzer. The sensitivity is high enough to notice relative variations as low as 0.1%. With this extension magnetic disaccommodation of the magnetoimpedance can also be measured.

10.3 Magnetic Characterization in a Pulsed Field Magnetometer (PFM)

Industrial producers and consumers of magnets are increasingly demanding systems which allow fast and reliable online tests of the hysteresis properties of magnets. High-quality permanent magnets based on rare-earth intermetallic compounds such as Sm–Co and Nd–Fe–B exhibit coercivities of 2 T and sometimes even higher, which are too high for Fe–yoke-based systems [10.7, 29].

The current conventional methods, namely vibrating-sample magnetometers (**VSMs**) and permeameters have limiting physical constraints. Fe–yoke-based **VSMs** and permeameters offer only a limited field strength (maximum 1.5 T). Permeameters are used for measuring the

second quadrant of the hysteresis loop and need careful sample preparation (cutting, polishing). **VSMs** that use a superconducting solenoid require liquid helium for cooling and are generally expensive; additionally standard magnetometers are currently only available for relatively small samples (mm sizes). Additionally superconducting solenoids allow only limited field-sweep rates (dH/dt rates) which are of the order of T/min . Generally all these systems need special sample preparation and measurement times that are unacceptable for industrial purposes. It will be shown that a **PFM** is a new instrument that is well suited for fast and reliable measurement of the hysteresis loops of hard magnetic materials.

10.3.1 Industrial Pulsed Field Magnetometer

A short-pulse system (typical pulse duration 1–50 ms) has a condenser battery as an energy source, which has a certain size given in kJ (typical values are 10–100 kJ). The available power determines the time constant of the total system.

Figure 10.30 shows a block diagram of a pulsed field magnetometer (PFM) [10.10, 30]. A pulsed field magnetometer consists of:

1. the energy source, generally a capacitor battery; the stored energy is given by $CU^2/2$. The maximum charging voltage can be 1–30 kV. The capacitance determines the costs of such a system, the maximum sample size and the time constant. For a magnetometer that can measure the full loop, voltage reversal on the battery must be allowed.
2. the charging unit, which should generate a reproducible and selectable charging voltage; it determines the repeatability of the achieved field in the pulse magnet.
3. pulse magnet: for an existing energy, the pulse magnet determines, via its inductivity, the pulse duration. Additionally the volume (diameter, homogeneity) limits the dimensions of the experiment inside of the magnet. Heating during a pulse may be also a problem when high repetition rates are desired.
4. measuring device: this consist of the pick-up system and the measuring electronics (amplifiers, integrators, PCs, data storage). A careful design of the pick-up system is very important in order to achieve a high degree of compensation and consequently a good sensitivity.
5. electronics: this consist either of a digital measuring card or of a storage oscilloscope which is connected to a modern data-acquisition system on a standard PC, which allows a software-supported operation of the PFM (charging, discharging and the measurement with an evaluation of the resulting loop). In order to obtain a reasonable accuracy the analog-to-digital converters (ADCs) of the storage oscilloscope (measuring card) should have a resolution of at least 12 bits.

High-Field Magnets

The pulse magnet has to be optimized with respect to the available power, the heating of the magnet and the stresses. The field homogeneity over the desired length of the experiment should be better than 1%. In systems

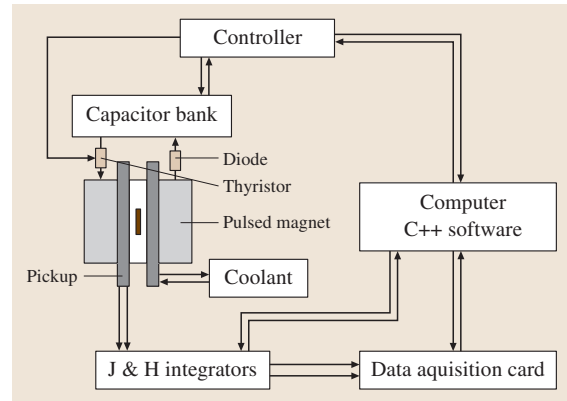

Fig. 10.30 Block diagram of a typical capacitor-driven industrial PFM

where the hysteresis loop is measured, the pulse magnet has to be optimized with respect to low damping and also for a certain measuring task (maximum field, pulse duration, pulse shape, sample volume).

Pick-up Systems

Generally the magnetization is measured using a pick-up coil system, which has to be compensated in order to measure the magnetization M instead of the induction B . For this purpose different arrangements of pick-up coils have been developed (Fig. 10.31). It was found that a coaxial system based on Maxwell coils is best suited to this purpose [10.31]. The main idea of constructing a pick-up system is that the space distribution of the field around the sample is first developed into a dipole (and quadruple) contribution. These contributions should be compensated in order to cancel the effect of the external field. Therefore such systems consist of at least two coils (Fig. 10.31c). The induced voltages can be written

Fig. 10.31 Scheme of a coaxial pick-up system for measuring the magnetization

as

$$u_1(t) = -\mu_0 N_1 K_1 \left(R_1^2 \pi \right) \left(\frac{dH}{dt} + \frac{dM}{dt} \right),$$

$$u_2(t) = -\mu_0 N_2 K_2 \left(R_2^2 \pi \right) \left(\frac{dH}{dt} \right); \quad (10.45)$$

where u_i , N_i , K_i , R_i ($i = 1, 2$) are the induction voltage, number of windings, coupling factor, radius of the outer ($i = 1$) and inner ($i = 2$) pick-up coil, respectively.

Dipole compensation is fulfilled when $R_1^2 N_1 = R_2^2 N_2$ is valid. The coupling factor with respect to the field H is the same for both coils, but not with respect to the sample. It is assumed that for the outer coil the voltage due to the magnetization can be neglected (in reality there exists a small induction voltage due to M which only reduces the calibration factor). Subtracting now the signal of the two antiparallel-wound coils causes a cancelling of the effect of the field, which yields the dipole compensation. Also higher multipoles can be compensated, which leads to a more complex pick-up system for which more space is necessary. Therefore for pulsed field systems usually only the dipole compensation is used.

For some applications the pick-up system should be cooled in order to hold a stable temperature, which is especially important for a room-temperature system with a high repetition rate. The details of such a pick-up system as well as electronic balancing are described in [10.32].

For an industrial system a reasonable sample size is important; typical values are samples up to 30 mm in diameter and 10 mm in length within a $\pm 1\%$ pick-up homogeneity range. For magnetic measurements exact positioning (reproducibility better than 0.1 mm) in the PFM is necessary.

10.3.2 Errors in a PFM

The Demagnetizing Factor

In a magnetically open circuit the correction for the demagnetizing factor N is a very important step to get the true hysteresis loop as a function of the internal field H_{int} . For ellipsoids and spheres the demagnetizing field H_d is simply written:

$$H_{\text{int}} = H_{\text{ext}} - NM,$$

$$H_d = NM. \quad (10.46)$$

The demagnetizing factor N is just a number $0 < N < 1$ for a sphere ($N = 1/3$) or an ellipsoid. In all other cases the demagnetizing field H_d is no longer constant.

Fig. 10.32 Demagnetizing curve as obtained for a spherical and a cylindrical anisotropic Ba-ferrite (HF 24/16)

Important points such as the remanence and the working point, but also the energy product $(BH)_{\text{max}}$, depend strongly on N . Unfortunately in industry more complex shapes, such as cylinders, cylinders with holes and even arc segments, are used. In this case N can become a tensor according to the symmetry of the sample. For complex shapes a finite-element package has to be used in order to calculate the stray field.

In order to investigate the effect of N for simple shapes in Fig. 10.32 the demagnetizing curves in the second quadrant for an anisotropic ferrite HF 24/16 are drawn. The two samples were from the same batch, one was a cylinder and one a sphere. The shape of the loops agrees very well. This means that in this special case the use of a constant number for N even for the cylinder is sufficient for the correction.

Fig. 10.33 Hysteresis loop of a cylindrical sample with a hole of plastic-bonded Nd-Fe-B-type material

Figure 10.33 shows the hysteresis loop as measured on a cylindrical sample with a hole (outer diameter 19 mm, hole: 3.17 mm; $h = 2$ mm) of plastic-bonded Nd-Fe-B-type material. Assuming $N = 0.45$ gives a remanence of 0.666 T, whereas assuming $N = 0.55$ delivers a remanence of 0.682 T. The static value measured with an electromagnet was 0.682 T. This demonstrates the problem of such an unknown demagnetizing factor. It is impossible to say what the correct value is really.

Finally it should be mentioned that the problem discussed here of an unknown demagnetizing factor is not only a problem for the FM; this is a general problem for all magnetometers using a magnetically open circuit, such as e.g. in a VSM or also in a SQUID.

Transient-Field Errors

The application of transient fields causes errors, which have to be considered. Two possible errors may arise in pulsed field measurements due to the field sweep rate dH/dt :

- Eddy current errors,
- Magnetic viscosity effects.

Eddy Currents and their Solution [10.33]

A time-dependent external magnetic field in a metallic conducting sample causes, according to Maxwell equations, currents (*eddy currents*), which create a dynamic magnetic moment that is antiparallel to the external field, as is demonstrated in Fig. 10.34. The time behavior is exponential: $I(t) = I_{0\text{eddy}} \exp(-r/M)t$, where M is a dynamic mutual inductance and r is also a differential resistance due to the path of the eddy currents.

It can be shown [10.33] by solving the Maxwell equations for an electrical conducting material (without considering the permeability) that the dynamic magnetization due to eddy currents can be written as

$$\mathbf{M} = \text{curl} \mathbf{j} = -\sigma \frac{\partial}{\partial t} (\text{curl} \mathbf{A}) = \sigma \frac{\partial \mathbf{B}}{\partial t} = \frac{\mu}{\rho} \frac{\partial \mathbf{H}}{\partial t}. \quad (10.47)$$

This means that plotting the magnetization m due to eddy currents versus dH/dt of a conducting sample delivers a linear relation where the slope is proportional to σ (specific electrical conductivity) which is equal to $1/\rho$ (specific electrical resistivity), as is also found experimentally.

The maximum eddy-current density [$J_{\text{max}} = J(r_{\text{sample}}, z = 0)$] of all samples with different pulse duration and their magnetic moment m_{FEMM} , m_{FEMM} can also be calculated using a finite element package such as FEMM by Meeker [10.34] (2D finite-element soft-

Fig. 10.34 The principle of eddy currents in a metallic sample

ware). For samples that are not large and frequencies that are not high a linear relation between the eddy-current density and the radius r holds, which gives a rather simple solutions for calculating the dynamic eddy-current magnetization, as follows.

The magnetization for a cylinder is

$$M = \frac{j_{\text{max}} r_s}{4}. \quad (10.48)$$

Hence, the magnetization is independent of the height of the cylinder.

A similar calculation delivers the magnetization for a sphere

$$M = \frac{j_{\text{max}} r_s}{5}. \quad (10.49)$$

To prove the assumption that the magnetization due to the eddy-current density increases linear with the radius but stays constant with the height of the sample, several cylindrical and spherical samples of Cu were

Fig. 10.35 Dependence of the maximum eddy-current magnetization on the radius

studied [10.33]. It was demonstrated that the measured maximum magnetization can be fitted with a function $f = Cr^2$, where r is the radius of the sample, which gives, as theoretically expected, a quadratic dependence as shown in Fig. 10.35.

On the experimental side, in agreement with the formulas above, the eddy currents were found to be independent of the height of the sample [10.35].

Conducting, Magnetic Samples – $f/2f$ Method [10.36, 37]

In a magnetic material the eddy currents are determined by the electrical conductivity σ but also by the permeability μ , where the latter is also a nonlinear function of the external field. In this case the eddy-current problem cannot be solved analytically. Here, numerical methods are the only possible way. However in some cases simplifications are possible. In order to correct the hysteresis loop of a hard magnetic material as measured in a PFM for the eddy-current error a special method was developed. The hysteresis loop of each sample is measured with two different pulse durations, f and $2f$, which generate the same J signal with respect to the applied field but with the addition of different dynamic magnetizations due to eddy-current distributions. The eddy currents are related to the frequency; the eddy-current magnetization is approximately proportional to dH/dt , as was shown already. By processing the two measurements it is possible to remove the error due to eddy currents, producing the direct equivalent of a static hysteresis plot; this approach is known as the $f/2f$ method [10.36, 37]. This method is based on the following equations

$$H_m = H_{\text{ext}} - H_{\text{eddy}} + H_d, \quad (10.50)$$

where H_{ext} is the external field applied by the pulse, H_{eddy} is the dynamic field caused by the eddy currents, and H_d is the demagnetizing field.

The polarization J appearing in a pulse-field experiment consists of two components, the true polarization $J_{\text{DC}}(H_{\text{DC}})$ as measured as a function of a DC field H_{DC} and the apparent polarization due to eddy currents J_{eddy} . Now performing two experiments, one with a short pulse (described by “s”) and one with a long pulse (described by “l”) one gets a set of field data and polarization data

$$H_{\text{ext},s} + \frac{J_{\text{eddy},s}}{\mu_0} = H_{\text{ext},l} + \frac{J_{\text{eddy},l}}{\mu_0}. \quad (10.51)$$

Based on these equations a mathematical procedure was developed which delivers the so-called $f/2f$ correction. This method can be applied under the general

assumption of a sufficiently small eddy-current error, which means less than 20%. The validity and the limits of the $f/2f$ method were investigated and proofed by a three-dimensional (3D) finite-element calculation [10.38]. Therefore, this so-called $f/2f$ method seems to be a good way to correct eddy-current errors in the measured hysteresis loop.

Application of the $f/2f$ Correction to a Magnet

To test the $f/2f$ correction a large cylindrical commercial Nd-Fe-B magnet from VAC (Vacodym 510, Charge 210105) was measured (Fig. 10.36). This cylinder had a diameter of $d = 20$ mm, and a height of 6.9 mm. The static data measured by VAC were: remanence $B_R = 1.296$ T, and coercivity $iH_C = 1255$ kA/m.

The $f/2f$ -corrected coercivity value was found to be 1275 kA/m, which is 2% too high. The measured remanence value of 1.25 T is about 2% too low. This is experimental proof of the validity of this $f/2f$ correction.

Magnetic Viscosity

The magnetic viscosity can influence the shape of a in a PFM-measured hysteresis loop. This leads especially to higher coercivity values measured in a transient field. The general questions are: how large is this error, when is this error not negligible, what is the origin of this error, and can this error be corrected?

The effect of magnetic viscosity has been well known for many years and has been investigated for

Fig. 10.36 Room-temperature hysteresis loop as obtained on a large (20-mm diameter) sintered Vacodym 510 magnet. One loop was measured with a long pulse (time duration of 57 ms) and one with a short pulse (time duration of 40 ms) (outer loop). The inner lying loop represents the corrected hysteresis

many hard magnetic materials [10.39, 40]. It has also been shown that the magnetic viscosity coefficient S_v can be used to determine the activation volume, an important parameter for the understanding of the coercivity mechanism [10.41]. The viscosity coefficient is usually determined by static field measurement. One measures the loop $M(H)$ and stops in the second quadrant with this measurement at a certain field H . There under the condition $H = \text{const.}$ the time dependence of M is measured, from which the magnetic relaxation coefficient $S = dM/d \ln t$ can be determined. For calculating S_v one needs also the irreversible susceptibility χ_{irr} . One has to consider that the typical field sweep rate in pulsed field experiments dH/dt is approximately 1000 T/s, which is 10^6 orders of magnitude larger than the field sweep rate dH/dt that can usually be achieved in VSMs using an electromagnet or a superconducting coil. Generally, the viscosity coefficient (S_v) determined from static field measurements (denoted by S_{vj}) is much smaller than that obtained from PFM measurements (denoted as S_{vp}). However, it may be of great importance that the time windows in these two experiments are completely different.

Experimental Method to Determine Viscosity

In order to obtain the coercive field of the specimen under fields with different sweep rates, hysteresis loops of the samples are recorded at a fixed temperature by using a pulse field magnetometer (PFM) applying a sufficiently high maximum field. The sweep rate dH/dt can be changed either by varying the capacitance of the condenser battery or by changing the amplitude of the field or both; with this method field sweep ranges from about 0.5 up to $20 \text{ GAm}^{-1}\text{s}^{-1}$ and even higher are possible. The dependence of the coercivity on the field sweep rate dH/dt can be used to estimate the viscosity S_v (10.52)

$$S_{vp} = \frac{H_{C1} - H_{C2}}{\ln [(dH_1/dt) / (dH_2/dt)]} \quad (10.52)$$

This method and its limitation were recently demonstrated on the model material $\text{SmCo}_{5-x}\text{Cu}_x$ and related compounds [10.42]

The Magnetic Viscosity in $\text{SmCo}_{5-x}\text{Cu}_x$ alloys [10.42]

SmCo_5 is nowadays a standard permanent-magnet material. However, substituting Co by Cu causes a change of the coercivity mechanism from nucleation to pinning. Additionally it was found that in $\text{Sm}(\text{Co}, \text{Cu})_5$ a large magnetic-viscosity effect appears. Therefore this

Fig. 10.37 Coercive field as a function of the sweep rate dH/dt measured in as-cast and annealed $\text{SmCo}_{5-x}\text{Cu}_x$ alloys

is also a model material in order to investigate viscosity effects in a PFM. In Fig. 10.37 the coercive field as a function of dH/dt , as measured in as-cast and annealed $\text{SmCo}_{5-x}\text{Cu}_x$ magnets, is presented. The coercivity increases with dH/dt , providing evidence for the existence of a strong magnetic aftereffect.

Conclusion

a) Eddy-current errors. The application of a transient field causes eddy currents in metallic samples which lead to a dynamic magnetization M_{eddy} that is proportional to dH/dt [10.33]; the proportionality factor is the specific electrical conductivity. Additionally, M_{eddy} scales with R^2 (R is the radius of a rotational symmetrical sample), which means that the error increases quadratically with increasing sample diameter [10.33]. Fortunately most of the metallic permanent magnets are sintered materials where the specific resistivity (typically $2 \times 10^{-4} \Omega \text{ m}$) is generally a factor 50–100 higher than that of Cu. Therefore the error in magnetization measurements due to eddy currents is rather small. These considerations have led to the development of eddy-current correction for hysteresis loops measured in pulsed fields, which is called the $f/2f$ method. In this case one measures the loop with two different pulse durations and calculates the corrected loop point by point, applying an extrapolation procedure [10.36, 37]. It was shown by finite-element calculations that for eddy-current errors that were not too large (less than 20%) the corrected loop agrees with the true loop within 2%. This means that the effect of

eddy currents is understood and can be corrected in most cases [10.38].

b) Magnetic viscosity effects. When the hysteresis loop of hard magnetic materials is measured in transient fields the so-called magnetic viscosity causes a difference between the measured loop and the true loop. The magnetic viscosity is also observed in nonconducting materials (e.g., ferrites), therefore it is not due to eddy currents. It has to be mentioned that the time constant of the exponential decay of eddy currents (in metallic samples) is of the order of typical values of microseconds, whereas that of the logarithmic decay of the viscosity lies between milliseconds and seconds. Additionally eddy currents depend on the geometry of the sample whereas this is not the case for the viscosity.

10.3.3 Calibration [10.1]

Field Calibration

The field is calibrated using a small pick-up coil whose effective winding area is known from an NMR calibration. The induced voltage $u(t)$ is then fitted using (10.53), in order to determine the field calibration factor k , the damping factor and the pulse duration (including the effect of the damping)

$$\begin{aligned}
 H &= H_0 \exp(-at) \sin \omega t, \\
 u_i(t) &= -NA \frac{dB}{dt} \\
 &= -NA\mu_0 H_0 \frac{d}{dt} [\exp(-at) \sin \omega t] \quad (10.53)
 \end{aligned}$$

The damping factor a determined in this way can be compared with the value given by a PFM circuit using $a \approx R/2L$ (where R is the resistivity of the pulse magnet, and L is the inductivity of the pulse magnet).

The calibration factor k is also determined as a function of the gain (integrator gain and the gain of preamplifier). The calibration factor k gives a relation

between the induced voltage and the field at the search coil. At the same time the integrated voltage (using different gain factors) of the H -measuring coil (which is located at the pick-up rod) on the magnetometer system is recorded.

It was shown that the calibration factor k was also determined as a function of the gain using an analogue integrator [10.1]. The scattering of the k factor was below $\pm 1\%$. This indicates that the linearity of the gain is better than 1%. Using such a procedure, an absolute field calibration of better than 1% is achieved, including the time constants (gain) of the integrator.

Magnetization Calibration

The magnetization is calibrated using well-known materials such as Fe and Ni (in which the eddy-current error causes an uncertainty) or preferably a nonconducting sample such as Fe_3O_4 or a soft magnetic ferrite, such as 3C30 (Philips). All calibration measurements are performed at room temperature. The results of the magnetization calibration measurements are summarized in Table 10.3. To check the reproducibility all measurements were repeated 10 times to give an average value $\langle M \rangle$. Additionally measurements using a shorter pulse duration (40 ms) were performed, which were generally in good agreement with that of the long pulse. For the metallic samples an error of 1–2% due to the eddy currents occurs.

The mean value of the deviations $D_{mv} = 1.6\%$ is higher than the true values. It should be mentioned that no significant differences in the measured magnetization values were obtained, when different pulse duration were employed.

The mean value of the deviations $D_{mv} = 1.6\%$ has a standard deviation of 0.95%. The standard deviations concerning the reproducibility gave a mean value of 0.19%. Therefore, the deviation is, in the worst case, 1.14%. This means that the magnetization value could be calibrated with an absolute accuracy of $\pm 1.14\%$.

Table 10.3 Summary of calibration results

Sample	Shape	$\mu_0 H_{\max}(T)$ $t = 57 \text{ ms}$	$\langle \mu_0 M \rangle$ (T)	$\mu_0 M_{\text{literature}}$ (T)	Error (%)	$\mu_0 M(T)$ $t = 40 \text{ ms}$
Fe_3O_4	Sphere $2r = 5.5 \text{ mm}$	1.5	0.5787 ± 0.001	0.569 [10]	+1.6	0.5782
Ni	Cylinder $D = 4; h = 8 \text{ mm}$	1.5	0.6259 ± 0.0008	0.610 [11]	+2.6	0.6322
Fe	Cylinder $D = 4; h = 8 \text{ mm}$	4.5	2.1525 ± 0.0051	2.138 [12]	+1.4	2.1826

Reliability of Calibration

For testing the reliability of the calibration procedure a “calibrated sample” from the Physikalisch-Technische Bundesanstalt (PTB) in Braunschweig, Germany was measured. This sample was an anisotropic barium–ferrite from Magnetfabrik Schramberg with a cylindrical shape, with a height of 10 mm and a diameter of 6 mm. The mass was 1.417 g. The hysteresis measurement was performed by applying an external field of 2 T and a pulse duration of 56 ms. In order to reduce the statistical error the measurement was repeated 7 times.

The mean value of the remanence magnetization determined in this way is $B_r = (0.3644 \pm 0.0002)\text{T}$, which corresponds to an error of $\pm 0.05\%$. PTB gave a remanence value of $B_r = (0.3625 \pm 0.0044)\text{T}$. So the difference between the PFM and the PTB value is about 0.5%, which is smaller than the given calibration error.

In order to test the effect of pulse duration, the PTB-calibrated sample was measured under the same conditions but with different pulse durations (56 ms and 40 ms) (Fig. 10.38). The difference in the remanence magnetization is below 1%. It should be noted that also the measured coercivity is only 2% higher, than the PTB value, which strongly supports the reliability of our field calibration.

Influence of Sample Geometry on Magnetization Values

In order to investigate the effect of the sample geometry on the accuracy of the magnetization measurements in the PFM, a set of industrial soft magnetic ferrites with different shapes were used [Philips (3C30)]. All samples were from one batch. This material has a magnetization at room temperature of about 0.55 T, whilst the Curie temperature was about 240 °C. The density is 4800 kg/m³. Since this material is an insulator, there are no eddy-current effects. The chosen shapes are given in Table 10.5.

The samples were measured in an external field with an amplitude of 2 T and a pulse duration of 56 ms. All samples were measured at room temperature (21 °C \pm 1 °C) using the same amplification factor and the same mechanical adjustments. Small deviations are visible in the shape of the hysteresis loops, especially where the saturation enters the high-permeability region (Fig. 10.39). This is due to the fact that the mean demagnetization factor causes an error, which becomes especially significant in this part of the loop.

The results are summarized in Table 10.6: The magnetization values of the three different cubes show

Table 10.4 Summary of calibration measurement

Sample	$\mu_0 M_{\text{meas}}$ (T)	S (%)	$\mu_0 M_{\text{literature}}$ (T)	Deviation (%)

Medium cube	0.555
Big cube	0.557

a difference of up to 0.6% (Table 10.6). The value for the sphere exhibits the largest difference of 2% with respect to the average value of the cubes. (This may be a result of the grinding process in an air-pressure-driven mill. The sample is forced to rotate rapidly in a container of corundum.) It is possible that the surface structure of the sample may have been destroyed. If a disturbed surface layer of 40 μm is assumed, this could account for the deviation of the magnetization value.

Fig. 10.40 Temperature dependence of the saturation magnetization of 3C30 compared with that of Fe₃O₄

Discussion of the Calibration Procedure

The field of a PFM is calibrated using a small pick-up coil, where the effective winding area is known from NMR calibration. Using such a procedure allows an absolute field calibration of better than 1%, including the time constants (gain) of the integrator. The obtained field calibration also agrees within 2% with that of the PTB-calibrated magnet coercivity value.

In principle, nonconducting materials, such as Fe₃O₄ or a soft magnetic ferrite like 3C30, are better suited for this calibration. Unfortunately, the temperature dependence of the magnetization of the industrially available ferrite 3C30 is much worse than that of Fe₃O₄ (Fig. 10.40).

The calibration constants using Fe₃O₄, Fe and Ni agree within 1.6%. The reproducibility of the different magnetization measurements – especially using Fe or Ni samples – was better than 0.3%. The error due to eddy currents in the rather long pulse duration (56 ms) is negligible. The zero signal of the system is less than 10% of the Fe₃O₄ sample signal, which has the smallest sample signal. According to these considerations, one can conclude that the sensitivity of the PFM investigated here is high enough to measure Nd–Fe–B magnet samples as small as 0.3 g mass, which corresponds to a cube of 3 mm × 3 mm × 3 mm. Such a PFM is, however, also capable of measuring samples with diameters up to 30 mm. It has to be mentioned that the sensitivity for a certain sample size depends mainly on the coupling between the sample and the pick-up system. Therefore the sensitivity can be improved by adjusting the pick-up system to a certain sample dimension.

If one works very carefully, an absolute magnetization calibration within ±1% is possible. Due to the good linearity of the analogue measuring electronics available nowadays and the high resolution of ADC cards (14 bit), a relative measurement – which is most important for a quality-control system – with a relative accuracy better than 0.5% is possible.

10.3.4 Hysteresis Measurements on Hard Magnetic Materials

Comparison Static Measurement – Dynamic Measurement

For testing a PFM system a set of commercial permanent-magnet samples was chosen: isotropic and anisotropic barium ferrite, anisotropic low- and high-

Fig. 10.41 Hysteresis loop as measured on the isotropic BaFeO HF 8/22 spherical sample

coercivity Nd–Fe–B magnets. The shape of the samples was cylindrical: diameter 4 mm, length 5 mm; a demagnetizing factor of 0.255 was used. In order to allow a comparison between static hysteresis and dynamic hysteresis measurements a set of spheres (from the same batch of samples) were produced at the Technical University (T.U.) of Vienna.

In order to test the reliability of dynamic measurements pulsed field hysteresis loops were compared with static loops. In Fig. 10.41 the hysteresis loop as measured on an isotropic barium ferrite obtained in the static system at the Centre National de la Recherche Scientifique (CNRS) in Grenoble is compared with that measured in the T.U. PFM. The use of barium ferrite has the advantage that there are no eddy currents because this material is an insulator. The difference is within the line thickness.

Figure 10.42 also shows for comparison hysteresis measurements on a Nd–Fe–B magnet as performed in the PFM (T.U. Vienna) and in the static magnetometer (CNRS Grenoble). There are differences in the slope of the $M(H)$ curve close to the coercivity. It is believed that this is due to small differences in the sphericity of the samples. This cannot be due to eddy currents in the sample because the coercivity value is the same. This shows that, for sample sizes below 10 mm, and for the pulse duration here used (15.7 ms) the eddy-current effects are negligible.

Rare-Earth-Based Magnets

For the following discussion of different types and shapes of rare-earth-based industrial magnets the room-temperature hysteresis loops were measured in the industrial PFM located at T.U. Vienna.

Figures 10.43 and 10.44 show such a loop as obtained from Vacodym 510 (a Nd–Fe–B magnet); the agreement between the static and pulsed data is very good. The applied field, especially in the second half wave, is not sufficient.

10.3.5 Anisotropy Measurement

Generally the magnetocrystalline anisotropy constants are determined from measurements on a single crystal in a torque magnetometer or similar device. Unfortunately single crystals are not available from many materials. In this case, polycrystalline material can sometimes be aligned in an external field and then the magnetization $M(H)$ is measured parallel and perpendicular to the external field. Curves determined in this way can be fitted, which also allows an estimate of the magnetocrystalline anisotropy to be made.

Fig. 10.42 Room-temperature hysteresis loop of a spherical Nd–Fe–B 210/220 magnet measured in a static magnetometer and in the pulsed field magnetometer

Fig. 10.43 Room-temperature hysteresis loop as obtained on a cube of Vacodym 510 (an Nd–Fe–B magnet)

Another, sometimes better, possibility is to determine the magnetocrystalline anisotropy field H_a using the so-called singular point detection (SPD) technique [10.43]. The principle of the SPD method is shown in Fig. 10.45. Single crystals are not necessary for the SPD method, and it allows the determination of the physically relevant anisotropy field even for polycrystalline samples. This is especially important when

Fig. 10.44 Room-temperature hysteresis loop as obtained on a cylinder of Vacodym 510 (an Nd–Fe–B magnet)

investigating technically relevant compositions, which often consist of many phases and exhibit rather complex compositions, such as e.g. $\text{Sm}(\text{Co}, \text{Fe}, \text{Cu}, \text{Zr})_{7.5}$ which is typical for a so-called 2/17-based technical magnet [10.44]. Additionally many new technologies, such as rapidly quenching, hydrogenation disproportionation desorption recombination (HDDR), nitrogen loading or even thin films, lead to isotropic material, where single crystals are not possible in principal. In this case the SPD technique is the only possibility to determine the anisotropy field. Up to now this method was restricted to uniaxial systems. Recently it was extended to easy plane systems [10.45], which is essentially for many 3D-dominated compounds.

Limitations of the SPD Method

The SPD method delivers only the anisotropy field H_a . This is technically relevant, but it is not sufficient for a deeper analysis based on the anisotropy constants. At least the anisotropy energy and its temperature dependence have to be known. If the real saturation magnetization can be determined the anisotropy energy can be calculated from H_a . Unfortunately an accurate determination of the saturation magnetization is not simple in hard magnetic compounds, because insufficiently high fields are available in usual magnetometers. For this purpose accurate magnetization measurements up to fields which are comparable to H_a (or larger) are necessary, and at different temperatures. When the tem-

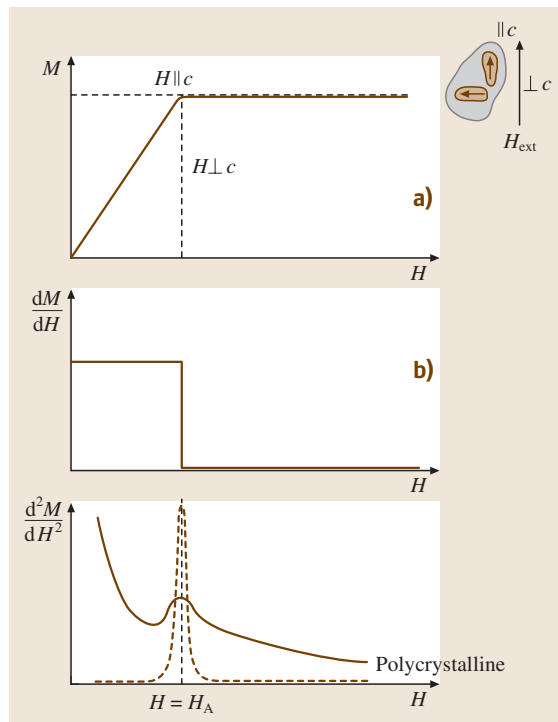

Fig. 10.45 The principle of the SPD measurement for determining the anisotropy field

perature dependence of the anisotropy energy and that of the magnetization is known, various types of analysis such as scaling laws can be used in order to come to an understanding of these data. From such an analysis, information about the origin of the anisotropy can be deduced.

Studies performed in existing pulsed field systems (in Vienna and Parma) showed that the SPD method works well for anisotropy fields up to about 20 T. The reason for this limitation is that the maximum external field has to be at least 50% higher than H_a in order to make the singularity visible. Another limitation comes from the fact that at higher fields (above approximately 25 T) the vibrations and consequently the noise of the high-field system increases drastically, although this is not yet fully understood. Because the SPD method is based on a differentiating technique ($d^2M(t)/dt^2$) the noise appearing at higher fields limits the measurable H_a values.

One of the basic problems here is that using a differentiating technique greatly increases all type of noise; and the high-frequency noise in particular increases with ω^2 .

In the meantime the SPD method has been used to investigate the anisotropy field of many hard magnetic materials [10.46–48]. Some materials of interest recently where the measurement of the anisotropy field is only possible using the SPD method are the exchange coupled nanocrystalline hard magnetic materials.

The Anisotropy Field of Nanocrystalline Materials

It is not an easy task to determine the anisotropy field in these intrinsic isotropic samples. In addition, the strong magnetic exchange interaction among nanocrystallites makes measurements even more difficult. In this re-

Fig. 10.46 The temperature dependence of the anisotropy field for hot-pressed mechanically alloyed Pr–Fe–B

Fig. 10.47 The SPD peak measured at 300 K for mechanical alloyed hot-pressed Pr–Fe–B samples with nanosized grains

spect, singular point detection (SPD) provides a unique method for the direct determination of the anisotropy field of isotropic samples. In Fig. 10.46 the temperature dependencies of the anisotropy field measured for mechanically alloyed, nanocrystalline $\text{Pr}_9\text{Fe}_{85}\text{B}_6$, $\text{Pr}_{11.76}\text{Fe}_{82.36}\text{B}_{5.88}$ and $\text{Pr}_{18}\text{Fe}_{76}\text{B}_6$ is shown [10.49]. Here the sample $\text{Pr}_9\text{Fe}_{85}\text{B}_6$ represents a nanocomposite with $\text{Pr}_2\text{Fe}_{14}\text{B}$ and $\alpha\text{-Fe}$; the $\text{Pr}_{11.76}\text{Fe}_{82.36}\text{B}_{5.88}$ should be single phase containing only $\text{Pr}_2\text{Fe}_{14}\text{B}$ grains whereas the $\text{Pr}_{18}\text{Fe}_{76}\text{B}_6$ should contain $\text{Pr}_2\text{Fe}_{14}\text{B}$ grains that are decoupled by an excess of Pr.

It is worth noting that the anisotropy field measured by using the SPD technique corresponds only to that of the hard magnetic phase. In the case of $\text{Pr}_9\text{Fe}_{85}\text{B}_6$ which consists of $\text{Pr}_2\text{Fe}_{14}\text{B}$ and $\alpha\text{-Fe}$, that is the $\text{Pr}_2\text{Fe}_{14}\text{B}$ phase. The reduction of the anisotropy field in the nanocrystalline $\text{Pr}_{12}\text{Fe}_{82}\text{B}_6$ grains is a strong indication of the presence of magnetic exchange interactions. In the case of microcrystalline sintered Pr–Fe–B magnets the magnetic exchange interaction among the micro-sized grains is insignificant to influence the easy magnetization direction (EMD) of the grains. Thus the anisotropy field measured in the microcrystalline magnets corresponds to the anisotropy field of isolated $\text{Pr}_2\text{Fe}_{14}\text{B}$ grains. However, when the average grain size is reduced to nanometer size ($D_V < 50\text{ nm}$), the exchange interaction among the hard magnetic grains may become so strong that the EMDs of the nanocrystallites can be slightly tilted without the presence of external fields. The actual direction of the final EMD could be an energetic compromise of the surrounding nanocrystallites. This slightly tilted EMD gives a naturally reduction of the anisotropy field. This reduction of H_a also becomes visible in the SPD peak of the measurement of d^2M/dt^2 versus H , where the peak indicates the position of H_a (Fig. 10.47). From Fig. 10.46 a systematic decrease of $H_a(\text{T})$ with increasing coupling between the grains going from excess Pr content (18% Pr) to a stoichiometric sample (12% Pr) to a low-Pr-content material (9% Pr) becomes clearly visible for higher temperatures. For lower temperatures, because of the increasing anisotropy, a decoupling of the grains occurs that causes equal values of H_a for all three samples.

10.3.6 Summary: Advantages and Disadvantages of PFM

A PFM generally allows fast magnetization measurements in sufficiently high magnetic fields. Reproducible, nondestructive fields up to 40 T are nowadays the state of the art. Using a capacitor bank as an energy

store allows the generation of a pulsed magnetic field in a volume that is best suited to solve a technical task. Therefore for many applications a PFM is much better suited than a standard static magnetometer, which is less flexible.

Comparison with static hysteresis loops demonstrated that, if both systems are calibrated carefully, PFM measurements of hard magnetic materials are reliable and achieve a similar accuracy to that of a static system.

In terms of the demagnetizing field, correction for industrial shapes is not simple. For shapes like cylinders or cubes that are not too complex the use of a single factor is sufficient, but for other shapes this problem is still open. This is not only a problem for PFM, but occurs in all magnetic open circuits.

A general understanding of eddy currents now exists. The $f/2f$ method is a good fast method to correct for eddy-current errors in PFM measurements.

In principle magnetic viscosity causes an error in all hard magnetic materials. However, it seems that

pinning-type materials exhibit a larger magnetic viscosity. The magnetic viscosity generally increases with the magnetocrystalline anisotropy. Therefore for room-temperature measurements on nucleation-type materials (ferrites, Nd-Fe-B, SmCo₅-based) this effect seems to be sufficient small.

To summarize, PFMs can be constructed that show better results than many static hysteresisgraphs however with the advantage that in a PFM higher fields are available, a faster measurement is possible and no special sample preparation is generally necessary. For ferrites and Nd-Fe-B-based magnets, fields up to 5 T are necessary, whereas for materials such as SmCo₅-based magnets, fields of approximately 10 T are necessary.

Beside the possibility of measuring a magnetization (hysteresis loop) a PFM can also be used to determine the anisotropy field using the SPD method, as was shown. This method is unique because it works even for polycrystalline materials.

10.4 Properties of Magnetic Thin Films

Magnetic thin films are receiving growing interest both from a fundamental scientific point of view and because of a variety of novel applications, in particular for magnetic-field sensors and information storage. Some of their specific properties relating to new technologies have already been mentioned in Sect. 10.1.5. In the present section the most important magnetic properties of magnetic thin films are discussed together with the most suitable methods of measuring the related quantities.

10.4.1 Saturation Magnetization, Spontaneous Magnetization

Phenomena

The saturation magnetization of a material M_{sat} , defined as the magnetic moment per volume, is of great technical interest because it determines the maximum magnetic flux that can be produced for a given cross section. However, M_{sat} as the *magnetization at technical saturation* is not a well-defined quantity because a large enough external magnetic field must be applied to produce a uniform magnetization by eliminating magnetic domains and aligning the magnetization along the field against magnetic anisotropies; however, at the same time the magnetization at any finite temperature $T > 0$

will continue to increase with increasing applied field (*high-field susceptibility*). The only well-defined quantity, hence, is the spontaneous magnetization M_S i. e. the uniform magnetization inside a magnetic domain in zero external field.

In practice, M_S is determined by measuring the magnetization as a function of the external field, $M(H)$ (which means the magnetization component parallel to the applied field) up to technical saturation, with a linear extrapolation of the data within the saturated region back to $H = 0$. A linear fit is a good approximation for temperatures well below the Curie temperature of the ferromagnetic material.

The method proposed above works best by applying the external field along an easy axis of magnetization and is especially well suited for thin films because of the absence of a demagnetizing field for in-plane magnetization; usually a relatively small field is sufficient for saturation and the extrapolation to $H = 0$ is not required. Of course, higher fields are required for magnetically hard materials. In films having a dominating intrinsic anisotropy with a perpendicular easy axis the measurement should be done along the film normal.

When comparing the magnetization of a thin film to the value of the corresponding bulk material two different effects can be important:

1. the magnetization or the magnetic moment per atom in the ground state, i.e. at absolute zero temperature, might be enhanced. Depending on the specific combination of ferromagnetic material and substrate the enhancement may reach 30% for a single atomic layer (e.g. Fe on Ag or Au), but will disappear 3–4 atomic layers away from the interface. Depending on the band structure of the materials the magnetic moments at the interface may also be reduced in some cases (e.g. for Ni on Cu);
2. thermal excitations which result in a decrease of M_S with increasing temperature are more pronounced in thin films compared to bulk material. In a film of 10 atomic layers of Fe on Au, M_S at room temperature is reduced by about 10% compared to bulk Fe. The origin of this effect is the reduced (magnetic) coordination at surfaces and interfaces, which leads to an enhanced excitation of spin waves; for the same reason the Curie temperature is reduced in ultrathin films compared to the bulk material.

Measurement Techniques and Instruments

A variety of methods are used to measure the magnetic properties of thin films. In many cases, especially for relatively thick films, the techniques used for bulk material can be applied as well (see the overview in Sect. 10.1.6). Here, the emphasis is put on the high sensitivity required for films thinner than about 100 nm and for ultrathin films with thicknesses down to 1 nm or less.

Magnetic moments, m , in terms of absolute values are determined with a suitable magnetometer from the field dependence of the moment, the so-called magnetization loop, $m(H)$. The magnetization $M(H)$, i.e. magnetic moment per volume, is found by dividing the moment by the magnetic volume. For ultrathin films the main uncertainty on M often comes from the determination of the volume rather than from the magnetic moment itself.

Vibrating-Sample Magnetometer (VSM)

The vibrating-sample magnetometer (VSM) is probably the most widely used standard instrument. The principle

Fig. 10.48 Schematic view of a commercial SQUID magnetometer consisting of a liquid-He cryostat, a superconducting magnet, the variable-temperature sample chamber with thermometers and the detection coils close to the sample position. After [10.50]

Fig. 10.49 Schematic diagram of the circuit of a commercial **SQUID** magnetometer (Quantum Design Inc.). All the coils are superconducting. The **SQUID** amplifier transforms any flux change sensed by the detector coils into a current, which is fed to the feedback coils such that this flux change is exactly compensated. This compensating current at the same time constitutes the output signal of the magnetometer. After [10.50]

of operation is described in Sect. 10.2 (Fig. 10.7). When the specimen oscillates between a set of pick-up coils with a frequency of several 10 Hz to a few 100 Hz, the amplitude of the AC voltage induced in the pick-up coils is proportional to the magnetic moment of the specimen and the vibration amplitude of the sample. The factor of proportionality depends on the entire geometry including the shape and size of the sample. This must be taken into account when an absolute calibration is carried out. The principle of measurement can be combined with an iron core electromagnet, or with air coils for low-field operation, or with a superconducting magnet for high-field applications. The **VSM** allows relatively fast measurements (1–10 min for a complete $M(H)$ loop, depending on the type of magnet and the required sensitivity), is flexible and easy to use. In particular, measurements at various angles can be made with the great precision required for the determination of magnetic anisotropies. The sensitivity attainable depends largely on the geometry and position of the pick-up coils. Standard versions are useful for magnetic moments corresponding to Fe or NiFe films more than 5 nm thick (assuming a lateral size of 1–2 cm). Thinner films down to 1 nm can be measured with an optimized **VSM**. The sensitivity is generally reduced for variable-temperature measurements when a cryostat or oven must be mounted.

The SQUID Magnetometer

The **SQUID** magnetometer is based on the same principle as the **VSM** but with a superconducting pick-up coil circuit and a superconducting quantum interference device (**SQUID**) as the flux detector. The structure of a commercial **SQUID** magnetometer is schematically shown in Fig. 10.48 [10.50].

The sample executes a periodic linear motion with a vibration frequency of 0.1–5 Hz. This causes a change of magnetic flux in the pick-up coils, which are part of the totally superconducting circuit outlined in Fig. 10.49.

The **SQUID** itself is operated in a constant-flux mode and serves as an extremely sensitive zero-detector in the feedback loop outlined in Fig. 10.49. The output signal of the magnetometer is proportional to the current in the feedback coil required to compensate the flux change sensed by the pick-up coils.

The detection limit of the **SQUID** magnetometer for magnetic moments is about 1000 times lower than that of the **VSM**, i. e. about 10^{-9} Gcm³ or 10^{-18} Vsm. It is usually combined with a superconducting magnet and a variable-temperature He cryostat, which allows for measurements in high fields (3–7 T for commercial instruments) and at low temperatures. The biggest challenge is to make use of the high sensitivity of

the **SQUID** in the presence of unavoidable fluctuations of the field from the external magnet. The most efficient solution is to use carefully balanced pick-up coils in the form of a gradiometer of first or second order (e.g. a second-order gradiometer is shown in Fig. 10.49).

Typical measuring times for a complete magnetization loop may range from 30 min up to a full day depending on the field range and number of data points. For precision measurements a careful calibration that takes into account the specific sample geometry is necessary. For most purposes the **SQUID** magnetometer is the most suitable and versatile instrument for measuring extremely thin films in a wide range of temperatures (typically 2–400 K) and applied magnetic fields (up to 7–9 T).

The Alternating (Field) Gradient Magnetometer

The alternating (field) gradient magnetometer (**AGM** or **AFGM**) is a modification of the well-known Faraday balance that determines the magnetic moment of a sample by measuring the force exerted on a magnetic dipole by a magnetic field gradient. The principle of the instrument [10.51] is sketched in Fig. 10.50. The force is measured by mounting the sample on a piezoelectric bimorph, which creates a voltage proportional to the elastic deformation and, hence, to the force acting on the sample. By driving an alternating current through the gradient coils, with lock-in detection of the piezo voltage and by tuning the frequency of the field gradient to the mechanical resonance of the sample mounted on the piezoelectric element by a glass capillary a very high sensitivity can be achieved that approaches that of a **SQUID** magnetometer under favorable conditions. The main advantage of the **AGM** is its relative immunity to external magnetic noise and the resulting high signal-to-noise ratio and short measuring time. A major disadvantage is the difficulty in obtaining an absolute calibration of the magnetic moment because the signal is not only proportional to the sample magnetic moment but also to the Q -factor of the sample–capillary–piezo system, which varies with sample mass and temperature. This problem can be overcome by inserting a small calibration coil close to the sample position. Also, difficulty in obtaining an exact angular orientation of the sample relative to the external magnetic field is a drawback of this instrument. An **AGM** is relatively easy to build, but is also commercially available. It can be equipped with a cryostat or oven for variable-temperature measurements.

Fig. 10.50 Principle of the alternating (field) gradient magnetometer (**AGM**/**AFGM**); the gradient field coils are fed with an alternating current with a frequency tuned to the mechanical resonance of the sample–capillary–piezo system. The sample and gradient coils are mounted between the pole pieces of an electromagnet

Torque Magnetometers

Torque magnetometers in the form of a torsion pendulum (Sect. 10.2.2) have been successfully used for ultrathin films due to the high sensitivity attainable [10.52]. However, they measure the effective magnetic anisotropy of the sample; therefore, the different contributions to the anisotropy of the given sample must be known in order to determine the magnetic moment. This is further discussed in the next section.

Magneto-Optic Techniques

When only the shape of the magnetization loop, or the relative variation of the magnetization with temperature, orientation of the external field or another external parameter is of interest, *magneto-optic effects* (magneto-optic Faraday effect or Kerr effect, **MOKE**) are very useful. Because of the limited penetration depth of light magneto-optic techniques only probe the first 10–50 nm

Fig. 10.51 Outline of a set up for magneto-optic Kerr-effect (MOKE) measurements (see text)

below the surface of a metallic sample and are therefore well suited for the fast characterization of magnetic thin films. For these, **MOKE** is a particularly powerful technique [10.53].

A typical arrangement is sketched in Fig. 10.51.

Upon reflection from a magnetic surface a beam of linearly polarized light in general will change its state of polarization depending on the relative orientation of the magnetization of the sample and the polarization axis. Both the ellipticity, ε_K , and Kerr rotation angle of the polarization, δ_K , occurring due to reflection can be used to measure a certain magnetization component defined by the specific arrangement. Basically, there are three different arrangements: i) the polar Kerr effect is measured with (nearly) perpendicular incidence of the light beam; the magnetizing field is applied perpendicular to the film plane and δ_K is proportional to the perpendicular component of the magnetization; ii) the longitudinal Kerr effect is observed with the light beam at oblique incidence and the in-plane magnetization component parallel to the plane of incidence is measured; iii) the transverse Kerr effect, which is observed in the same geometry as the longitudinal **MOKE**, produces a change of the intensity of the reflected beam and is proportional to the magnetization component perpendicular to the plane of incidence.

Gas lasers like He–Ne or laser diodes are equally used for **MOKE** measurements provided that the intensity and polarization are sufficiently stable. Various modulation techniques in combination with synchronous detection have been used to enhance the signal-to-noise ratio. A careful arrangement allows for very high sen-

sitivity that is sufficient to measure the magnetization loops of films of less than a single atomic layer [10.54].

A major advantage of the **MOKE** technique is the possibility to focus the laser spot at the sample surface to less than $1\ \mu\text{m}$ and thus measure magnetic properties with high lateral resolution. This is especially useful when the thickness dependence of properties is investigated by producing wedged samples with a lateral thickness variation. Another characteristic feature is the limited penetration depth of visible light of a few 10 nm in typical metal films; this allows measurements with a qualitative depth resolution, which is especially interesting for investigating multilayer structures. This can be further enhanced by choosing an appropriate wavelength for the light source according to the materials of interest, because the Kerr angle δ_K and Kerr ellipticity ε_K vary with the material and wavelength of the light.

MOKE, on the other hand, does not allow for a quantitative measurement of the absolute value of the magnetization. However, it is one of the most useful tools to investigate magnetic anisotropies, temperature dependence of magnetization and fast magnetization dynamics in magnetic films.

Magneto-optic effects in the (soft) X-ray energy range, in particular X-ray circular magnetic dichroism (XMCD), offer a unique potential: by tuning the photon energy to a core-level absorption edge it is possible to measure magnetic moments in an element-specific way. Furthermore, orbital and spin magnetic moments of electrons can be separately determined via so-called sum rules. This technique requires a synchrotron radiation source with circular polarization.

10.4.2 Magneto-Resistive Effects

Magneto-resistance means that the electric resistance of a material changes upon the application of a magnetic field. All conductive materials show magneto-resistive effects. However, here the discussion is restricted to magneto-resistance of ferromagnetic materials based on several different mechanisms.

Anisotropic Magneto-Resistance (AMR)

The dependence of the electric resistance on the angle θ between the magnetization and the current in a ferromagnetic material is called anisotropic magneto-resistance (AMR) and can be described by

$$R(\theta) - R_0 = a \cos^2 \theta. \quad (10.54)$$

The relative resistance change amounts to a fraction of a percent in most materials, up to 3% in Permalloy

films. The AMR effect has proved to be very useful for magnetic sensors.

Giant Magneto-Resistance (GMR)

The giant magneto-resistance effect is observed in layered magnetic film systems consisting of at least two ferromagnetic layers separated by a nonmagnetic metallic interlayer. When the magnetization in neighboring magnetic layers is switched from an antiparallel to a parallel configuration the electric resistance changes by an amount ranging from a few percent for two ferromagnetic layers to about 200% in special multilayer stacks. The GMR effect results from the spin-dependent scattering of electrons inside the layers and at the interfaces. For most materials the overall scattering rate is stronger for the antiparallel configuration, making it the high resistance state. In principle, the GMR can be observed both with the current flowing in the film plane [current-in-plane (CIP) configuration] or perpendicular [current-perpendicular-to-plane (CPP) configuration]. However, measurement of the CPP-GMR due to the small junction resistance requires either the use of superconducting leads or restricted lateral junction dimensions of 100 nm or less.

An obvious application of GMR junctions is for magnetic-field sensors. The most suitable configuration is the so-called spin valve, which consists of a free magnetic layer that is easily magnetized along a small external field, a nonmagnetic metallic interlayer (Cu in most cases) and a hard magnetic layer with its magnetization pinned to a fixed direction by exchange coupling to an antiferromagnetic layer. The resistance R of such a device varies with the angle θ of the free layer magnetization as

$$R(\theta) - R_{\min} = c \cos \theta. \quad (10.55)$$

Compared to the characteristics of an AMR element it is obvious that GMR is more useful as an angle sensor, and this is indeed an attractive application of this effect. The most successful application, however, is still in read heads for hard-disc drives, where it has contributed to the steady increase in areal storage density.

Tunnel Magneto-Resistance

The tunnel magneto-resistance (TMR) is observed in ferromagnetic double-layer structures with an intermediate insulating layer. If the insulator is very thin, i.e. typically 1–2 nm, and a small voltage is applied between the two magnetic metallic contacts then a current will flow by a quantum-mechanical tunneling process. Similarly to the GMR effect the current depends on the relative orientation of the magnetization in both layers, with a large current flowing in the parallel configuration. The magnetization in one of the layers is frequently pinned by exchange coupling to an antiferromagnet (*exchange bias*) as in a spin-valve. As a consequence, the tunnel resistance varies with the angle of the magnetization of the free layer in the same way as for GMR as discussed above. Over the years the TMR ratio at room temperature in state-of-the-art magnetic tunnel junctions of FeCo layers and Al-oxide tunnel barriers has been increased to about 50% in moderate external fields, which makes them a very attractive field sensor. It should be noted, however, that the TMR ratio decreases strongly with increasing bias voltage and tunneling current. This has to be taken into account when different magnetic tunnel junctions (MTJs) are compared.

The most spectacular application of MTJs is in all-solid-state fast magnetic random-access memories (MRAMs), which are now in an early state of production. A very promising recent achievement is a room-temperature TMR ratio of more than 500% obtained in junctions with an MgO tunnel barrier. This opens the way to an even brighter future for devices based on the TMR effect.

Colossal Magneto-Resistance

Extremely large magneto-resistance effects of more than 10 000% have been observed in certain compounds, especially in manganites with a Perovskite structure. This effect is related to a metal–insulator transition which can be driven by a magnetic field. However, the largest effects are only observed at low temperatures and in very high fields, making these materials of limited technical value.

Optical Properties

At present, optical measurement methods are the most powerful tools for basic and applied research and inspection of the characteristic properties of a variety of materials, especially following the development of lasers and computers. Optical measurement methods are widely used for optical spectroscopy including linear and nonlinear optics and magneto-optics, conventional and unconventional optical microscopy, fiber optics for passive and active devices, optical recording for CD/DVD and MO disks, and various kinds of optical sensing.

In this chapter, as an introduction to the following sections, the concept and fundamentals of optical spectroscopy are described in Sect. 11.1, including optical measurement tools such as light sources, detectors and spectrometers, and standard optical measurement methods such as reflection, absorption, luminescence, scattering, etc. A short summary of laser instruments is also included. In Sect. 11.2 the micro-spectroscopic methods that have recently become quite useful for nano-science and nano-technology are described, including single-dot/molecule spectroscopy, near-field optical spectroscopy and cathodoluminescence spectroscopy using scanning electron microscopes. In Sect. 11.3 magneto-optics such as Faraday rotation is introduced and the superlattice of semi-magnetic semiconductors is applied for the imaging measurement of magnetic flux patterns of superconductors as an example of spintronics. Sect. 11.4 is devoted to fascinating subjects in laser spectroscopy, such as nonlinear spectroscopy, time-resolved spectroscopy and THz spectroscopy. In Sect. 11.5 fiber optics is summarized, including transmission properties, nonlinear optical properties, fiber gratings, photonic crystal fibers, etc. In Sect. 11.6 optical recording technology for high-density storage is described in detail, including the measurement methods for the characteristic properties of phase-change and magneto-optical materials. Finally, in Sect. 11.7 a variety of optical sensing methods are described, including the measurement of distance, displacement, three-

dimensional shape, flow, temperature and, finally, the human body for bioscience and biotechnology.

This chapter begins with a section on basic technology for optical measurements. Sections 11.2–11.4 deal with advanced technology for optical measurements. Finally Sections 11.5–11.7 discuss practical applications to photonic devices.

11.1 Fundamentals of Optical Spectroscopy

11.1.1 Light Source

There are many light sources for use in scientific and industrial measurements [11.1–4]. This subsection deals with the features of various light sources. For source selection, various characteristics should be considered, such as wavelength range, radiant flux, directionality, stability in time and space, lifetime, area of emission, and temporal behavior. Spectral output, whether it is a continuum, a line, or a continuum-plus-line source, should also be considered. No light source covers all wavelengths simultaneously from the ultraviolet (UV) to infrared (IR) wavelength region. Although a black-body with extremely high temperature could realize such an ideal light source, the melting point of the materials that form the electrodes must be extremely

high, and it is impossible to construct it. We, therefore, should select an adequate source that covers the required wavelength region from the UV to the IR region. In general, we use a gas discharge lamp for the UV region and a radiation source from a solid for the visible and the IR region. At present, many kinds of light sources covering each wavelength region, as shown in Fig. 11.1, are available. Those can be broadly classified into: 1) thermal radiation sources such as a tungsten filament lamp (W lamp) and an incandescent lamp in the IR region such as a Nernst glower and a glouber, 2) arc lamps such as a high-pressure xenon arc lamp (Xe lamp), a high- or low-pressure mercury lamp, a hydrogen and a deuterium–hydrogen arc lamp (D₂ lamp) based on electrical discharge in gas, 3) a light-emitting diode (LED) or a laser diode (LD) basing on emission

Fig. 11.1 Wavelength regions of various light sources

from the pn junction of a semiconductor, and 4) narrow-line sources using an atomic or molecular transition lines such as a hollow cathode discharge tube and an electrodeless discharge lamp, including many kinds of lasers. Recently, synchrotron radiation and terahertz emission in the far-UV and sub-millimeter wavelength regions, respectively, have become available, mainly for research purposes.

Among those light sources, one of the most stable, well-known, and intensively characterized in the visible and the near-IR region is the W lamp (or tungsten-filament white bulb). Although the spectral emissivity of tungsten is about 0.5 in the visible region and about 0.25 in the near-IR region, its spectral distribution of emission agrees relatively well with that of Planck's blackbody radiation. The W lamp can be used in an arbitrary color temperature up to 3100 K. However, more than 90% of the total emission energy is distributed in the IR wavelength region and less than 1% in the UV region below 400 nm. Therefore, it cannot be used in the UV region. The UV region, however, is especially important in the field of spectrochemical analysis. To cover the lower energy in the UV region, the D₂ lamp is used in combination with the W lamp, although the D₂ lamp has some problems in terms of emission stability and ease of operation.

For the tungsten white bulb, a vacuum bulb is used for color temperatures up to 2400 K. A gas bulb sealed in nitrogen, argon, or krypton gas at around 1 atm is used for color temperatures between 2000 K and 2900 K. For color temperatures around 3100 K, a tungsten-halogen bulb is used. In order to prevent deposition of tungsten atoms onto the inner surface of the bulb, the pressure of argon or krypton gas is maintained at several atmospheres and the bulb is made mechanically rigid by using quartz. Furthermore, by mixing a small amount of halogen molecules such as I₂, Br₂, or Cl₂ into the gas, the decrease in transmittance due to the deposition of tungsten atoms on the inner surface of the bulb is effectively prevented. This process is known as a halogen cycle. To make the process effective, the bulb temperature must be kept relatively high. The lifetime of the lamp is extended by about two times compared to a lamp that does not benefit from this process.

One of the most significant developments in light sources during the last 15 years is blue or UV LEDs. Blue and UV LDs have even appeared. The blue LED is used mainly for traffic signals and the blue and UV LD as recording or read-out light sources for circular discs and digital videodiscs. However, they also have great potential as light sources for scientific measurement. At

present, UV LEDs and UV LDs with an emission wavelength around 365–375 nm are commercially available. Such LEDs and LDs are based on emission from gallium nitride (GaN) materials. GaN is a direct-transition-type semiconductor and has an energy gap of about 3.44 eV at room temperature, which corresponds to the UV emission wavelength. By adding indium (In) and aluminum (Al) to the GaN, one can obtain blue emission. When using gallium phosphorus (GaP) instead of GaN materials, and when adding In and Al, one can obtain green emission. When adding only In, one can obtain red emission. Another light source to be noted is the white LED, which has been commercialized rapidly as a back-illumination light source for liquid crystal displays. The white LED consists of a blue or UV LED and fluorescent materials deposited onto the LED in the same package. The blue or UV LED is used as an excitation light source for the fluorescent materials, which may be yttrium aluminum garnet (YAG) materials or some kinds of rare-earth compounds. The excitation light and fluorescence together make the white light. A high-power white LED exceeding 5 W has been developed. Figure 11.2 shows typical emission spectra of such LEDs and that of the UV LD.

For scientific measurements or for spectrochemical analyses, a pulsed light source in the UV wavelength region is important, for example, for distance measurements, fluorescence lifetime measurements, and so on. For such requirements, a picosecond light pulsar with a pulse duration around 60 ps, a wavelength of 370 nm, and a repetition frequency of 100 MHz has appeared on the market. However, in general, such a laser has a problem in wavelength selection and cost. To solve such problems, a technique to drive the Xe lamp in

Fig. 11.2 Emission spectra of a blue, UV, and white LED, and that of a UV LD

a nanosecond pulsed mode has been developed [11.5–7]. A technique to modulate the Xe lamp sinusoidally has also been developed so that it can be used in combination with a lock-in light-detection scheme. The UV or the blue LED also can be driven with a large current pulse, resulting in a pulse duration less than 1.5 ns [11.8–10].

11.1.2 Photosensors

This subsection deals with sensing features of various photosensors [11.1–4]. The photosensor is the terminology used for a photodetector when used for a sensing purpose. Photodetectors can be broadly classified into quantum-effect (QE) detectors (or photon detector) and thermal detectors. The QE detector can be subdivided into an external and an internal type, as shown in Table 11.1 Furthermore, the internal type is subdivided into a photoconductive (PC) detector, a photovoltaic (PV) detector, and a photoelectromagnetic (PEM) detector. Figure 11.3 shows the spectral response of each photodetector.

The operating principle of the external QE detector is based on the photoelectron emissive effect of a metal. Representative detectors are a phototube (PT) and a photomultiplier tube (PMT). A variety of photosensitive cathodes, having different spectral responses, are available from the UV to the near-IR wavelength region. A photocathode whose principal component is gallium arsenic (GaAs) gives high quantum efficiency and has sensitivity at longer wavelengths exceeding 1 μm. The

PT consists of two electrodes sealed in a vacuum tube: a photocathode and an anode. The PT had been used for light sensing at relatively high powers. At present, it is mainly used for measuring ultra-short light pulses by taking advantage of its simple structure. Such a special PT is known as a biplaner type. The PMT consists of the photocathode, the anode, and 6–12 stages of dynodes aligned between the two electrodes. The role of each dynode is to emit a larger number of secondary electrons than are incident on it. The total amplification factor is typically 10⁶, depending on the number of dynodes and the applied voltage. Because of its stability, wide dynamic range, and large specific detectivity *D*^{*}, the PMT is widely used for precise light detection. The PMT can be considered as a constant-current source with high impedance. Therefore, the intensity of the output signal is mainly determined by a value of the load resistor. The response time is determined by a time constant calculated from the load resistor and an output capacitance. By cooling the photocathode and adopting a photon counting technique, shot-noise-limited weak-light measurement is possible. Recently, a small type of a metal-packaged PMT has become available [11.11]. By taking advantage of its shorter electron-transit time and smaller time spread of secondary electrons, a new gating technique with a resolution time of less than 0.3 ns has been proposed [11.12].

The operating principle of the PC detector is based on the photoconductive effect of a semiconductor. The electric conductivity of materials, especially semicon-

ductors, varies depending on the intensity of the incident light. For UV and visible wavelength regions, intrinsic semiconductors are used. For the IR region, impurity semiconductors are used. The upper limit on wavelength sensitivity for intrinsic semiconductors is determined by the band gap energy (E_g) and that for impurity semiconductors by the ionized potential of the impurities. Generally, CdS ($E_g = 2.4\text{ eV}$) and CdSe are ($E_g = 1.8\text{ eV}$) used in the UV and the visible region. For the IR region, PbS, PbSe, PbTe, and $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ are used, where a cooling procedure is often required to suppress noise.

The operating principle of the PV detector is based on the photovoltaic effect. When a light flux whose energy is larger than the energy gap of the pn junction of a semiconductor is incident, a photo-induced voltage proportional to the incident light intensity is generated. Silicon detectors are popular and can be used from the visible to the near-IR region. The dynamic range for the incident intensity is more than 10^5 . To achieve sensitivity in the UV region, detectors with a processed surface or made from GaAsP have been devised; commercially these are known as blue cells. Compared to PC detectors, the PV detector gives a faster response time. Another advantage is that it requires no power supply. The PV detector has two operation modes: the photovoltaic mode and photoconductive mode (or photodiode mode). In the photovoltaic mode, the detector is used with zero bias voltage and the detector is considered as a constant-voltage source with low internal

resistance. In the photoconductive mode, the detector is used with a reverse bias voltage and can be considered as a constant-current source with high impedance. The photoconductive mode gives a wide dynamic range and a fast response. When one needs a high-speed sub-nanosecond response, use of a pin photodiode or an avalanche photodiode (APD) should be considered [11.13, 14].

The PEM detector utilizes contributions of an electron-hole pair to the photovoltage. The electron-hole pair is generated on the surface of an intrinsic semiconductor such as InSb. By applying the external magnetic field to the semiconductor during a diffusion process, the pair is divided in opposition directions, each contributing to the voltage. This type of detector is, however, not commonly used now.

In a thermal detector, optical power absorbed on the surface of the detector is converted to thermal energy and a temperature detector measures the resulting change of temperature. A variety of techniques have been developed to attain high-speed response and high sensitivity, which is a tradeoff. Although, in principle, an ideal thermal detector does not have a wavelength-dependent sensitivity, one cannot realize such an ideal detector. Typical thermal detectors are thermocouples, thermopiles, pneumatic detectors, Golay cells, pyroelectric detectors etc.

A multichannel (MD) detector has been developed that integrates many internal QE detectors onto a silicon substrate. Electric charges produced by the incident light, usually in the UV and visible range, are

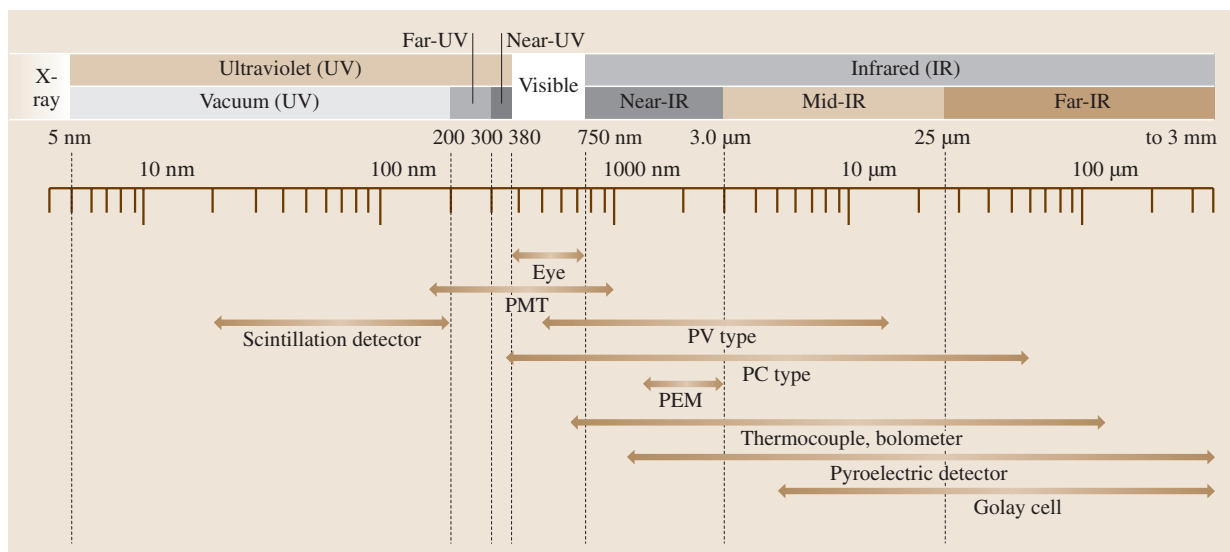

Fig. 11.3 Applicable wavelength regions of various photodetectors

accumulated on individual detectors. A metal–oxide–semiconductor-type (MOS) detector employs electric switches to read out the electric charge. A charge-coupled device (CCD) has a larger integration density than the MOS type because of the simplicity of the process of charge accumulation and transfer. The sensitivity is $10^7\text{--}10^8$ photons/cm² and the dynamic range is $10^3\text{--}10^4$. Recently, infrared image sensors using HgCdTe have appeared in the market. This MD can be used not only as a spectral photosensor but also as a position sensor.

To select the optical detector, the fundamental issues to be considered are: 1) spectral response, 2) sensitivity, 3) detection limit, and 4) time response. Concerning the spectral response, spectral matching with the light source should be considered. The spectral distribution of the background light also should be taken into account. The sensitivity of the detector is defined by the ratio of the intensity of the output signal to that of the incident light. Generally, overall (or all-spectral) sensitivity is employed. To determine the sensitivity, a standard light source whose spectral distribution is known is used as the incident light: a tungsten lamp of 2856 K for the UV and the visible region and a pseudo-blackbody furnace of 500 K for the IR region. The detection limit is usually represented by the noise-equivalent power (NEP) or

the specific detectivity D^* , where $\text{NEP} = P V_n / V_s$ and $D^* = \sqrt{A \Delta f} / \text{NEP}$, where P is the radiation flux, V_s is the output signal, V_n is the root mean squared value of output noise, A is area of the detector, and Δf is the noise-equivalent frequency bandwidth. The time response is represented by a step response or a steady-state frequency response. The step response is represented by a rise time or a fall time, which are used especially for detectors with a nonlinear response. For high-speed detectors, the time constant is important; this is calculated by the internal resistance of the detector and the parallel output capacitance. Impedance matching with the following electronics is also important.

11.1.3 Wavelength Selection

In a practical measurement, it is often necessary to select a suitable wavelength from the light source. This section deals with some wavelength-selection techniques [11.1–4]. In order to select the monochromatic or quasi-monochromatic light, we usually use a dispersion element, such as an optical filter, a prism, and a diffraction grating. Generally, the diffraction grating is installed in a monochromator (MON). To gather all spectral information simultaneously, one uses a polychromator (POL) in combination with a multichannel detector (MD).

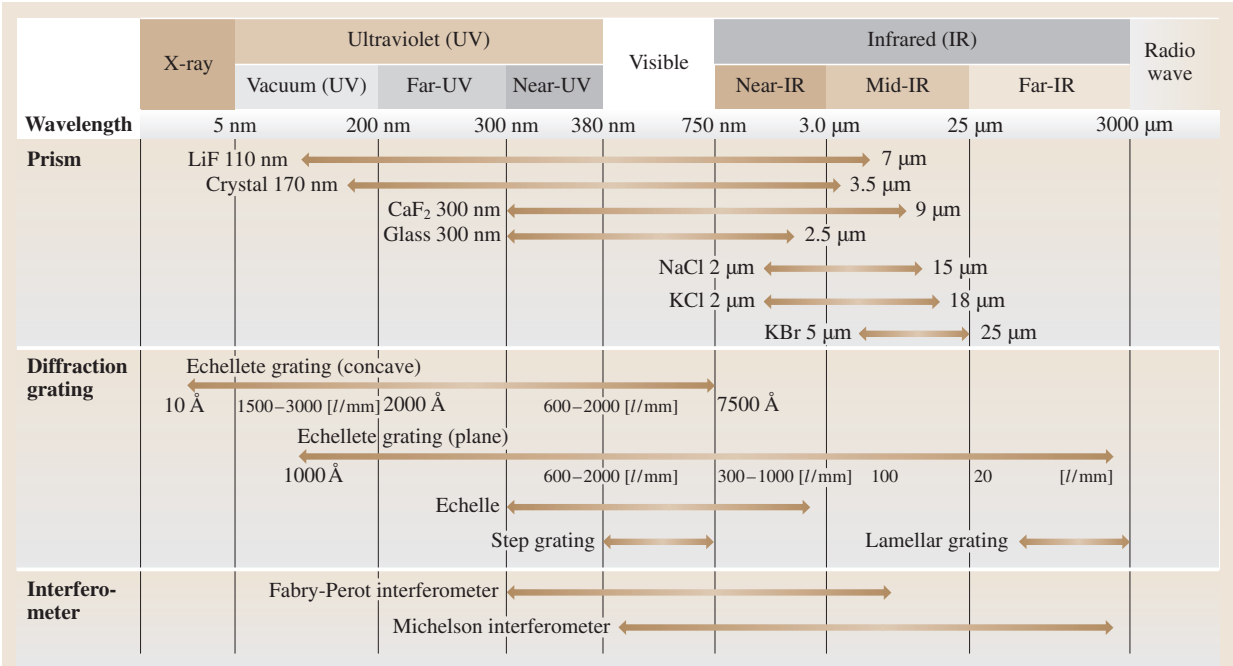

Fig. 11.4 Wavelength regions of various wavelength-selection elements and devices

In the IR region, a Michelson-type interferometer is sometimes used for a Fourier-transform spectrometer (FTS) [11.15]. For extremely high spectral-resolution measurements, a Fabry–Perot interferometer should be considered. [11.16] Figure 11.4 shows various elements, devices, systems applicable in each wavelength region.

The prism has been used as the main dispersion element. Dispersion occurs in the prism primarily because of the wavelength dependence of the refractive index of the prism material. Many materials for the prism have been used, for example, glass (350 nm–1 μ m), quartz (185 nm–2.7 μ m), CaF (125 nm–9 μ m), NaCl (200 nm–17 μ m), KCl (380 nm–21 μ m). When the wavelength is λ (or $\lambda + \Delta\lambda$) and the angle between the incident beam and the deviated monochromatic ray is θ (or $\theta + \Delta\theta$), the angular dispersion, $\Delta\theta/\Delta\lambda$, is given by $\Delta\theta/\Delta\lambda = \Delta\theta/\Delta n \cdot \Delta n/\Delta\lambda = 2 \sin(\alpha/2) / \sqrt{1 - n^2 \sin^2(\alpha/2)} \Delta n/\Delta\lambda$, where n and α are the refractive index and the apex angle of the prism, respectively. In order to increase the spectral resolution, $\lambda/\Delta\lambda$, we should use a prism with a long base L because $\lambda/\Delta\lambda = L \cdot (\Delta n/\Delta\lambda)$.

A plane diffraction grating is made by ruling parallel closely spaced grooves on a thin metal layer deposited on glass. When collimated light flux strikes the grating in a plane perpendicular to the direction of the grooves, different wavelengths are diffracted and constructively interfere at different angles. Although there are two types of gratings, transmission and reflection, the reflection type is invariably used for wavelength selection. If the incident angle is α and the diffraction angle is β , measured from the normal to the grating plane, and the groove interval is d , the following grating formula holds, $d(\sin \alpha + \sin \beta) = m\lambda$, where m is the order of diffraction. In the formula, the order m as well as the diffraction angle β is taken as positive for diffraction on the same side of the grating normal as the incident ray and negative on the opposite side. Then, the angular dispersion is given by $\Delta\beta/\Delta\lambda = m/(d \cos \beta)$ and the resolution power is given by $\lambda/\Delta\lambda = mN$, where N is the total number of grooves. From the formula, we can understand that many wavelengths are observed for a specified diffraction angle β for a given α and d . This phenomenon is known as overlapping orders. From the following two equations, $d(\sin \alpha + \sin \beta) = m\lambda = (m+1)(\lambda - \Delta\lambda)$, we can obtain $\Delta\lambda = \lambda/(m+1)$; the value $\Delta\lambda$ is called the free spectral range. The overlapping orders are usually separated by limiting the source bandwidth with a broadband filter, called the order sorter, or with a pre-disperser.

Figure 11.5 shows a typical shape of the cross section of the groove. When the angle between the grating plane and the long side of the groove is γ so that $\gamma - \alpha = \beta - \gamma$, the incident and the diffracted light satisfy the relation for specular reflection on the long side of the triangle. Then, we obtain the relation $2d \sin \gamma \cos(\alpha - \gamma) = m\lambda$. When, we put $\alpha = \beta = \gamma$ and $m = 1$, then $2d \sin \gamma = \lambda$. Such a wavelength λ and angle γ are called the blaze wavelength and angle, respectively. The blazed grating is often called an echelle. In this situation, the maximum diffraction efficiency is obtained. For high-resolution spectral measurements, an echelle grating is used, which is a relatively coarse grating with large blaze angles. The steep side of the groove is employed at very high orders.

A concave grating is the same as a plane grating but the grooves are ruled on a concave mirror so that the grooves become a series of equally spaced straight lines when projected onto a plane perpendicular to the straight line connecting the center of the concave shape and a center of its curvature. A circle, whose diameter is equal to the radius of the curvature and which is on a plane perpendicular to the grooves, is called the Rowland circle. Rays starting from a point on the Rowland circle and diffracted by the grating are focused onto a point on the same circle. The two points form an optical conjugate pair with respect to each other. Usually, an entrance and an exit slit are placed on the two points. A problem concerning the concave grating is the presence of relatively large astigmatism. It is, however, used for the UV region because no additional reflection optical element that introduces reflection energy loss is necessary. Recently, various kinds of holographic gratings have been developed to solve the problem of aberration, including astigmatism.

Fig. 11.5 Cross section of a blazed grating. By tilting the groove facet by an angle γ , the zeroth-order ray does not correspond to the specularly reflected ray from the groove surface

When choosing a wavelength-selection method, significant parameters to be considered are the dispersion characteristics, resolution power, solid angle and F -number (or optical throughput factors), degree of stray light, and optical aberration. One of the most convenient and simplest ways is to use a spectroscopic filter such as a color glass filter or an interference filter. However, those lack versatility. The MON is a multipurpose apparatus, which has a grating, an entrance, an exit slit, additional optics, and a wavelength-selection mechanism in one box, by which monochromatic light can be extracted. Many types of mounting and optical arrangement of the optics including the grating, have been proposed.

Although the dispersion-type MON is widely used for the purpose of wavelength selection, it has some drawbacks. In principle, its optical throughput is not large because of the presence of the entrance slit. Furthermore, because of the requirement of the wavelength-scanning mechanism for measuring a continuum spectrum, the total number of wavelength elements limits the signal-gathering time allocatable to a unit wavelength element, resulting in lowering signal-to-noise (SNR) ratio. On the contrary, the FTS has optical throughput and multiplex advantages over the dispersion-type MON. This is because the FTS requires no entrance slit and the entire spectrum is measured simultaneously in the form of an interferogram. However, the multiplex advantage is given only when the detector noise is dominant, such as for an IR detector. Nevertheless, it is sometimes used in the visible region. This is because of the presence of the optical throughput advantage, high precision in wavenumber, and the possibility of realizing extremely high spectral resolution. However, even for the dispersion-type MON, when used in a form of a POL together with the MD, the multichannel advantage is generated. Table 11.2 summarizes the SNR of the FTS, $(\text{SNR})_{\text{FTS}}$, and that of the POL with an MD, $(\text{SNR})_{\text{POL}}$, over that of the dispersion MON with a single detector, $(\text{SNR})_{\text{MON}}$, for cases of when the de-

tector noise, the shot noise, and the scintillation noise is dominant. In the table, n is the total number of spectral elements.

11.1.4 Reflection and Absorption

Reflection or absorption spectra provide rich information on the energy levels of the material, such as inner or valence electrons, vibrations or rotations of molecules or defects in condensed matters, a variety of energy gaps and elementary excitations, e.g. phonons and excitons.

Reflection and Transmission

When a light beam incident on a material surface passes through the material, some of the light is reflected at the surface, while the rest propagates through the material. During the propagation the light is attenuated due to absorption or scattering. The coefficients of *reflectivity* R and *transmittance* T are defined as the ratio of the reflected to the incident power and the transmitted to the incident power, respectively. If there is no absorption or scattering, $R + T = 1$. A schematic diagram for measuring R or T is shown in Fig. 11.6. A tunable light source, a combination of a white light (Sect. 11.1.1) and a monochromator (Sect. 11.1.3) or a tunable laser (Sect. 11.1.5), is used here. Details of detectors are reviewed in Sect. 11.1.2. Changing the wavelength λ of the tunable light source, one can obtain a reflectivity spectrum $R(\lambda)$ or a transmittance spectrum $T(\lambda)$. For convenience the white light directly irradiates the sample and the reflected or transmitted light is detected with a combination of a spectrometer and an array detector, e.g. CCD, if the luminescence from the sample caused by the white light is negligible.

If the beam propagates in the x direction, the intensity $I(x)$ at position x satisfies the following relation:

$$\Delta I(x) = I(x + dx) - I(x) = -\alpha I(x) dx , \\ \therefore dI(x)/dx = -\alpha I .$$

Table 11.2 Comparisons of the SNR of the FTS, $(\text{SNR})_{\text{FTS}}$, and that of the POL with a MD, $(\text{SNR})_{\text{POL}}$, over that of the MON with a SD, $(\text{SNR})_{\text{MON}}$, for cases when the detector noise, the shot noise, and the scintillation noise are dominant, where n is the total number of spectral elements

Noise	Detector noise	Shot noise	Scintillation noise

Fig. 11.6 Schematic diagram of reflection or transmission measurement

Here α is called the *absorption coefficient*. The integrated form is

$$I(x) = I_0 \exp(-\alpha x), \quad (11.1)$$

where I_0 is the intensity of the incident light. The position at $x = 0$ corresponds to the surface of the material. This relation is called *Beer's law*. If the scattering is negligible, the transmittance T is described by

$$T = (1 - R_1) \exp(-\alpha l) (1 - R_2), \quad (11.2)$$

where R_1 and R_2 are the reflectivities of the front and back surfaces, respectively, and l is the sample thickness.

Optical Constants

If the light propagates in the x direction, the electric field is described by

$$E(x, t) = E_0 \exp[i(kx - \omega t)], \quad (11.3)$$

where k is the wavevector of the light and ω is an angular frequency. In a transparent material with refractive index n , k and the wavelength in vacuo λ are related each other through

$$k = \frac{2\pi}{\lambda/n} = \frac{n\omega}{c}. \quad (11.4)$$

This formula can be generalized to the case of an absorbing material by introducing the *complex refractive index* [11.17]:

$$\tilde{n} = n + i\kappa, \quad (11.5)$$

$$k = \frac{\tilde{n}\omega}{c}, \quad (11.6)$$

where κ is called the *extinction coefficient*. The imaginary part of \tilde{n} leads to an exponential decay of the electric field; the absorption coefficient can be described by

$$\alpha = \frac{2\kappa\omega}{c} = \frac{4\pi\kappa}{\lambda}. \quad (11.7)$$

The *amplitude reflectivity* r , the ratio of the electric field of the incident light to that of the reflected light, in the case of normal incidence is described by [11.18]

$$r = \frac{\tilde{n} - 1}{\tilde{n} + 1}. \quad (11.8)$$

If we define the real and imaginary part of r by:

$$r \equiv R \exp(i\theta), \quad (11.9)$$

then the (intensity) reflectivity can be described by

$$R = \left| \frac{\tilde{n} - 1}{\tilde{n} + 1} \right|^2 = \frac{(n - 1)^2 + \kappa^2}{(n + 1)^2 + \kappa^2}, \quad (11.10)$$

and conversely, n and k are written as

$$n = \frac{1 - R}{1 + R - 2\sqrt{R} \cos \theta}, \quad (11.11)$$

$$\kappa = \frac{2\sqrt{R} \sin \theta}{1 + R - 2\sqrt{R} \cos \theta}. \quad (11.12)$$

Ellipsometry enables us to obtain the amplitude reflectivity [11.19]. Thus one can obtain the complex refractive index by measuring the reflectivity.

The optical response of the material, e.g. light propagation described in the complex refractive index, originates from the polarization induced by the incident light. If the electric field E of the light is weak and within linear regime (cf. Sect. 11.4), the polarization P is given by

$$P = \epsilon_0 \chi E, \quad (11.13)$$

where ϵ_0 and χ are the vacuum dielectric constant and the *electric susceptibility*, respectively. The electric displacement is

$$D = \epsilon_0 E + P, \quad (11.14)$$

$$\equiv \epsilon_0 \epsilon E.$$

where ϵ is the *complex dielectric constant*;

$$\epsilon = \epsilon_0 (1 + \chi), \quad (11.15)$$

$$= \epsilon_1 + i\epsilon_2, \quad (11.16)$$

where ϵ_1 and ϵ_2 are the real and imaginary parts of the ϵ . From the Maxwell equation [11.1],

$$\epsilon/\epsilon_0 = \tilde{n}^2, \quad (11.17)$$

$$\epsilon_1/\epsilon_0 = n^2 - \kappa^2, \quad (11.17)$$

$$\epsilon_2/\epsilon_0 = 2n\kappa, \quad (11.18)$$

and conversely,

$$n = \sqrt{\frac{\varepsilon_1 + \sqrt{\varepsilon_1^2 + \varepsilon_2^2}}{2}}, \quad (11.19)$$

$$\kappa = \sqrt{\frac{-\varepsilon_1 + \sqrt{\varepsilon_1^2 + \varepsilon_2^2}}{2}}. \quad (11.20)$$

Kramers–Kronig Relations

The Kramers–Kronig relations allow us to find the real (imaginary) part of the response function of a linear passive system, if one knows the imaginary (real) part at all frequencies. The relations are derived from the principle of causality [11.17]. In the case of the complex refractive index, the relations are written as

$$n(\omega) = 1 + \frac{2}{\pi} \text{P} \int_0^\infty \frac{\omega' \kappa(\omega')}{\omega'^2 - \omega^2} d\omega', \quad (11.21)$$

$$\kappa(\omega) = -\frac{2}{\pi\omega} \text{P} \int_0^\infty \frac{\omega'^2 [n(\omega') - 1]}{\omega'^2 - \omega^2} d\omega', \quad (11.22)$$

where P indicates the Cauchy principal value of the integral. Using these relations one can calculate n from κ , and vice versa. The θ in (11.9) is calculated from the reflectivity R using the following formula

$$\theta(\omega) = -\frac{\omega}{\pi} \text{P} \int_0^\infty \frac{\ln \left[\frac{R(\omega')}{R(\omega)} \right]}{\omega'^2 - \omega^2} d\omega', \quad (11.23)$$

thus n and κ are determined using (11.11, 12) from the reflectivity spectrum. This analysis is very useful for materials with strong absorption in which only the reflectivity is measurable. The Kramers–Kronig analysis of reflection spectra with synchrotron radiation, which covers extremely wide wavelength regions from the far-IR to X-rays, reveals the electronic structures of a huge number of materials [11.20].

The Lorentz Oscillator Model (Optical Response of Insulators)

The responses of bound (valence) electrons in insulators can be written by the equation of motion of a damped harmonic oscillator:

$$m \frac{d^2 x}{dt^2} = -m\gamma \frac{dx}{dt} - m\omega_0^2 x - eE_0 \exp(-i\omega t), \quad (11.24)$$

where m and e are the mass and charge of the electron, γ is the damping constant, ω_0 is the resonant frequency,

E_0 is the amplitude of the electric field of the light. If we assume $x(t) = x_0 \exp(-i\omega t)$,

$$x_0 = -eE_0 / [m(\omega_0^2 - \omega^2 - i\gamma\omega)]. \quad (11.25)$$

Thus the *polarization* is given by

$$P_{\text{resonant}} = ne^2 / [m(\omega_0^2 - \omega^2 - i\gamma\omega)], \quad (11.26)$$

where n is the number of electrons per unit volume. Now we can write the electric displacement:

$$\begin{aligned} D &= \varepsilon_0 E + P_{\text{background}} + P_{\text{resonant}}, \\ &= \varepsilon_0 E + \varepsilon_0 \chi_{\text{background}} E + P_{\text{resonant}}, \end{aligned}$$

where the electric susceptibility $\chi_{\text{background}}$ accounts for all other contributions to the polarization. Using (11.15, 16), we obtain the following equations:

$$\varepsilon(\omega) = 1 + \chi + ne^2 / [\varepsilon_0 m(\omega_0^2 - \omega^2 - i\gamma\omega)], \quad (11.27)$$

$$\begin{aligned} \varepsilon_1(\omega) &= 1 + \chi + ne^2(\omega_0^2 - \omega^2) \\ &\quad / \left\{ \varepsilon_0 m \left[(\omega_0^2 - \omega^2)^2 + (\gamma\omega)^2 \right] \right\}, \end{aligned} \quad (11.28)$$

$$\varepsilon_2(\omega) = ne^2 \gamma \omega / \left\{ \varepsilon_0 m \left[(\omega_0^2 - \omega^2)^2 + (\gamma\omega)^2 \right] \right\}. \quad (11.29)$$

The dielectric constants in the low and high frequency limit are defined as

$$\varepsilon(0) \equiv \varepsilon_{\text{ST}}, \quad \varepsilon(\infty) \equiv \varepsilon_\infty.$$

Figure 11.7 shows the frequency dependence of the optical constants introduced in this section.

Typical Absorption Spectrum of Insulators

A schematic plot of a typical absorption spectrum of insulators is shown in Fig. 11.8. There are sharp absorption lines due to *phonons* in the far-infrared region and due to *excitons* in the visible or ultraviolet region; a phonon is a quantized lattice vibration and an exciton is a bound state of an electron and hole like a hydrogen atom. The shape of the absorption or reflection spectra of phonons or excitons can be analyzed by using the Lorentz oscillator model. If the coupling between the photon and the phonon (exciton) is strong, we have to introduce a coupled mode of a photon and a phonon (exciton), *phonon–polariton* (*exciton–polariton*) [11.21]. Phonon sidebands usually accompany the exciton absorption lines and provide information on the phonons and excitons [11.22].

Above the exciton lines, strong interband absorption is observed. The absorption edge is caused by the onset of the interband transition, in which free electrons and free holes are created simultaneously across the band gap of the insulator. We can obtain a variety of information on the band structure of the material from the interband absorption spectra. Between the phonon and exciton lines there are two weak bands: the multiphonon absorption band due to the combination of several phonons lies around the mid-infrared region and the Urbach tail appears as the onset of optical absorption in the near-infrared or visible region at finite temperature. The shape of the Urbach tail is expressed as [11.21]

$$\alpha(\omega) \propto \exp\left(-\sigma \frac{\hbar(\omega_0 - \omega)}{k_B T}\right), \quad (\omega < \omega_0), \quad (11.30)$$

where σ is an empirical steepness parameter. The σ indicates the strength of the exciton–phonon coupling, because the Urbach tail is caused by phonon-assisted processes. Generally, there is a minimum in the absorption coefficient between the multiphonon region and the Urbach tail. In the case of SiO₂ glasses this minimum lies in the near-infrared region around 1 eV. Thus optical fibers operate between 1.2–1.6 μm (Sect. 11.1.5).

Drude Model (Optical Response in Metals)

The responses of free electrons in metals can be written by the equation of motion (11.24) without a restoring force

$$m d^2x/dt^2 = -m\gamma dx/dt - eE_0 \exp(-i\omega t). \quad (11.31)$$

If we assume $x(t) = x_0 \exp(i\omega t)$,

$$x_0 = eE_0 / [m(\omega^2 + i\gamma\omega)]. \quad (11.32)$$

Thus the polarization is given by

$$\begin{aligned} P &= -nex, \\ &= -ne^2 E / [m(\omega^2 + i\gamma\omega)]. \end{aligned} \quad (11.33)$$

$$\begin{aligned} D &= \epsilon_0 E + P \\ &\equiv \epsilon_0 \epsilon E, \\ \therefore \epsilon &= 1 - ne^2 / [\epsilon_0 m(\omega^2 + i\omega/\tau)] \\ &= 1 - \omega_p^2 / [\epsilon_0 m(\omega^2 + i\omega/\tau)]. \end{aligned} \quad (11.34)$$

$$\tau \equiv 1/\gamma,$$

$$\omega_p = \left(ne^2/\epsilon_0 m\right)^{1/2}, \quad (11.35)$$

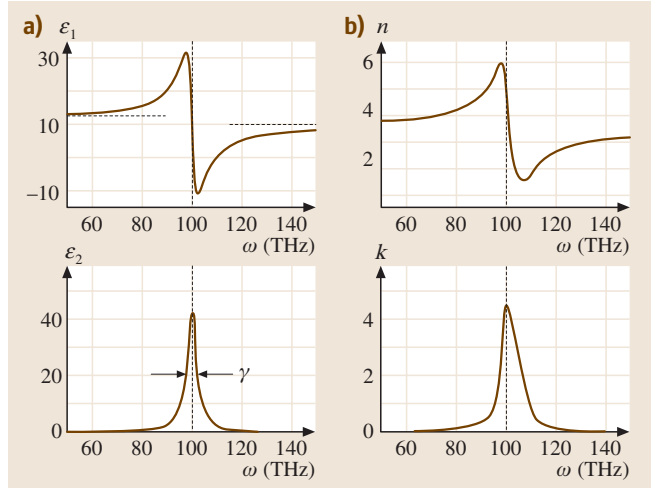

Fig. 11.7 (a) Frequency dependence of the real and imaginary parts of the dielectric constant, and (b) Frequency dependence of the complex refractive index, calculated in the case of $\omega_0 = 100$ THz, $\gamma = 5$ THz, $\epsilon_{ST} = 12$ and $\epsilon_\infty = 10$ using (11.28, 29)

where τ is the relaxation time and ω_p is called the *plasma frequency*. Figure 11.9 shows the reflectivity R in the case of $\gamma = 0$ using (11.10). Perfect reflection occurs for $\omega \leq \omega_p$, and then R decreases for $\omega > \omega_p$, approaching zero.

Electric conductivity can be generalized to the optical frequency region. The current density \mathbf{j} is related to the velocity of free electrons and the electric field through

$$\mathbf{j} \equiv -Ne d\mathbf{x}/dt = \sigma \mathbf{E}, \quad (11.36)$$

Fig. 11.8 Schematic illustration of the absorption spectrum of insulators

where σ is called the *optical conductivity*. From (11.23) and (11.27),

$$\sigma(\omega) = \sigma_0 / (1 - i\omega\tau), \quad (11.37)$$

where

$$\sigma_0 \equiv (ne^2\tau/m). \quad (11.38)$$

σ_0 corresponds to the **DC** conductivity. Thus the **DC** conductivity can be estimated by purely optical measurements without electrical contacts. Optical conductivity is written in terms of the dielectric function as follows:

$$\sigma(\omega) = -i\varepsilon_0\omega[\varepsilon(\omega) - 1]. \quad (11.39)$$

The Kramers–Kronig relations of the optical conductivity are as follows:

$$\sigma_1(\omega) = \frac{2}{\pi} \text{P} \int_0^\infty \frac{\omega' \sigma_2(\omega')}{\omega'^2 - \omega^2} d\omega', \quad (11.40)$$

$$\sigma_2(\omega) = \frac{-2\omega}{\pi} \text{P} \int_0^\infty \frac{\sigma_1(\omega')}{\omega'^2 - \omega^2} d\omega', \quad (11.41)$$

where $\sigma_1(\sigma_2)$ is the real (imaginary) part of the σ .

Optical Conductivity of Superconductors

Superfluid electrons in superconductors can move without dissipation, therefore one can take the limit $\tau^{-1} \rightarrow 0$ in (11.28),

$$\sigma(\omega) \rightarrow -\frac{ne^2}{i\omega m},$$

where n_S corresponds to the superfluid electron density. Accordingly, the real part σ_1 for the superfluid electrons

is zero unless $\omega = 0$. Using (11.40), σ_1 is expressed by a delta function,

$$\sigma_1(\omega) = \left(\pi n_S e^2 / m \right) \delta(\omega).$$

Finally, the optical conductivity of superfluid electrons is given by

$$\sigma(\omega) = \frac{\pi n_S e^2}{m} \delta(\omega) - \frac{n_S e^2}{i\omega m}. \quad (11.42)$$

Superconductivity originates from the formation of Cooper pairs. In the higher-frequency region above the binding energy of the Cooper pair, σ_1 should be finite. A schematic illustration of optical conductivity spectrum in superconductors is depicted in Fig. 11.10. Here Δ is called the Bardeen–Cooper–Schrieffer (BCS) gap parameter and 2Δ corresponds to the energy gap in the superconductor [11.17]. Thus we can measure the superconducting gap by optical spectroscopy in the infrared region.

11.1.5 Luminescence and Lasers

Materials emit light by *spontaneous emission* when electrons in the excited states drop to a lower level. The emitted light is called *luminescence*. Such materials with excited electrons can amplify the incident light via *stimulated emission*, which is utilized in *lasers*, an acronym for light amplification by stimulated emission of radiation.

Emission and Absorption of Light

The processes of spontaneous emission, stimulated emission and absorption are illustrated in Fig. 11.11 in the case of a two-level system.

Fig. 11.9 The reflectivity of free electrons in the case of $\gamma = 0$

Fig. 11.10 Optical conductivity of a normal metal (*dashed line*) and a superconductor (*solid line*)

The rate equations are as follows:

$$dN_2/dt = -A_{21}N_2, \quad (11.43)$$

$$dN_2/dt = -B_{21}N_2\rho(\nu), \quad (11.44)$$

$$dN_1/dt = -B_{12}N_1\rho(\nu), \quad (11.45)$$

where N_1 and N_2 are the populations of a ground state $|1\rangle$ and an excited state $|2\rangle$, respectively, $\rho(\nu)$ is an energy density of the incident light, and A_{21} , B_{21} and B_{12} are Einstein coefficients. The right-hand side of (11.43) shows spontaneous emission (Fig. 11.11a) of a photon with the energy $h\nu = E_2 - E_1$. A radiative lifetime τ_R of the excited state is defined by

$$\tau_R = 1/A_{21}. \quad (11.46)$$

The right-hand side of (11.44) shows stimulated emission (Fig. 11.11b) from $|2\rangle$ to $|1\rangle$. The rate is proportional to the energy density at the resonant frequency ν . Equation (11.45) represents absorption (Fig. 11.11c) from $|1\rangle$ to $|2\rangle$. As seen in the derivation of Beer's law, (11.1), the rate of absorption is proportional to the energy density of the incident light. Combining (11.43–11.45), we obtain the rate equation:

$$dN_2/dt = -A_{21}N_2 - B_{21}N_2\rho(\nu) + B_{12}N_1\rho(\nu). \quad (11.47)$$

In the steady state, $N_1/dt = N_2/dt = 0$, then

$$A_{21}N_2 + B_{21}N_2\rho(\nu) = B_{12}N_1\rho(\nu). \quad (11.48)$$

In thermal equilibrium, the Planck distribution for cavity radiation is

$$\rho(\nu) = \frac{8\pi h\nu^3}{c^3} \frac{1}{\exp\left(\frac{h\nu}{kT}\right) - 1}, \quad (11.49)$$

and the Boltzmann distribution between two levels is

$$\frac{N_2}{N_1} = \exp\left(-\frac{E_2 - E_1}{kT}\right) = \exp\left(-\frac{h\nu}{kT}\right). \quad (11.50)$$

From (11.48–11.50) we obtain the *Einstein relations*:

$$\frac{A_{21}}{B_{21}} = \frac{8\pi h\nu^3}{c^3}, \quad (11.51)$$

$$B_{21} = B_{12}. \quad (11.52)$$

Luminescence

Luminescence is categorized as follows:

1. **Photoluminescence (PL)**
The re-emission of light after absorbing an excitation light. Details are described in this section.
2. **Electroluminescence (EL)**
The emission of light caused by an electric current

Fig. 11.11a–c Transition processes in a two-level system: (a) spontaneous emission, (b) stimulated emission, and (c) absorption

flowing through the material. This is utilized in optoelectronic devices: the light emitting diode (LED) and the laser diode (LD).

3. **Cathodoluminescence (CL)** The emission of light due to irradiation by an electron beam. Details are explained in Sect. 11.2.
4. **Chemiluminescence**
The emission of light caused by a chemical reaction. Bioluminescence which originates in an organism belongs to chemiluminescence.

The process involved in luminescence does not simply correspond to the reverse process of absorption in condensed matter. Non-radiative processes, e.g. a phonon-emission process, compete with the radiative process. Hence the decay rate of an excited state $1/\tau$ is described by

$$1/\tau = 1/\tau_R + 1/\tau_{NR}, \quad (11.53)$$

where the two terms on the right-hand side represent the radiative and non-radiative decay rates, respectively. The luminescence efficiency or quantum efficiency η is defined by

$$\eta = \frac{1/\tau_R}{1/\tau_R + 1/\tau_{NR}}. \quad (11.54)$$

If the radiative lifetime τ_R is faster than the non-radiative lifetime τ_{NR} , luminescence is a main de-excitation process and luminescence spectroscopy is a powerful method for the investigation of the excited state. Time-resolved measurements introduced in Sect. 11.4.3 provide direct information on $1/\tau_R$. In many cases, non-radiative decay processes give rise to heating of the material. Therefore, photocalorimetric or photoacoustic spectroscopy is utilized to obtain the information on the non-radiative decay processes [11.23].

PL Spectroscopy

The experimental set-up for the PL measurement is shown in Fig. 11.12. The sample is excited with a laser or a lamp. The PL spectrum is obtained by using array

detectors, e.g. a CCD, or by scanning the wavelength of the spectrometer with a PMT. The sample is usually mounted in a cryostat to cool it to liquid nitrogen or helium temperatures, because the non-radiative process is activated at higher temperature. Conversely, the temperature dependence of PL gives information on the non-radiative decay mechanism. The spectra obtained should be corrected to take into account the sensitivity of the detection system (the spectrometer and the CCD or PMT), while this correction is not required in the case of reflection and absorption measurements, in which the response function of the detection system is canceled in the calculation of I/I_0 [see (11.1)]. Reabsorption effects should also be taken into account [11.22] if the frequency region of the luminescence overlaps that of the absorption. Time-resolved PL spectroscopy provides the radiative decay time and direct information on the relaxation process in the excited states. The experimental set-up will be reviewed in Sect. 11.4.3.

PL excitation spectroscopy (PLE) in which the detection wavelength is fixed and the excitation wavelength is scanned allows the absorption spectrum to be measured in the case that direct transmission measurements are impossible because of very weak absorption or an opaque surface of the material. PLE spectroscopy is similar to ordinary absorption measurements but is subject to the condition that there exists a relaxation channel from the (higher) excited state to the emission state being monitored. *Fluorescence line narrowing* (FLN) or *luminescence line narrowing* is a high-resolution spectroscopic technique that uses laser excitation to selected

specific subpopulations optically from the inhomogeneously broadened absorption band of the sample, as shown in Fig. 11.23a, b [11.24]. One can obtain the homogeneous width using FLN spectroscopy (Sect. 11.2).

Optical Gain

Laser action arises from stimulated emission, while spontaneous emission prevents lasing. Using (11.43, 11.44, 11.51) the ratio between the rates of stimulated emission and spontaneous emission is calculated as

$$\frac{N_2 B_{21} \rho(\nu)}{N_2 A_{21}} = \frac{1}{\exp\left(\frac{h\nu}{kT}\right) - 1}. \quad (11.55)$$

This ratio is less than unity if T is positive. Hence a *negative temperature* is required for the lasing. From (11.50) this negative temperature corresponds to $N_2 > N_1$, which is called *population inversion*.

If population inversion is realized, the incident light, called *seed light*, is amplified by stimulated emission. In the case that the seed light originates from the luminescence of the material itself, *amplified spontaneous emission* (ASE) appears, as shown in Figure 11.13.

Optical gain is calculated using (11.44, 11.45) as an extension of Beer's law (11.1):

$$dI(x)/dx = (B_{21}N_2 - B_{12}N_1)g(\nu)h\nu I(x)/c, \quad (11.56)$$

where $g(\nu)$ is a spectral function which describes the frequency spectrum of the spontaneous emission. Then, using the Einstein relation (11.51), we obtain

$$I(x) = I_0 \exp[G(\nu)x], \quad (11.57)$$

$$G(\nu) = (N_2 - N_1)A_{21}c^2 g(\nu)/(8\pi\nu^2), \quad (11.58)$$

where I_0 and I are the input and output light intensities, respectively. $G(\nu)$ is called the *gain coefficient*.

The population inversion can be obtained in the following ways:

1. **Optical pumping**
This method is used in solid-state lasers (except LDs) and dye lasers.
2. **Electric discharge**
Gas lasers and flash lamps which are used for the optical pumping of solid state lasers, e.g. Nd:YAG laser.
3. **Electron beam**
Large excimer lasers are pumped with a large-volume electron beam.
4. **Current injection**
This method allows compact, robust and efficient laser device, LDs.

Fig. 11.12 Experimental set-up for PL measurement

Fig. 11.13 Schematic illustration of amplified spontaneous emission. The shaded area shows an excited volume where population inversion is established

Laser Configuration

A combination of the population-inverted medium and the optical cavity which gives optical feedback provides the laser oscillation, which is like an electronic oscillator. Thus the laser consists of a laser medium, a pumping source and an optical cavity. Figure 11.14 shows a schematic arrangement of a laser. ASE with the correct frequency and direction of propagation is reflected back and forth through the laser medium. One of the mirrors, called the *output coupler*, is partially transparent to extract the light within the cavity. The cavity acts as a Fabry–Perot resonator, so that the cavity modes are formed inside the cavity. The mode separation is expressed by

$$\Delta\nu = c/2l, \quad (11.59)$$

where l is a cavity length. We see lasing in the frequency region in which the intensity is above the threshold, as shown in Fig. 11.15. As seen in the figure, several modes oscillate simultaneously, which is called *multi-mode operation*. The random phases between these laser modes may cause a chaotic behavior of the output power. To avoid this effect, there are two solutions: *single-mode operation* in which a single cavity mode is selected by introducing another interferometer within the cavity and *mode-locked operation*, which is introduced in Sect. 11.4.2. The former operation achieves very narrow line widths down to 1 Hz.

Typical Lasers

Typical lasers are concisely summarized in the following. The lasers are classified depending on the laser media: gas, liquid and solid. Solid-state lasers are categorized into rare-earth metal lasers, transition-metal lasers and semiconductor lasers (LD). There are two

Fig. 11.14 Schematic arrangement of a laser. The partial reflector corresponds to the output coupler

laser operation modes: continuous wave (CW) and pulsed.

Gas lasers utilize atomic or molecular gases, as shown in Table 11.3. Though they are fixed-wavelength lasers in principle, multiple lines exist in molecular gas lasers and tunable operation is possible in CO₂ lasers. Excimer lasers utilize an excited diatomic molecule “excimer”, which is unstable in the ground state, and provide high-intensity pulses at UV wavelengths.

Dye lasers provide tunable operation, because dyes are organic molecules and have broad vibronic emission bands due to interaction with the solvent. Figure 11.16 shows the tuning range of typical dye lasers.

Solid-state lasers with transition-metal ions, as summarized in Table 11.4, also show broad emission bands (except the ruby laser) caused by the strong interac-

Fig. 11.15 Schematic illustration of laser output spectrum

Table 11.3 Typical gas lasers

Laser media	Oscillation wavelength (μm)	Notes
He-Ne	0.6328, 1.15/1.52/3.39, 0.604/0.612, 0.594, 0.543	CW, used in metrology (length standard) and in optical alignment
He-Cd	0.636, 0.538, 0.442, 0.325	Typical CW laser in UV region
Cu (vapor)	0.511, 0.578	Pulse operation with 10 kHz repetition in visible region
Ar ion	0.275–1.09 (discrete), 0.515, 0.488 (typical lines)	Typical CW laser in visible region
CO ₂	9–11 (tunable), 10.6	CW or pulse operation, giant pulse in infrared region, used in material processing
N ₂	0.337	Compact pulsed laser
XeCl	0.308	Used in pumping for dye lasers
KrF	0.248	Highest power among excimer lasers
ArF	0.193	LSI fabrication
F ₂	0.157	Commercially shortest wavelength

tion between 3d electrons and phonons, e.g. the Ti ion in sapphire provides very wide tuning range shown in Fig. 11.16 and are widely used, in particular, as ultrafast pulsed lasers (Sect. 11.4.2).

Solid-state lasers with rare-earth ions, as summarized in Table 11.5, work as fixed-wavelength lasers because of the narrow emission lines due to the weak interaction between 4f ions and their environments. They are pumped with flash lamps or LDs and, are themselves used for the optical pumping of tunable lasers.

Finally, semiconductor diode lasers, as summarized in Fig. 11.17, are nowadays most widely applied in tiny light sources for optical fiber communication, optical recording of CDs, DVDs, MOs, etc. Current injection is used for the laser pumping, which makes their combination with electronic circuitry feasible.

11.1.6 Scattering

Scattering is the phenomenon in which the incident light changes its wavevector or frequency. Scattering is called *elastic* if the frequency is unchanged, or *inelastic* if the frequency changes.

Elastic Scattering

This phenomenon occurs due to variation of the refractive index of the material. The scattering can be classified into two types depending on the size of the variation *a* as follows [11.18]:

- 1. Rayleigh scattering: in the case of $a \ll \lambda$
The probability (cross section) of Rayleigh scattering is proportional to $1/\lambda^4$.
- 2. Mie scattering: in the case of $a \geq \lambda$
The size dependence of the probability of the Mie scattering is not simple but is approximately proportional to $1/\lambda^2$ in the case of $a \approx \lambda$. This phenomenon enables us to monitor the sizes of the particles in the air or in transparent liquid.

Inelastic Scattering

This phenomenon occurs due to fluctuation of the electric susceptibility of electrons or lattices in a material. The electric field *E* of the incident light and the polarization *P* of the material are described by (Sect. 11.1.4)

$$E = E_0 \cos \omega t ; \quad P = P_0 \cos \omega t . \tag{11.60}$$

If the fluctuation of the electric susceptibility can be written by

$$\chi = \chi_0 + \chi' Q \cos \Omega t , \tag{11.61}$$

tering caused by acoustic phonons has a special name: *Brillouin scattering*. The frequency shift with respect to the incident light is called the *Raman shift*, and is determined by the phonon energy. In other words, the energy of the phonons or other elemental excitations can be obtained by Raman spectroscopy. Nowadays Raman spectroscopy is indispensable for material science and is applied to a huge number of materials [11.25].

Selection Rules for Raman Scattering

In the case of Raman or Brillouin scattering of phonons in crystals, energy and momentum conservation rules hold:

$$\omega_i = \omega_s \pm \Omega, \quad (11.63)$$

$$k_i = k_s \pm K, \quad (11.64)$$

where ω_i and k_i (ω_s , k_s) are the frequency and wavevector of the incident (scattered) photon and Ω and K are those of the phonon. The plus sign corresponds to the Stokes process, which is shown in Fig. 11.20 and the minus sign corresponds to the anti-Stokes process.

If the incident light is in the optical region (from IR to UV), the wavevector is negligibly small in comparison with the Brillouin zone of the crystal. Hence, phonons with $q \approx 0$ are usually observed in the Raman scattering.

In a crystal with inversion symmetry, the phonon modes which are observed in the Raman scattering, called *Raman-active modes*, are not *infrared active* (not

the polarization of the material is described as

$$\begin{aligned}
 P &= \varepsilon_0 \chi E_0 \cos \omega t + \varepsilon_0 \chi' E_0 Q \cos \Omega t \cos \omega t \\
 &= \varepsilon_0 \chi E_0 \cos \omega t + (1/2) \varepsilon_0 \chi' E_0 Q \\
 &\quad \times [\cos(\omega + \Omega)t + \cos(\omega - \Omega)t]. \quad (11.62)
 \end{aligned}$$

The first term corresponds to the Rayleigh scattering and the second term means that new frequency components with $\omega \pm \Omega$, called *Raman scattering*, arises from the fluctuation. The down- and upshifted components are called the *Stokes scattering* and the *anti-Stokes scattering*, respectively.

In the case of the Raman scattering due to phonons, the Stokes (anti-Stokes) process corresponds to a phonon emission (absorption), as shown in Fig. 11.19. The scat-

Fig. 11.18 Oscillator model for light scattering

Fig. 11.19 Energy-level diagram of the Raman processes. Stokes and anti-Stokes processes are illustrated

observed in the infrared absorption), and vice versa. This is called the *rule of mutual exclusion* [11.26].

In general, the coefficient χ' of the Raman scattering term in (11.61) is a tensor and is related to a Raman tensor \mathbf{R} , which is determined by the symmetry of the crystal or molecule. The intensity of the Raman scattering I is proportional to

$$I \propto |\mathbf{e}_i \mathbf{R} \mathbf{e}_s|, \quad (11.65)$$

where \mathbf{e}_i and \mathbf{e}_s are the polarization vectors of the incident and scattered light, respectively. The configuration for Raman spectroscopy is specified as $\mathbf{k}_i(\mathbf{e}_i \mathbf{e}_s) \mathbf{k}_s$ and the allowed combination of the polarizations are found if the Raman tensor \mathbf{R} is given. This is called the *polarization selection rule* [11.26].

Electronic Raman Scattering

An electronic transition as well as a phonon is observed in the Raman scattering. This is called *electronic Raman*

Fig. 11.20 Schematics of the Stokes scattering process. The wavevector conservation rule is also depicted

scattering. This is a very useful probe for plasmons in semiconductors, magnons in magnetic materials, or in determining the superconducting gap and the symmetry of the order parameter of superconductors, in particular, strongly correlated electron systems; a new type of elementary excitation was found by this technique [11.27].

Resonant Raman Scattering

If the frequency of the incident light ω_i approaches the resonance of the material ω_0 , the scattering probability is enhanced and the process is called *resonant Raman scattering*. In this case violation of the selection rules and multiple-phonon scattering occur. In the just-resonant case ($\omega_i \approx \omega_0$), the discrimination between the scattering, which is a coherent process, and the luminescence, an incoherent process, is a delicate problem. The time-resolved measurement of resonant Raman scattering reveals the problem and provides information on the relaxation process of the material [11.28].

Experimental Set-up

The configuration for Raman spectroscopy is similar to that used for luminescence spectroscopy, but a spectrometer with less stray light is required, because strong incident laser or Rayleigh scattering is located near the signal light. A double or triple spectrometer instead of a single spectrometer is usually used in Fig. 11.12 to reduce the stray light. An alternative method is to cut the laser light with a very narrow-line sharp-cut filter placed just in front of the entrance slit of a single spectrometer. This kind of filter is called a “notch filter”, which is a kind of dielectric multilayer interference filter.

11.2 Micro-spectroscopy

In nanoscience and nanotechnology the optical spectroscopic study of the individual properties of nanostructured semiconductor materials or biomolecules with ultrahigh spatial resolution is useful. This is achieved by avoiding the inhomogeneity caused by differences in the size, shape or surrounding environment. This kind of spectroscopy is called *single-quantum-dot or single-molecule spectroscopy*. In this section, we will introduce the principles and the application of three kinds of micro-spectroscopic methods based on conventional microscopy, near-field optical microscopy and cathodoluminescence spectroscopy with the use of scanning electron microscopy.

11.2.1 Optical Microscopy

Since light has a wave nature and suffers from diffraction, the spatial resolution of an optical microscope cannot go below approximately a half of the optical wavelength: the so-called diffraction limit. The typical set-up of micro-photoluminescence spectroscopy is illustrated in Fig. 11.21. A laser beam for the photoexcitation source is focused on a sample surface with a spot diameter of about one micrometer through an objective lens with a high magnification factor. The luminescence from the sample is collected by the same objective lens and passed through an achromatic beam splitter to separate the luminescence from the scattered light of the excitation laser, and the luminescence image is focused onto a CCD camera or the luminescence spectrum is analyzed through the combination of spectrometer and intensified CCD camera.

The principle of single-quantum-dot or single-molecule spectroscopy is illustrated in Fig. 11.22. For example, the luminescence from the ensemble of quantum dots of semiconductors having a size distribution shows the inhomogeneous spectral broadening due to the size-dependent luminescence peak energy, as shown in (a). If the spot size of the focused point is comparable to the mean separation distance between the quantum dots, the number of quantum dots detected by the objective lens is limited and the sharp luminescence lines with discrete photon energies are detected, as shown in (c). If the distribution of the dots is dilute enough, one can detect a single dot, as shown in (b) where the line width is limited by intrinsic homogeneous broadening corresponding to the inverse of the phase relaxation time of the excited state.

As an example of laser micro-photoluminescence spectroscopy, Fig. 11.23 shows the result of the ZnCdSe quantum dots grown on a ZnSe substrate [11.29]. Although the diameter of the quantum dots is 10 nm on average and has a wide size distribution, the micro-photoluminescence spectra show the spiky structures that critically depend on the spot position of observation. From the top to the bottom spectra, the spot position is shifted successively by 10 μm distance. The bottom spectrum is taken at the original position to check the reproducibility, from which one notes that the change in the spectra comes from fluctuation not in time but in position.

As another example of single-molecule spectroscopy, Fig. 11.24 illustrates the micro-luminescence excitation spectroscopy for light-harvesting complexes LH2 acting as an effective light antenna in photosynthetic purple bacteria at 2 K [11.30]. The complexes contain two types of ring structure of bacteriochlorophyll molecules (BChl a) with 9 and 18 molecules stacked against each other. Since the 9- and 18-molecule rings have their absorption bands at 800 nm and 860 nm, respectively, the ensemble of LH2 complexes, as illustrated in curve (a), shows two broad peaks with inhomogeneous broadening caused by different surrounding environment. On the other hand, when the complexes are dilutely dispersed in polyvinyl acetate (PVA) polymer film, individual complexes are found to show different spectra, as illustrated in (b)–(f). Here sharp structures are found around 800 nm, while still

broad structures around 860 nm. The former result indicates the localization of photo-excitation energy at one molecule, while the latter, indicates delocalization over the ring.

11.2.2 Near-field Optical Microscopy

In order to realize the spatial resolution beyond the diffraction limit, one can illuminate the sample with an extremely close light source of evanescent wave having large wavevectors produced from an aperture smaller than the wavelength of light. Here, the lateral resolution is mainly limited by the aperture size of the light source, if the distance between the light source and the sample surface is much smaller than the wavelength of light. Such a microscopy is called near-field optical microscopy. A schematic diagram of near-field microscope is illustrated in Fig. 11.25. One end of the optical fiber is sharpened by melting or chemically etching and used as a microprobe tip not only for the optical tips but also for atomic-force tips. To avoid the leakage of the light from the side of the tip end, the tip end is coated with Al or Au. The distance of the probe tip end from the surface of the sample is kept constant to within a few tens of nanometers using the principle of the atomic-force microscope (AFM). Laser light is sent through the optical fiber and the light emitted from the ultra-small aperture that illuminates the sample surface with a spot size similar to the aperture size (illumination mode). The transmitted or luminescent light from the sample is

collected by an objective lens and detected by a photodetector such as photomultiplier. For luminescence measurements a band-pass filter or a monochromator is placed before the photodetector. In some case to improve the spatial resolution the reflected or luminescence light is again collected by the same probe tip (illumination/collection mode). The lateral position of the tip end or the sample is scanned on the X-Y plane and the two-dimensional intensity image of the optical response of the sample can be recorded together with the topographical image of the sample surface. The minimum spatial resolution using the optical fiber tip end is considered practically to be a few tens of nanometers.

Figure 11.26 illustrates the example of images of the double monolayer of a self-organized array of polystyrene micro-particles with a diameter of $1\ \mu\text{m}$ on a glass substrate [11.31]. Figure (a) shows the AFM image of the sample surface where the close packed hexagonal array is observed. The near-field transmission image using light from a 514.5-nm Ar ion laser is shown in Fig. (b). Inside one micro-particle indicated by a white circle, one can see seven small bright spots with a characteristic pattern. The spot size is about 150 nm, which is restricted by the aperture size. Since the distance between these spots depends on the wavelength of light, the pattern represents nanoscale field distribution of a certain electromagnetic wave mode standing inside the particle double layer.

Another example of monitoring the spatial distribution of the wave function of electronic excited states is shown in Fig. 11.27 [11.32]. The near-field luminescence images of confined excitons and biexcitons in GaAs single quantum dots are observed using the illumination/collection mode with a probe tip with an aperture size of less than 50 nm. The size of the image of the exciton is found to be larger than that of the biexciton, reflecting the difference in effective sizes for the translational motion of the electronically excited quasi-particles.

11.2.3 Cathodoluminescence (SEM-CL)

Cathodoluminescence (CL) spectroscopy is one of the techniques that can be used to obtain extremely high spatial resolution beyond the optical diffraction limit. Cathodoluminescence refers to luminescence from a substance excited by an electron beam, which is usually measured by means of the system based on a scanning electron microscope (SEM), as illustrated in Fig. 11.28. The electron beam is emitted from an electron gun of the SEM, collected by electron lenses

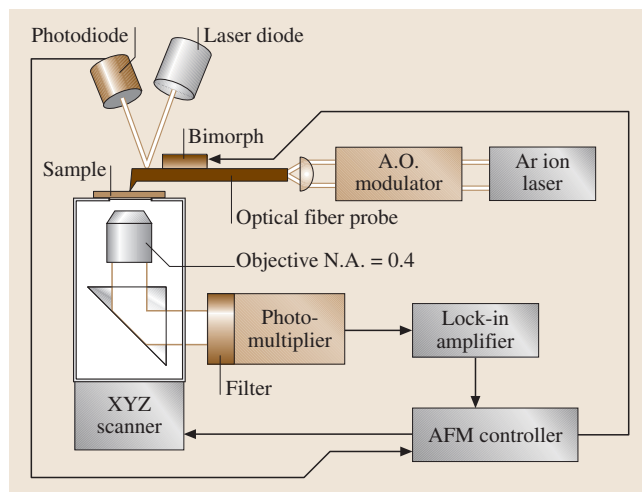

Fig. 11.25 Schematic diagram of a scanning near-field optical microscope (SNOM) in illumination mode. Near-field light coming out from a fiber probe illuminates a sample. Transmitted light is collected by an objective lens and fed to a photomultiplier

Fig. 11.26a,b $4.5\ \mu\text{m} \times 4.5\ \mu\text{m}$ images of a double monolayer film of self-organized 1.0- μm polystyrene spherical particles on a glass substrate: (a) AFM topographic image, and (b) SNOM optical transmission image. After [11.31]

and focused on a sample surface. The luminescence from the sample is collected by an ellipsoidal mirror, passed through an optical fiber and sent to a spectrometer equipped with a CCD camera. Lateral resolutions less than 10 nm are available in CL measurement, since the de Broglie wavelength of electrons is much shorter than light wavelengths. Moreover, energy- and wavelength-dispersive X-ray spectroscopy can be carried out simultaneously due to the high energy excitation of the order of keV. However, there are some difficulties in CL spectroscopy that are common to the observation of SEM images. A tendency toward charge accumulation at the irradiated spot requires that specimens have an electric conductivity, since it induces an electric field

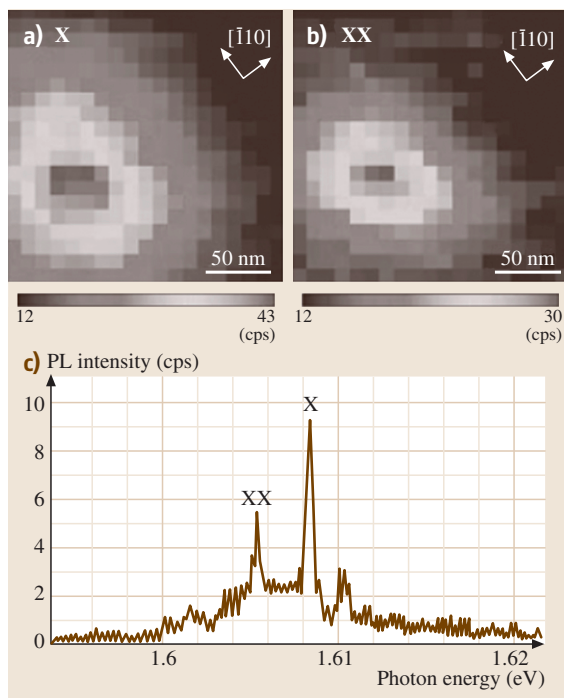

Fig. 11.27a–c High-resolution photoluminescence SNOM images of (a) X: exciton state, and (b) XX: biexciton state for a single GaAs quantum dot. The corresponding photoluminescence spectrum is also shown in (c). After [11.32]

which disturbs the radiative recombination of carriers. In addition, incident electrons with high kinetic energy often give rise to degradation of the sample. In CL spectroscopy, it is important to recognize those properties and to treat samples with a metal coating if needed.

Figure 11.29 illustrates an example of CL measurement on a system based on SEM. Spatial distribution of spectrally integrated CL intensity as well as SEM image is obtained, as shown in (a) and (b). The sample is ZnO : Zn which corresponds to ZnO with many oxygen vacancies near the surface, and is a typical green phosphor. The CL image consists of 100×100 pixels, and the brightness of each pixel shows the CL intensity under the excitation within an area of $63 \times 63 \text{ nm}^2$. The CL intensity is different among spatial positions at the nanoscale. The CL spectrum for each pixel can also be derived from this measurement, and the feature varies according to positions.

The penetration depth of incident electrons under electron-beam excitation is controllable by changing the accelerating voltage [11.33]. Electrons with high kinetic energy are able to penetrate deeper than photons which

Fig. 11.28 Configuration of the CL measurement system based on SEM

Fig. 11.29 (a) Spectrally integrated CL image of ZnO : Zn particles, and (b) SEM image at the same position

penetrate at most up to the depth corresponding to the reciprocal of the absorption coefficient, and therefore internal optical properties of substances can be examined in CL measurement. An example of accelerating voltage dependence of CL spectra is illustrated in Fig. 11.30. The sample is once again ZnO : Zn, in which free-exciton luminescence by photo-excitation is not observed at room temperature, since excitons are separated into electrons and holes due to the electric field in the surface depletion layer [11.34]. For an accelerating voltage of 2 kV, at which the penetration depth of incident electrons is comparable to the reciprocal of the absorption coefficient of photons, the CL spectrum does not show any structure in the exciton resonance region. On the other hand, the free exciton luminescence appears for an accelerating voltage of 5 kV, at which the penetration depth of the incident electrons is estimated to be about five times larger than that of photons. The luminescence is highly enhanced for an accelerating voltage of 10 kV, at which incident electrons are considered from the estimation of the penetration depth to spread throughout the electron-injected ZnO : Zn particle. Although the total number of carriers in the particle increases with the ac-

Fig. 11.30 Accelerating-voltage dependence of CL spectra in the exciton-resonance region at room temperature

celerating voltage, the change in carrier density should be small because of the increase in excitation volume, i.e. nonlinear enhancement of the luminescence is not attributed to any high density effects. These facts indicate that injected electrons penetrate into the internal

region where many excitons can recombine radiatively due to the lower concentration of oxygen vacancies, and the width of the depletion layer in the particle is of the order of the reciprocal of the absorption coefficient.

The electric field in the depletion layer can be screened by increasing the density of photo-excited carriers. However, photo-excitation with high carrier density also induces strong nonlinear optical response near the exciton resonance region, such as exciton–exciton scattering and electron–hole plasmas [11.35]. In CL measurements, nonlinear effects do not appear in ZnO : Zn, since the carrier density under electron-beam excitation in the system based on SEM is much lower than that under photo-excitation using pulsed lasers. The free exciton luminescence does not appear with low accelerating voltage and low beam current, as shown in Fig. 11.30, whereas it can be observed with larger beam current. In CL spectroscopy, the internal electric field in the depletion layer is weakened with high efficiency and the free exciton luminescence near the surface can be observed without high density effects, since electrons are directly supplied into the oxygen vacancies, which are a source of the internal field.

11.3 Magneto-optical Measurement

11.3.1 Faraday and Kerr Effects

It is well known in magneto-optical effect that the polarization plane of an electromagnetic wave propagating through matter is rotated under the influence of a magnetic field or the magnetization of the medium [11.36]. This effect is called the Faraday effect, named after the discoverer *Michael Faraday* [11.37]. This effect is phenomenologically explained as the difference of the refractive index between right and left circular polarizations. In this effect the angle of optical rotation is called the Faraday rotation angle. In the case of low applied magnetic field the Faraday rotation angle θ_F is proportional to the sample thickness l and the applied magnetic field H . Thus θ_F is written as:

$$\theta_F = VH, \quad (11.66)$$

where V is called the Verdet constant. The Faraday effect appears even without a magnetic field in an optically active medium, e.g. saccharide, etc. Furthermore, the magnetic Kerr effect is the Faraday effect for reflected light [11.38]. This effect is ascribed to the phase difference between right and left circular polarizations when

the electromagnetic wave is reflected on the surface of a magnetic material.

For practical use the Faraday effect is utilized for imaging of magnetic patterns. These magnetic patterns have been experimentally studied by various techniques,

1. moving a tiny magnetoresistive or Hall-effect probe over the surface,
2. making powder patterns with either ferromagnetic or superconducting (diamagnetic) powders (Bitter decoration technique),
3. using the Faraday magneto-optic effect in transparent magnetic materials in contact with the surface of a superconducting film as a magneto-optic layer (MOL).

In order to get a high-resolution image of the magnetic pattern, one of these methods, Faraday microscopy (3 above), is the most useful [11.39, 40]. A schematic drawing of the Faraday imaging technique is shown in Fig. 11.31.

The linearly polarized light enters the MOL, in which the Faraday effect occurs and is reflected at the mirror layer. In areas without flux, no Faraday rotation

takes place. This light is not able to pass through the analyzer that is set in a crossed position with respect to the polarizer, hence the superconducting regions stay dark in the image. On the other hand, in regions where flux penetrates, the polarization plane of the incident light is rotated by the Faraday effect so that some light passes through the crossed analyzer, thus the normal areas will be brightly imaged.

Fig. 11.31 shows the case of nonzero reflection angle, whereas in the experiment perpendicular incident light is normally used (Faraday configuration).

The Faraday rotation angle is transformed into light intensity levels. The sample surface is imaged onto a CCD detector array. In the case of crossed polarizer and analyzer the intensity of the signal from the CCD detector is

$$I(r, \lambda, B) = I_0(r, \lambda) \sin^2(\theta_F(r, \lambda, B)) + I_1(r, \lambda), \quad (11.67)$$

where r is the spatial coordinate on the CCD surface, λ is the wavelength of the incident light, B is the applied magnetic field, θ_F is the Faraday angle, and I_0 is the light intensity reflected by the sample. I_1 is the background signal ascribed to the dark signal of the CCD and residual transmission through the crossed polarizer and analyzer. When the analyzer is uncrossed by an angle θ ,

$$I(r, \lambda, B) = I_0(r, \lambda) \sin^2(\theta + \theta_F(r, \lambda, B)) + I_1(r, \lambda). \quad (11.68)$$

The angular position θ of the analyzer should be adjusted to obtain the best contrast between superconducting ($\theta_F = 0$) and normal ($\theta_F \neq 0$) areas. By changing the sign of θ , normal areas can appear brighter or darker than superconducting areas. In our experiment

Fig. 11.31 Schematic drawing of the Faraday effect

the angle θ is set to yield black in normal areas and gray in superconducting areas.

11.3.2 Application to Magnetic Flux Imaging

Experimental Set-up

Magneto-optical imaging is performed using a pumped liquid-helium immersion-type cryostat equipped with a microscope objective. This objective, with a numerical aperture of 0.4, is placed in the vacuum part of the cryostat and can be controlled from outside. The samples are studied in a magnetic field applied from exterior coils. The optical set-up is similar to a reflection polarizing microscope as shown in Fig. 11.32. Before measurement the samples are zero-field cooled to 1.8 K. The indium-with-QWs sample is illuminated with linearly polarized light from a Ti-sapphire laser, through a rotating diffuser to remove laser speckle. In the case of a lead-with-EuS sample a tungsten lamp with an interference filter is used the light source. Reflected light from the sample passes through a crossed or slightly uncrossed analyzer and is focused onto the CCD camera. The spatial resolution of 1 μm is limited by the numerical aperture of the microscope objective.

Magneto-optic Layers

Conventional magneto-optic layers. As for typical conventional MOLs, essentially, thin layers of Eu-based MOL (Eu chalcogenides, e.g. EuS and EuF₂ mixtures, EuSe) and doped yttrium iron garnet (YIG) films have been used [11.41]. These are usable up to the critical temperature of the ferromagnetic-paramagnetic transition ($\approx 15\text{--}20\text{ K}$) because their Verdet constants decrease with increasing temperature.

Since EuS undergoes ferromagnetic ordering below $T_c \approx 16.3\text{ K}$, a mixture of EuS with EuF₂ is better used. EuF₂ stays paramagnetic down to very low temperatures, therefore the ordering temperature of the mixture can be tuned by the ratio EuS : EuF₂. But there are several problems; difficulty of preparation due to difference of melting temperatures, and the need for a coevaporation technique.

Then the single-component EuSe layer has been further used because, even in the bulk, EuSe is paramagnetic down to 4.6 K and has a larger Verdet constant. Below 4.6 K, EuSe becomes metamagnetic, however, the reappearance of magnetic domains in the EuSe layers is not seen down to 1.5 K. However, there is also a problem owing to the toxicity of Se compounds.

On the other hand, due to their high transition temperature (Curie temperature), bismuth- and gallium-

doped yttrium–iron garnets (YIG) have been developed and used for the study of high- T_c superconductors. They are disadvantageous since they show ferrimagnetic domains, however, these MOLs are developed further by the introduction of ferrimagnetic garnet films with in-plane anisotropy. Using such films, the optical resolution is about $3\text{ }\mu\text{m}$, but a direct observation of the magnetic flux patterns is possible and the advantages of the garnet films, i.e. high magnetic field sensitivity, large temperature range, are retained.

Generally this kind of MOL often has the demerit of poor spatial resolution because of their thickness of several micrometers. Furthermore, self-magnetic ordering that may modify the flux distributions in superconducting samples may limit their use. However, it was recently reported that an optimized ferrite garnet film allowed the observation of single flux quanta in superconducting NbSe₂ [11.42].

Novel magneto-optic layers. In this section we refer to an alternative type of MOL [11.39, 40] based on semimagnetic semiconductor (SMSC) $\text{Cd}_{1-x}\text{Mn}_x\text{Te}$. It consists of SMSC [also called diluted magnetic semiconductor (DMS)] $\text{Cd}_{1-x}\text{Mn}_x\text{Te}$ quantum wells (QWs) embedded in a semiconductor–metal optical cavity. It is well-known that SMSCs exhibit a large Faraday rotation mainly due to the giant Zeeman splitting of the excitonic transition ascribed to sp–d exchange interactions between spins of magnetic material and band electron spins. The most advantageous point is no self-magnetic ordering due to paramagnetic behavior of Mn ions. Therefore, it is very convenient since there is no possibility to modify the magnetic flux patterns of intermediate

state of type-I superconductors. There are several other advantages of this MOL. It is easy to increase Faraday rotation by making an optical cavity (metal/semiconductor/vacuum) with a thickness of $= (2n + 1)\lambda/4$. Multiple reflections of light take place inside the cavity. Moreover, in order to adjust the cavity thickness at the desired wavelength, a wedged structure is constructed. The highest spatial resolution is obtained when the superconducting film is evaporated directly onto the MOL. This is because, the smaller the distance between the MOL and the sample, the better the magnetic imaging becomes since there is little stray-field effect.

In addition to these ideas already proposed for conventional MOL (EuSe) [11.41], there is another strong point. Using QWs is also interesting due to low absorption, easy adjustment of the balance between absorption and Faraday rotation by choosing the number of QWs, and the possibility to have a thin active layer (QWs) in a thick MOL in order to keep good spatial resolution. When a $\text{Cd}_{1-x}\text{Mn}_x\text{Te}$ QW is inserted in an optical cavity the Faraday rotation can be further increased by using a Bragg structure, that is, placing the QWs at antinodes of the electric field in the optical cavity.

In order to make an optical cavity Al, or the superconductor itself if it is a good reflector, should be evaporated on top of the cap layer as a back mirror. In order to obtain the largest Faraday rotation, a minimum of the reflectivity spectrum has to be matched with the QWs transition. This is the resonance condition. However, the reflectivity, which decreases at the QW transition when the resonance condition is fulfilled, has to be kept to a reasonable level that is compatible with a good signal-to-noise ratio. Therefore an

Fig. 11.32 Experimental set-up for the Faraday imaging technique

optimum number of QWs has to be found in multi-quantum-well structures. The Mn composition of the QWs also has to be optimized. It governs not only the Zeeman splitting of the excitonic transition but also the linewidth.

The time decay of the magnetization of the Mn ions in SMSC is known to be fast, in the sub-nanosecond range, since it is governed by spin–spin relaxation rather than by spin–lattice relaxation [11.43, 44]. This opens the way for time-resolved imaging studies with good temporal resolution, e.g. the study of the dynamics of flux penetration. On the other hand, there are also problems in fabrication. It is troublesome to remove the GaAs substrate by chemical etching while retaining fragile layers. Furthermore, the chemical etching solution strongly reacts with some metals e.g. lead.

Lead with europium sulfide magneto-optic layers. Since lead reacts strongly with the chemical etching solution used to remove the GaAs substrate from the

Fig. 11.33 Schematic drawing of Pb with EuS sample. The thickness of EuS, Al, and Pb are 145 nm, 150 nm, and 120 μm, respectively. EuS is fabricated by Joule-effect evaporation. The EuS MOL is fixed on the Pb by pressing overnight

Fig. 11.34 Right scale: light reflection spectrum for zero applied magnetic field $H = 0$ mT at $T = 2$ K. Left scale: Faraday rotation-angle spectrum for $H = 53.3$ mT (T. Okada, unpublished)

SMSC sample, we tried to use EuS as a MOL. The sample is shown in Fig. 11.33.

The thickness of the EuS MOL fabricated by Joule-effect evaporation on a 0.4 mm glass substrate is 145 ± 15 nm, hence it is thin enough for good spatial resolution. A 150-nm-thick Al layer is evaporated on the EuS MOL as a mirror in order to get high reflectivity. The EuS MOL is pressed onto Pb with a weight and left overnight.

A typical reflectivity spectrum and Faraday angle curve of EuS MOL are displayed in Fig. 11.34. The Ti-sapphire laser is tuned to 700 nm to get good reflected light and large Faraday rotation angle from the sample. Indeed EuS MOL may be expected to disturb the flux pattern, but no self-magnetic domain could be observed in this EuS sample, probably because the layer consists of a mixture of EuS and EuO. Figure 11.35 shows the images of the magnetic flux pattern at the surface of a 120-μm-thick superconducting lead film for magnetic field values of 20 mT. The temperature is 2 K, that is, much lower than the critical temperature of lead (7.18 K). The critical field of lead at 2 K is $H_c(2\text{ K}) = 74.1$ mT.

The raw image has to be processed in order to correct the intensity fluctuations of the reflected light for thickness fluctuations in the MOL and for the sensitivity of CCD detector. In order to obtain an intensity level proportional to the Faraday angle, the gray level of each pixel should be calculated as

$$I' = I_H^\alpha / I_{H=0}^\alpha \quad (11.69)$$

Fig. 11.35 The image of the magnetic flux patterns at the surface of 120-μm-thick superconducting Pb revealed with an EuS magneto-optical layer in an applied magnetic field of 20 mT ($h = 0.270$). Normal and superconducting domains appear in black and gray, respectively. The image size is $233 \mu\text{m} \times 233 \mu\text{m}$. The temperature is $T = 2$ K. (T. Okada, unpublished)

Fig. 11.37 Left scale: light reflection spectrum for zero applied magnetic field $H = 0$ mT at $T = 2$ K. Right scale: Faraday rotation-angle spectrum for $H = 56$ mT.

where I_H^α is the raw gray level obtained for an applied field H and an analyzer angle α and θ is the Faraday angle. The quality of the image is further improved by Fourier-transform filtering, but the magnetic contrast is not very good because the contact between lead and the MOL may not be as good as for an evaporated metallic sample.

Indium with quantum-well magneto-optical layers.

The sample consists of an indium layer as the superconducting material and a $\text{Cd}_{1-x}\text{Mn}_x\text{Te}/\text{Cd}_{1-y}\text{Mg}_y\text{Te}$ heterostructure as the MOL. The structure is sketched in Fig. 11.36 [11.40].

The semiconductor heterostructure was grown by molecular beam epitaxy. The $\text{Cd}_{0.85}\text{Mg}_{0.15}\text{Te}$ buffer was deposited on (001) GaAs substrate without rotation of the sample holder, resulting in a slight gradient of both the thickness of the buffer and its refrac-

Fig. 11.38 The image of the magnetic flux patterns at the surface of 10- μm -thick superconducting In film revealed with the $\text{Cd}_{1-x}\text{Mn}_x\text{Te}$ QWs structure as the magneto-optical layer in an applied magnetic field of 6.3 mT ($h = 0.325$). Normal and superconducting domains appear in black and gray, respectively. The edge of the indium film can be seen on the right-hand side of images where the flux pattern disappears. The image size is $527 \mu\text{m} \times 527 \mu\text{m}$. The analyzer was uncrossed by $\alpha = 20$ deg with respect to the polarizer. The temperature is $T = 1.9$ K. (T. Okada, unpublished)

tive index. The buffer was followed by three 10-nm $\text{Cd}_{0.94}\text{Mn}_{0.06}\text{Te}$ QWs separated by $\text{Cd}_{0.85}\text{Mg}_{0.15}\text{Te}$ barriers that were 55.8 nm thick. A 10- μm -thick indium layer was then evaporated directly on top of the 61.7-nm $\text{Cd}_{0.85}\text{Mg}_{0.15}\text{Te}$ cap layer. The MOL is designed as an optical cavity and indium serves both as the superconducting layer and the cavity back mirror. The first and third QWs are nearly located at antinodes of the electric field in the cavity in order to enhance Faraday rotation. The indium-covered side was glued onto a glass plate and the GaAs substrate was removed by mechanical thinning and selective chemical etching. For the Faraday microscopy the spatial resolution was checked as $1 \mu\text{m}$, with a magnetic resolution of 10 mT; the range of temperature for use should be up to 20 K.

A typical reflectivity spectrum and Faraday angle curve are displayed in Fig. 11.37. The reflectivity spectrum presents an interference pattern associated with the metal/semiconductor/vacuum optical cavity. This pattern shows a spectral shift when the illuminating spot is scanned along the sample surface, according to the thickness variation of the cavity. The maximum Faraday angle is observed when a minimum of reflectivity is matched with the QW transition energy (the cavity resonance condition). The peak Faraday angle was found to vary linearly with the applied magnetic field H . The measured slope equals $54.4^\circ \text{ T}^{-1}$ at the QWs (e1-hh1) exciton transition. Fig. 11.38 shows an intermediate state struc-

ture at the surface of the indium superconducting layer obtained at $T = 1.9$ K at magnetic field values 6.3 mT. The critical field of indium at 1.9 K is 19.4 mT.

Black and gray areas are normal and superconducting state, respectively. The intricate flux pattern results from the competition between long-range repulsive magnetic interactions between normal zones and short-range interactions due to the positive in-

terfacial energy between normal and superconducting areas [11.45,46].

In the same way as for the lead sample, the raw images were processed in order to eliminate intensity fluctuations of the reflected light due to thickness inhomogeneities of the MOL and the sensitivity of CCD detector. The quality of the image is further improved compared with Fig. 11.35.

11.4 Nonlinear Optics and Ultrashort Pulsed Laser Application

Nonlinear optical effects with lasers are utilized in frequency conversion, optical communication (Sect. 11.5) and spectroscopy of materials. This chapter deals with nonlinear optics and its application to pulsed lasers.

11.4.1 Nonlinear Susceptibility

Definition of Nonlinear Susceptibility and Symmetry Properties

Nonlinear optical phenomena originate from nonlinearity of materials. Linear and nonlinear polarization induced in the material is expressed as follows:

$$P_i = \chi_{ij} E_j + \chi_{ijk}^{(2)} E_j E_k + \chi_{ijkl}^{(3)} E_j E_k E_l + \cdots, \quad (11.70)$$

where i, j, k and l represent x, y , or z and $\chi^{(n)}$, which is an $(n+1)$ -th-rank tensor, is called the n -th-order *nonlinear optical susceptibility*. Each term corresponds to the n -th order polarization:

$$P_{i_1}^{(n)} = \chi_{i_1 i_2 \cdots i_{n+1}}^{(n)} \overbrace{E_{i_2} E_{i_3} \cdots E_{i_{n+1}}}^n, \quad (11.71)$$

where i_1, i_2, \dots , or i_{n+1} represents x, y , or z . The second-order nonlinearity in the argument ω is described by

$$P_i^{(2)}(\omega_1 + \omega_2) = \chi_{ijk}^{(2)}(\omega_1 + \omega_2; \omega_1, \omega_2) \times E_j(\omega_1) E_k(\omega_2). \quad (11.72)$$

The $\chi^{(2)}$ tensor has the following symmetry properties [11.47]:

1. Intrinsic permutation symmetry

$$\chi_{ijk}^{(2)}(\omega_1 + \omega_2; \omega_1, \omega_2) = \chi_{ikj}^{(2)}(\omega_1 + \omega_2; \omega_2, \omega_1). \quad (11.73)$$

2. Permutation symmetry for materials without losses

$$\begin{aligned} \chi_{ijk}^{(2)}(\omega_1 + \omega_2; \omega_1, \omega_2) \\ = \chi_{jki}^{(2)}(\omega_1; -\omega_2, \omega_1 + \omega_2) \\ = \chi_{kij}^{(2)}(\omega_2; \omega_1 + \omega_2, -\omega_1). \end{aligned} \quad (11.74)$$

3. Kleinman's relation (for the non-resonant case, χ is independent of the frequency ω .)

$$\chi_{ijk}^{(2)} = \chi_{jki}^{(2)} = \chi_{kij}^{(2)} = \chi_{ikj}^{(2)} = \chi_{jik}^{(2)} = \chi_{kji}^{(2)}, \quad (11.75)$$

where the arguments are $(\omega_1 + \omega_2; \omega_1, \omega_2)$. A consideration of crystal symmetry allows us to reduce the number of elements of the $\chi^{(n)}$ tensor of the material [11.47,48]. A typical example is as follows:

If the material has inversion symmetry,

$$\begin{aligned} -P_i^{(2)} &= \chi_{ijk}^{(2)}(-E_j)(-E_k), \\ P_i^{(2)} &= 0. \end{aligned}$$

In the same way, we obtain

$$P^{(2n)} = 0 \quad (n : \text{integer}).$$

Then if the material has inversion symmetry,

$$\chi^{(2n)} = 0 \quad (n : \text{integer}). \quad (11.76)$$

Oscillator Model Including Nonlinear Interactions

The nonlinear optical susceptibility can be calculated quantum mechanically using the density matrix formalism [11.47]. Here we use a classical model [11.49], modifying the Lorentz oscillator model (11.15) to include nonlinear interactions of light and matter as follows:

$$\begin{aligned} m \frac{d^2 x}{dt^2} &= -m\gamma \frac{dx}{dt} - m\omega_0^2 x - amx^2 \\ &\quad - bmx^3 + eE(t), \end{aligned} \quad (11.77)$$

where the third and fourth terms on the right-hand side correspond to the second- and third-order anharmonic potentials, respectively. Here we assume that the driving term can be expressed by

$$E(t) = \left\{ E_1 [\exp(-i\omega_1 t) + \exp(i\omega_1 t)] + E_2 [\exp(-i\omega_2 t) + \exp(i\omega_2 t)] \right\} / 2. \quad (11.78)$$

We can solve (11.77) by perturbative expansion of $x(t)$ in powers of the electric field $E(t)$,

$$x(t) \equiv x^{(1)} + x^{(2)} + x^{(3)} + \dots,$$

where $x^{(i)}$ is proportional to $[E(t)]^i$. Then we get the successive equations as follows:

$$d^2 x^{(1)} / dt^2 + \gamma dx^{(1)} / dt + \omega_0^2 x^{(1)} = eE(t) / m, \quad (11.79)$$

$$d^2 x^{(2)} / dt^2 + \gamma dx^{(2)} / dt + \omega_0^2 x^{(2)} = a(x^{(1)})^2, \quad (11.80)$$

$$d^2 x^{(3)} / dt^2 + \gamma dx^{(3)} / dt + \omega_0^2 x^{(3)} = 2ax^{(1)}x^{(2)} + b(x^{(1)})^3. \quad (11.81)$$

If we define a common denominator:

$$D(\omega) \equiv 1 / (\omega_0^2 - \omega^2 - i\gamma\omega), \quad (11.82)$$

the solution of (11.79) is expressed by

$$x^{(1)} = [E_1 D(\omega) \exp(-i\omega_1 t) + E_2 D(\omega) \exp(-i\omega_2 t)] \times e / 2m + \text{c.c.}, \quad (11.83)$$

where c.c. means complex conjugate. This is just a superposition of (11.94). Then we substitute this result for the right-hand side of (11.80). The solution consists of five groups as follows:

$$x^{(2)}(2\omega_1) = - [E_1^2 D(2\omega_1) D(\omega_1)^2 \times \exp(-2i\omega_1 t)] a e^2 / (4m^2) + \text{c.c.}, \quad (11.84)$$

$$x^{(2)}(2\omega_2) = - [E_2^2 D(2\omega_2) D(\omega_2)^2 \times \exp(-2i\omega_2 t)] a e^2 / (4m^2) + \text{c.c.}, \quad (11.85)$$

$$x^{(2)}(\omega_1 + \omega_2) = - \{ E_1 E_2 L(\omega_1 + \omega_2) D(\omega_1) D(\omega_2) \times \exp[-i(\omega_1 + \omega_2)t] \} a e^2 / (2m^2) + \text{c.c.}, \quad (11.86)$$

$$x^{(2)}(\omega_1 - \omega_2) = - \{ E_1 E_2^* D(\omega_1 - \omega_2) D(\omega_1) \times D(\omega_2)^* \exp[-i(\omega_1 - \omega_2)t] \} \times a e^2 / (2m^2) + \text{c.c.}, \quad (11.87)$$

$$x^{(2)}(0) = - [|E_1|^2 D(\omega_1) + |E_2|^2 D(\omega_2)] \times a e^2 / (2m^2). \quad (11.88)$$

These equations indicate that new frequency components arise from the second-order nonlinearity. These components are used in frequency conversion. Details are discussed in the following subsection.

Next, the third-order nonlinearity is treated similarly, assuming three frequency components

$$E(t) = [E_1 \exp(-i\omega_1 t) + E_2 \exp(-i\omega_2 t) + E_3 \exp(-i\omega_3 t)] / 2 + \text{c.c.} \quad (11.89)$$

Then using (11.81–11.88) for all combinations of ω_1 , ω_2 and ω_3 , we finally obtain 22 groups:

$$x^{(3)} \text{ for } \omega_1 + \omega_2 + \omega_3, \omega_1 + \omega_2 - \omega_3, \omega_1 - \omega_2 + \omega_3, \\ -\omega_1 + \omega_2 + \omega_3, 2\omega_1 \pm \omega_2, 2\omega_1 \pm \omega_3, \\ 2\omega_2 \pm \omega_3, 2\omega_2 \pm \omega_1, 2\omega_3 \pm \omega_1, 2\omega_3 \pm \omega_2, \\ \omega_1, \omega_2, \omega_3, 3\omega_1, 3\omega_2 \text{ and } 3\omega_3.$$

For example,

$$x^{(3)}(\omega_1, \omega_2, -\omega_2) = - E_1 E_2 E_2^* D(\omega_1)^2 D(\omega_2) \times D(\omega_2)^* \exp(-i\omega_1 t) + \text{c.c.}, \quad (11.90)$$

$$x^{(3)}(\omega_1, \omega_1, -\omega_2) = - E_1^2 E_2^* D(2\omega_1 - \omega_2) \times D(\omega_1)^2 D(\omega_2)^* \exp[-i(2\omega_1 - \omega_2)t] [3b/2 - 2a^2 D(\omega_1 - \omega_2) - a^2 D(2\omega_1)] e^2 / (4m^3) + \text{c.c.} \quad (11.91)$$

The i -th-order polarization is given by

$$P^{(i)} = -n e x^{(i)}. \quad (11.92)$$

Then from (11.71), (11.90) we obtain a frequency component of the third-order polarization:

$$P^{(3)}(\omega_1) = n e D(\omega_1)^2 |D(\omega_2)|^2 |E(\omega_2)|^2 E(\omega_1) \equiv \chi^{(3)}(\omega_1; \omega_1 + \omega_2 - \omega_2) |E(\omega_2)|^2 E(\omega_1). \quad (11.93)$$

This term means that the optical constant, e.g. refractive index n for the ω_1 light, can be controlled by the other light of ω_2 .

Table 11.6 Values of $\chi^{(2)}$ for typical nonlinear crystals

Material	Maximum value of $\chi^{(2)}$ (10^{-8} esu)	Fundamental wavelength (μm)
α -SiO ₂	0.19	1.06
Te	2.5×10^3	10.6
BaNaNb ₅ O ₁₅	9.6	1.06
LiNbO ₃	19	1.06
BaTiO ₃	-8.5	1.06
ADP(NH ₄ H ₂ PO ₄)	0.24	0.694
KDP(KH ₂ PO ₄)	0.25	1.06
β -BBO(BaB ₂ O ₄)	0.98	1.06
ZnO	-3.3	1.06
LiIO ₃	-2.8	1.06
CdSe	26	10.6
GaAs	95	10.6
GaP	18	3.39

Estimation of Nonlinear Susceptibility

We can estimate the value of $\chi^{(2)}$ using the anharmonic oscillator model, e.g. in the case of (11.83) as follows:

$$\begin{aligned} P^{(2)}(\omega_1 + \omega_2) &= -n\epsilon x^{(2)} \\ &\equiv \chi^{(2)}(\omega_1 + \omega_2, \omega_1, \omega_2) E(\omega_1) E(\omega_2), \end{aligned} \quad (11.94)$$

if we neglect the complex conjugate term,

$$\begin{aligned} \chi^{(2)}(\omega_1 + \omega_2, \omega_1, \omega_2) \\ &= D(\omega_1 + \omega_2) D(\omega_1) D(\omega_2) n a e^3 / m^2. \\ &= \chi^{(1)}(\omega_1 + \omega_2) \chi^{(1)}(\omega_1) \chi^{(1)}(\omega_2) m a / N^2 e^3. \end{aligned}$$

Then we obtain *Miller's rule*:

$$\begin{aligned} \chi^{(2)}(\omega_1 + \omega_2, \omega_1, \omega_2) / [\chi^{(1)}(\omega_1 + \omega_2) \chi^{(1)}(\omega_1) \\ \times \chi^{(1)}(\omega_2)] &= m a / n^2 e^3 (\text{const.}). \end{aligned} \quad (11.95)$$

The density is estimated approximately

$$n \approx 1/d^3,$$

where d is a lattice constant. If we assume $m\omega_0^2 d = m a d$,

$$a = \omega_0^2 / d.$$

In the non-resonant case, the denominator is approximated by

$$D(\omega) \approx 1/\omega_0^2.$$

Finally we can estimate the value of $\chi^{(2)}$

$$\begin{aligned} \chi^{(2)} &\approx e^3 / (m^2 \omega_0^4 d^4) \\ &\approx 10^{-8} \text{ esu}, \end{aligned} \quad (11.96)$$

Table 11.7 Second-order nonlinear effects

Name of frequency conversion	Conversion process
Second harmonic generation (SHG)	$\omega \rightarrow 2\omega$
Sum frequency generation (SFG)	$\omega_1, \omega_2 \rightarrow \omega_1 + \omega_2$
Difference frequency generation (DFG)	$\omega_1, \omega_2 \rightarrow \omega_1 - \omega_2$
Optical rectification	$\omega \rightarrow 0$ (DC)
Optical parametric generation (OPG)	$\omega \rightarrow \omega_1, \omega_2$ ($\omega = \omega_1 + \omega_2$)

if we assume $\omega_0 \approx 10^{16} \text{ s}^{-1}$ and $d \approx 0.1 \text{ nm}$. Table 11.6 shows values of $\chi^{(2)}$ for typical nonlinear crystals.

Frequency Conversion

As seen in (11.84–11.88), second-order nonlinearity enables frequency conversion by mixing of two photons. Frequency conversion processes using $\chi^{(2)}$ are summarized in Table 11.7.

Second-harmonic generation (SHG), expressed by (11.84), is widely used for generation of visible or ultraviolet lights, because most solid-state lasers including LDs deliver infrared or red lights; e.g. a green line at 532 nm is the SH of a Nd : YAG laser (1064 nm) and near-UV region (350–500 nm) is covered by the SH of a Ti : Sapphire laser (see Fig. 11.16). The SHG is also used to measure the pulse width of an ultrashort pulsed laser (Sect. 11.4.3).

Sum-frequency generation (SFG) in (11.86) is also used for the generation of the higher frequency region from the lower frequency region; the third-harmonic generation (THG) at 355 nm is achieved by SFG of the SH and fundamental of the Nd : YAG laser. The SFG provides up-conversion spectroscopy (Sect. 11.4.3).

Difference-frequency generation (DFG) in (11.87) is used for generation of infrared light. A combination of DFG and OPO enables us to tune the frequency in the infrared region (3–18 μm) with AgGaS₂ or GaSe crystals. *Optical rectification (OR)* in (11.88) is a special case of DFG and provides ultra-broadband infrared pulse generation by using femtosecond lasers (Sect. 11.4.5).

Optical-parametric generation (OPG) is the reverse process of SFG; one photon is divided into two photons. This process is utilized in a tunable laser, *optical-parametric oscillator (OPO)*, pumped with a fixed-frequency laser.

Phase-matching condition is crucial for efficient frequency conversion [11.47]. The wavevector should be conserved in the frequency conversion processes; in the

Fig. 11.39 SHG intensity with respect to crystal length

SHG case the phase-matching condition is described by

$$k(2\omega) = 2k(\omega), \quad (11.97)$$

where $k(\omega)$ is the wavevector at frequency ω . In other cases, the converted component 2ω and the incident component ω interfere with each other destructively, as seen in Fig. 11.39. Here the *coherence length* l_c is defined by

$$l_c = \pi c / 2[\omega |n(\omega) - n(2\omega)|], \quad (11.98)$$

where $n(\omega)$ is the refractive index at frequency ω . The condition in (11.97) means that l_c becomes infinity. The phase-matching condition can be achieved using birefringence of a nonlinear crystal [11.47].

Third-order Nonlinear Effects

The third-order nonlinearity causes a variety of effects, which are summarized in Table 11.8.

Though the *third-harmonic generation* (THG) is used in frequency conversion, this process is useful for obtaining the spectroscopic information on the magnitude of $\chi^{(3)}$ or electronic structures, which is called *THG spectroscopy* [11.50].

Refractive index of the material depends on the intensity of the incident light as follows:

$$n = n_0 + n_2 I, \quad (11.99)$$

where n_2 is nonlinear refractive index and I is the intensity of the light. As already seen in (11.93), the n_2 is proportional to $\chi^{(3)}$:

$$n_2 = \chi^{(3)} / (n_0^2 c \epsilon_0). \quad (11.100)$$

This refractive index change that is dependent on the light intensity is called the *optical Kerr effect* (OKE), and produces a nonlinear phase shift $\Delta\Phi$:

$$\Delta\Phi = (2\pi/\lambda)n_2 I l, \quad (11.101)$$

where l is the sample length. The nonlinear phase shift is utilized in optical switching (Sect. 11.5). The

Table 11.8 Third-order nonlinear effects

The third-order effect	Notes
Third-harmonic generation (THG)	$\omega \rightarrow 3\omega$
Optical Kerr effect (OKE)	$n \rightarrow n_0 + n_2 I$
Two-photon absorption (TPA)	$\alpha \rightarrow \alpha_0 + \beta I$
Four-wave mixing (FWM)	$\omega_1, \omega_2, \omega_3 \rightarrow \omega_4$

OKE gives rise to transverse variations of a light beam which cause the wavefront distortion that leads to *self-focusing* [11.47], used in Kerr lens mode-locking (Sect. 11.4.2) or Z-scan measurement (Sect. 11.4.4). The OKE also leads to temporal variations of the phase of the light pulse, called *self-phase modulation* (SPM), which cause frequency shift, called *frequency chirp* [11.51], shown in Fig. 11.40. If a strong beam is focused on a material with large nonlinearity, *white-light continuum* can be generated via the SPM. This phenomenon is widely used in spectroscopy (Sect. 11.4.4).

The imaginary part of the complex refractive index also depends on the intensity of the incident light due to the third-order nonlinearity. Thus the absorption coefficient is defined by

$$\alpha(I) = \alpha + \beta I, \quad (11.102)$$

where β is called the *two-photon absorption* (TPA) *coefficient*. TPA is explained in Sect. 11.4.4. We apply the Kramers–Kronig relation (11.21) to the nonlinear optical constants:

$$n_2(\omega) = \frac{c}{\pi} \int_0^\infty \frac{\beta(\omega')}{\omega'^2 - \omega^2} d\omega'. \quad (11.103)$$

Four-wave mixing (FWM) is a general name for the third-order nonlinear optical processes and has a number of variations. Its spectroscopic application is introduced in Sect. 11.4.4.

Fig. 11.40 Schematic illustration of a frequency chirp. The instantaneous frequency changes from red to blue

11.4.2 Ultrafast Pulsed Laser

Properties of Ultrashort Pulses [11.51]

The relationship between a temporal profile (envelope of the electric power $|E(t)|^2$) and a spectral shape is illustrated in Fig. 11.41. A CW laser, in particular a single-mode laser, delivers monochromatic light and the envelope is independent of time, as shown in Fig. 11.41a. On the other hand, a pulsed laser produces a pulsed light which consists of a number of frequency components; the pulse duration Δt and spectral width $\Delta \nu$ are finite in Fig. 11.41b. The relation between them is determined by the Fourier transformation:

$$\Delta \nu \Delta t \geq K, \quad (11.104)$$

where K is a constant determined by the pulse shape function, as shown in Table 11.9. The equal sign is valid only for pulses without frequency modulation and such pulses are called *Fourier-transform-limited*. This inequality corresponds to the uncertainty relation between energy and time in quantum mechanics.

The temporal shape of the ultrashort pulses with very broad spectral width is easily distorted by *group velocity dispersion*, $d v_g / d \omega$ [11.51], where v_g is a group velocity; the red component propagates through the material normally faster than the blue component. If the original pulse envelope is described by a Gaussian $\exp(-t^2/\tau_0^2)$, the pulse width broadens as

$$\tau = \tau_0 \sqrt{1 + \left(\frac{|\text{GDD}|}{\tau_0^2} \right)^2}, \quad (11.105)$$

Fig. 11.41 Relationship between temporal profile and spectral shape

where the *group delay dispersion* (GDD) is written as

$$\text{GDD}(\omega) = l \frac{d^2}{d\omega^2} \left[\frac{\omega}{c} n(\omega) \right], \quad (11.106)$$

where l is the sample length. The GDD is related to the group velocity dispersion as follows:

$$\text{GDD}(\omega) = \frac{d}{d\omega} \left(\frac{l}{v_g} \right). \quad (11.107)$$

The compensation of the pulse broadening in (11.105) is crucial when dealing with ultrashort pulses.

The time width of the ultrashort pulses is determined by an *auto-correlator* in Fig. 11.42. The incoming pulse is divided in a beam splitter; a part of the light passes through a fixed delay line, while the other part passes through a variable delay line. They overlap on the non-linear crystal surface and SHG occurs. The intensity of the SH light with respect to the time delay τ corresponds to the *autocorrelation function* $I_A(\tau)$ of the input pulse $I(t)$ as follows:

$$I_A(\tau) = \int I(t)I(t - \tau) dt. \quad (11.108)$$

The pulse width of the input pulse $I(t)$ is estimated from the width of the autocorrelation function $I_A(\tau)$ using Table 11.9, if the pulse shape function is known (or assumed).

Q-Switching

A *Q-switch*, which controls the Q value of a cavity, provides a short and very intense laser pulse. The Q value is a measure of how much light from the laser medium is fed back into itself by the cavity resonator. A high Q value corresponds to low resonator losses per round trip. A schematic description of Q-switching is il-

Fig. 11.42 Set-up of auto-correlator

Table 11.9 Calculated results of K , the relation between Δt , τ_A which is the width of the autocorrelation function for typical functions

Pulse shape function	K	$\Delta t/T$	τ_A/T	$\Delta t/\tau_A$
Gaussian: $\exp(-t^2/T^2)$	0.441	$2\sqrt{\ln 2}$	$2\sqrt{2\ln 2}$	0.707
Diffraction function: $\sin^2(t/T)$	0.886	2.78	3.71	0.751
Hyperbolic square: $\text{sech}^2(t/T)$	0.315	1.76	2.72	0.648
Lorentzian: $[1 + (t/T)^2]^{-1}$	0.221	2	4	0.500
One-sided exponential: $\exp(-t/T)$ ($T > 0$)	0.110	$\ln 2$	$2 \ln 2$	0.500

illustrated in Fig. 11.43. Without a Q-switch, the laser delivers pulses with a moderate intensity and pulse width, shown in Fig. 11.43a, according to the pumping condition, e.g. optical pumping with a flash lamp. With the Q-switch (off), initially the laser medium is pumped, while the Q-switch, producing the resonator with low Q, prevents feedback of light into the medium as shown in Fig. 11.43b. This produces population inversion; the amount of energy stored in the laser medium will increase, and finally reach some maximum level, as shown in Fig. 11.44, due to losses from spontaneous emission and other processes. At this point, the Q-switch is quickly changed from low to high Q, allowing feedback and the process of optical amplification by stimulated emission to begin, as shown in Fig. 11.43c. Because of the large amount of energy already stored in the laser medium, the intensity of light builds up

very quickly; this also causes the energy stored in the medium to be exhausted quickly, as seen in Fig. 11.44. The net result is a short pulse with a width of 1–100 ns, which may have a very high peak intensity. The typical example is a Q-switched Nd : YAG laser, which can deliver 1 MW.

Mode-Locking

If all modes shown in Fig. 11.15 operate with fixed phases among them, the laser output in a simple case is described by

$$\begin{aligned}
 E(t) &= \sum_{m=-N}^N E_0 \exp[i(\omega_0 + m\Delta\omega)t + m\theta_0], \\
 &= E_0 \frac{\sin[(2N+1)(\Delta\omega t + \theta_0)/2]}{\sin[(\Delta\omega t + \theta_0)/2]} \exp(i\omega_0 t),
 \end{aligned}
 \tag{11.109}$$

Fig. 11.43 Schematic illustration of Q-switching

where ω_0 is the center frequency of the laser spectrum, $\Delta\omega = \pi(c/l)$ from (11.59) and we assume that $2N+1$ modes with the same amplitude E_0 exist and that the phase difference between adjacent modes is constant θ_0 . The calculated envelope $|E(t)|^2$ is plotted in Fig. 11.45.

Fig. 11.44 Time evolution of cavity loss caused by the Q-switch, optical gain due to the pumping and laser intensity

The time interval between the strong peaks Δt is

$$\begin{aligned}\Delta t &= 2\pi/\Delta\omega \\ &= 2l/c,\end{aligned}\quad (11.110)$$

which corresponds to the round-trip time of the laser pulse inside the cavity. The pulse width of the peak δt is

$$\delta t = 2\pi/[(2N+1)\Delta\omega]. \quad (11.111)$$

This means that a broader spectral width results in a shorter pulse width, as expected from the energy–time uncertainty relation.

Mode-locking is achieved by modulation of the resonator loss synchronized to the round-trip time of the laser pulse. There are two types: *active mode-locking*

Fig. 11.45 A temporal profile of $|E(t)|^2$ in the case $N = 7$ in (11.104)

Fig. 11.46 Schematic construction of a mode-locked Ti:Sapphire laser

Fig. 11.47 Frequency map covered by the OPA system

and *passive mode-locking*. The former uses an AOM which acts as a shutter that is open during a certain duration separated by the round-trip time; a typical example is a mode-locked Nd : YAG laser. The most successful method for the passive mode-locking is *Kerr-lens mode-locking* (KLM), which manifests itself in a mode-locked Ti:Sapphire laser. KLM is based on the optical Kerr effect of the laser medium, Ti:Sapphire itself.

Figure 11.46 shows a schematic configuration of a Ti:Sapphire laser. An intense pulse which experiences large refractive index due to the n_2 is focused within the Ti:Sapphire rod, so the diameter of the pulse is reduced. Only the intense pulse can pass through the aperture inside the cavity with less loss and be amplified further. The very broad gain spectrum of the Ti:Sapphire crystal allows the formation of ultra-short pulses with 10-fs duration. The group velocity dispersion is compensated with the prism pair, which introduces different delays for the different frequency components. The repetition rate of the mode-locked lasers is determined by the cavity length, typically 80 MHz. Generation of more intense pulses is possible by reducing the repetition rate; a *regenerative amplifier* delivers intense pulses with energy of ≈ 1 mJ and repetition frequency of ≈ 1 kHz [11.51]. Such pulses bring a variety of nonlinear phenomena; an *optical parametric amplifier* (OPA) which utilizes parametric process in Sect. 11.4.1 boosts a seed light of white-light continuum and works as a tunable light source. Thus the OPA system with additional frequency converters in Fig. 11.47 pumped with a regenerative amplifier based on a Ti:Sapphire oscillator provides tunable light pulses with fs duration from the far-IR to UV region. This is a powerful tool for time-resolved and/or nonlinear spectroscopy.

11.4.3 Time-Resolved Spectroscopy

Time-resolved spectroscopy enables us to obtain the dynamics of electrons, phonons, spins, etc. in the materials in timescales down to femtoseconds. Pulsed lasers introduced in the last section are usually utilized as light sources, while many detection techniques are used depending on the timescale or the repetition rate of events. The techniques for time-resolved spectroscopy are classified into electrical methods with electronic apparatus and optical methods using nonlinear optics. Time-resolved measurements for the luminescence are reviewed in this section.

Electrical Methods

The electric signal from a photosensor, e.g. a PMT or PD (Sect. 11.1.2), is registered with electrical apparatus shown in Table 11.10 (except a streak camera). Their principles are illustrated in Fig. 11.48: 1) A *digital storage oscilloscope* with sample rates higher than 1 GS/s makes it possible to follow the electric signal with a time resolution of nanoseconds [11.52]. 2) A *boxcar integrator* stores the signal during a time window whose position and duration (wider than ns) can be set arbitrarily [11.52]. Though temporal profiles can be obtained by sweeping the time window, this apparatus is mainly used for the gating of the temporal signal with a low repetition rate of up to 1 KHz, e.g. in pump-probe experiments using a regenerative amplifier (Sect. 11.4.4).

3) A *time-to-amplitude converter (TAC)* is used with a multichannel analyzer (MCA) to perform *time-correlated single-photon counting (TCSPC)*. A schematic diagram of the TCSPC method is depicted in Fig. 11.49. Here CFD is an abbreviation of *constant fraction discriminator* which discriminates a signal pulse from a noise as follows. The CFD produces an output electric pulse when the input voltage exceeds a preset threshold value; the time delay between the input and output pulses does not depend on the input electric pulse height or shape. Very weak light behaves as a photon, which can be counted as an electric pulse from a PMT or APD. The time interval between the excitation pulse and the luminescence pulse from the sample reflects the decay time statistically; the accumulation of a number of such events reproduces the decay curve. The TAC produces an electronic pulse with a height which is proportional to the time difference between the start pulse triggered by the excitation pulse and the stop pulse from the detector. The MCA receives the electronic pulse from the TAC and converts the voltage into a channel address number of a storage memory. A histogram, which corresponds to the decay curve, is built up in the MCA with increasing numbers of events. The counting rate should be smaller than $\approx 1\%$, so that the probability of a simultaneous arrival of two photons is negligible ($< 0.01\%$). Thus a light source with a high repetition rate, e.g. a mode-locked laser, is required [11.53]. The

Fig. 11.48 Illustration of the principles for detecting transient electric signals

Fig. 11.49 Schematic diagram of the time-correlated single-photon counting method

time resolution of this technique is determined by the jitter of the electric circuit, not by the width of the electric signal from the photosensors. Therefore, time resolution of tens of picoseconds can be achieved with a specially

Table 11.10 Comparison between four electric methods

Apparatus	Time resolution	Features
Digital storage oscilloscope	\approx ns	Single-shot or repetitive events
Boxcar integrator	\approx sub-ns	Repetitive events
Time-to-amplitude converter (TAC)	\approx 10ps	Repetitive events, single photon counting
Streak camera	\approx ps	Single-shot or repetitive events

Fig. 11.50 Schematic construction of the streak camera

Fig. 11.51 Schematic illustration of the Kerr shutter

designed PMT or APD. Very accurate data can be obtained because of no linearity problems in the detector, but *convolution analysis* is usually required in sub-ns region, because an artifact, called *after-pulse*, due to the photosensors distorts the signal.

A *streak camera* is widely used in time-resolved spectroscopy, because it enables us to obtain temporal and spectral information simultaneously. A schematic construction of the streak camera is illustrated in Fig. 11.50. A spectrometer is usually installed before the streak camera in order to disperse the incoming light horizontally. The spectrally dispersed light impinges on a photocathode from which photo-electrons are emitted. The electrons are accelerated and temporally dispersed by deflection electrodes subjected to a rapidly changing sweep voltage in the vertical direction. Then the spectrally and temporally dispersed electrons hit a *microchannel plate* (MCP) which multiplies electrons while keeping their spatial distribution. The multiplied electrons irradiate a phosphor screen on which a so-called streak image appears. The image is recorded with a CCD camera. A time-resolved

spectrum can be obtained even for a single event, if the incident light is strong. This feature enables us to study a phenomenon which shows substantial shot-by-shot fluctuations [11.54]. Time resolution of 200 fs is achieved in single-shot detection. Usually repetitive events are integrated on a CCD chip. In this case, the electronic jitter of the trigger signal synchronized to the incident light pulse determines the time resolution of the streak camera. A synchroscan streak camera used for mode-locked lasers with high repetition rates of ≈ 100 MHz achieves picosecond time resolution [11.55]. In the case of very weak light, single-photon counting detection is possible using a fast-readout CCD camera, because the MCP has a large multiplication factor.

Optical Methods (Using Nonlinear Optics)

Optical Kerr shutters (OKS) utilize the optical Kerr effect (Sect. 11.4.1); a Kerr-active medium with large $\chi^{(3)}$ works as an optical gate. The schematic configuration of the OKS is depicted in Fig. 11.51. A strong laser pulse induces birefringence in the Kerr medium, so that the plane of the polarization of the incident light determined by a polarizer P1 is rotated. Thus the incident light, normally blocked by a crossed polarizer P2, can pass through the P2. This configuration is inserted between the collection lenses and the spectrometer in Fig. 11.12. The time-resolved spectrum is then obtained by changing the delay between the gate and incident pulses [11.56]. The extinction ratio of the crossed polarizers determines the background of this technique, while the time response of the Kerr medium determines the time resolution of the OKS.

Up-conversion spectroscopy is based on SFG (Sect. 11.4.1); the up-converted photon ω_s from IR

Fig. 11.52 Principle of up-conversion spectroscopy

Method	Time resolution	Features
Kerr shutter	sub-ps	Strong gating pulse is required.
Up-conversion	≈ 100 fs	Wavelength scanning is required.

luminescence ω_{IR} is emitted when the gating laser pulse ω_p irradiates the nonlinear crystal, as shown in Fig. 11.52. A combination of the pump pulse and the nonlinear crystal acts as an optical gate like a box-car integrator. By sweeping the delay time of the pump pulse, a temporal profile of the luminescence is obtained. A time-resolved spectrum is obtained by scanning the crystal angle (and monochromator) for the phase-matching condition [11.57]. Down-conversion for UV luminescence is also possible.

11.4.4 Nonlinear Spectroscopy

Nonlinear spectroscopy reveals electronic structures, relaxation processes in various materials and provides us rich information on the materials which cannot be supplied by linear spectroscopy. Though the application of nonlinear spectroscopy is very wide, this section focuses on the topics for time-resolved measurements.

Pump-Probe Experiment

In the *pump-probe experiment*, a pump pulse causes the absorption or reflection change of the material, which is observed in a probe pulse. This technique enables us to obtain a temporal evolution of an optical response of the material with ultrafast time resolution (shorter than 10 fs) by sweeping the time delay between pump and probe pulses. A schematic experimental set-up is shown in Fig. 11.53. Two laser beams are focused on the same spot of the sample. A delay line with variable length is used to change the optical path difference between pump and probe

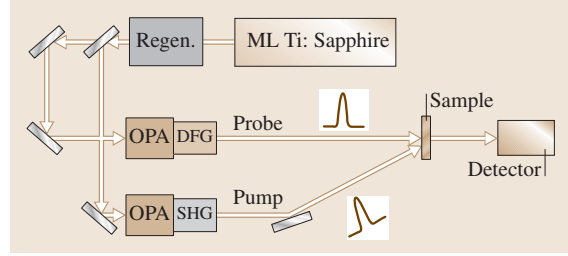

Fig. 11.53 Typical experimental set-up for the pump-probe transmission measurement. ML: mode-locked laser; Regen.: regenerative amplifier

paths. In the case of transmission pump-probe measurement, differential transmission change is defined as

$$\Delta T/T = \frac{I_{\text{on}} - I_{\text{off}}}{I_{\text{off}}}, \quad (11.112)$$

where I_{on} and I_{off} are the intensities of the probe pulses passing through the sample with and without the pump pulse, respectively. Pump-induced absorption change $\Delta\alpha$ is expressed by

$$\Delta\alpha l = \ln[1 + (\Delta T/T)], \quad (11.113)$$

where l is the sample thickness.

By scanning the probe frequency the spectrum of the absorption change can be obtained. A combination of white-light continuum in Sect. 11.4.1, which is available in the visible region, as a probe pulse and an array detector reduces the acquisition time remarkably. In this case, the frequency chirp of the white-light continuum should be corrected.

Transient Absorption and Two-Photon Absorption

A schematic diagram for transient absorption is illustrated in Fig. 11.54. If non-radiative processes is dominant and luminescence cannot be observed, the transient absorption measurement provides decay process of the excited state ($|e_1\rangle$). In addition, the higher excited state ($|e_2\rangle$), which cannot be observed in the linear (one-photon) absorption, may be found in the transient absorption. Here materials with inversion symmetry have a selection rule

$$\langle g|r|e_1\rangle \neq 0, \langle e_1|r|e_2\rangle \neq 0, \langle g|r|e_2\rangle = 0, \quad (11.114)$$

if $|g\rangle$ and $|e_2\rangle$ are even, $|e_1\rangle$ is odd. Absorption decrease called *bleaching*, corresponding to a negative signal of $\Delta\alpha l$, shows population decrease in the ground state $|g\rangle$. This signal reflects a process of ground-state recovery.

Fig. 11.54 Schematic diagram for transient absorption

Fig. 11.55 Comparison between transient absorption and two-photon absorption

Fig. 11.56 Typical example of the absorption change

The transient absorption shows an exponential decay profile, while *two-photon absorption (TPA)* in which pump and probe pulses absorbed simultaneously results in an instantaneous response following the temporal profile of the pump pulse, as illustrated in Fig. 11.55. The TPA reveals hidden electronic levels which are not detectable in linear spectroscopy.

Example of Pump-Probe Measurement

A typical example of the absorption change is shown in Fig. 11.56 [11.58]. The signal consists of two components: a Gaussian pulse with 0.2-ps width which is determined by the pulse duration of the laser and an exponential decay with decay constant $\tau = 1$ ps. The former is caused by the TPA. Changing the pump and probe frequencies, we can obtain a TPA spectrum directly [11.59]. The latter arises from the transient absorption from the excited state $|e_1\rangle$ to the higher excited state $|e_2\rangle$ in Fig. 11.55. Its decay constant reflects the decay time of the excited state $|e_1\rangle$. It is noted that convolution analysis is required in this case in which the decay time is comparable to the pulse duration. Here we calculated a convolution of Gaussian shape with 0.2-ps width and a single exponential decay with a 1-ps decay constant, shown in the figure by a broken line.

Z-scan

This simple technique allows us to measure both the sign and magnitude of the nonlinear refractive index n_2 . A schematic set-up is shown in Fig. 11.57. A laser beam with a Gaussian spatial beam profile is focused at $z = 0$ and the sample position is varied. The intensity transmitted through the aperture is measured as a function of the sample position z shown in Fig. 11.57b. Here the sample acts as a lens whose focal length depends on the position z . Numerical calculation shows [11.60]

$$\Delta T \approx 0.4 \Delta \Phi, \quad (11.115)$$

where (11.101) is used. Thus we can obtain n_2 directly.

Four-Wave Mixing

There are many variations of four-wave mixing (FWM) with two or three beams, which have the same frequency (degenerate) or different frequencies (non-degenerate). This phenomenon is based on the interference between several beams inside the material [11.61]. FWM spectroscopy generally provides information on coherent processes in the excited states. This technique is also used to estimate the value of $\chi^{(3)}$.

Fig. 11.57 (a) Schematic illustration of Z-scan measurement, and (b) normalized transmission against z

11.4.5 Terahertz Time-Domain Spectroscopy

As a unique application of ultrashort pulsed lasers, terahertz (THz) time-domain spectroscopy (TDS) is introduced in this section. The THz region is located between microwave radiation and infrared light. Due to the lack of a suitable light source and detector, spectroscopy in this region was difficult and tedious. After the development of the mode-locked Ti:Sapphire laser, THz TDS is intensively applied to many materials, e.g. doped semiconductors, superconductors, biomaterials [11.62]. The TDS enables us to obtain a waveform of the THz electric field $E(t)$ itself, not $|E(t)|^2$ as in conventional spectroscopy. This provides us a lot of advantages, e.g. simultaneous determination of real and imaginary parts of the dielectric function.

A schematic illustration of the generation and detection method for a THz pulse using a photoconductive antenna is depicted in Fig. 11.58 [11.63]. The antenna structure is fabricated on a substrate of semi-insulating semiconductors, e.g. low-temperature grown (LT)-GaAs. As an emitter, the antenna is subjected to a DC voltage and irradiated with a femtosecond laser around the gap between the dipoles, as illustrated in Fig. 11.58a. Then the mono-cycle THz pulse $E(t)$ is emitted according to the simple formula:

$$E(t) \propto \frac{\partial j_e}{\partial t}, \quad (11.116)$$

where j_e is the surge current due to photo-carriers created by the irradiation of the laser pulse. Over 30 THz generation has been reported by using 15-fs pulses. The alternative method is OR (Sect. 11.4.1) of ultrashort pulses; generation of ultra-broadband infrared pulse beyond 100 THz by using 10-fs pulses and GaSe crystals has also been demonstrated [11.64].

The antenna is also used as a receiver; photo-carriers created by the pulse irradiation provide a transient current $j_d(t)$ which is proportional to the instantaneous THz electric field $E(\tau)$ as follows:

$$j_d(t) \propto \int E(\tau) N(t - \tau) d\tau, \quad (11.117)$$

where $N(t)$ is the number of photo-carriers created by the laser pulse. If the pulse duration and the decay time of the $N(t)$ is negligibly short, $N(t) = N_0 \delta(t)$, then

$$j_d(t) \propto E(t). \quad (11.118)$$

Thus the THz electric field can be reproduced by sweeping the time delay between the laser pulse and the THz pulse. Figure 11.59a shows a typical example of tempo-

Fig. 11.59 (a) Temporal waveform of ultra-broadband THz radiation detected with a PC antenna. (b) Fourier-transformed electric-field spectrum of (a)

ral waveform of the ultra-broadband THz emission by OR with a 10-fs laser and a thin GaSe crystal detected with a PC antenna [11.65]. Its Fourier-transformed spec-

Fig. 11.60 Experimental set-up for THz TDS

trum is also shown in Fig. 11.59b. The high-frequency region beyond 80 THz is detectable using a PC antenna. The alternative method is to use electro-optic

sampling, which achieves ultra-broad-band detection beyond 120 THz [11.66].

An experimental set-up is shown in Fig. 11.60. Parabolic mirrors are used for focusing light in the far- and mid-IR region.

The complex Fourier transformation of $E(t)$ is defined by

$$E(\omega) = 1/(2\pi) \int E(t) \exp(-i\omega t) dt. \quad (11.119)$$

In the transmission measurement, the complex refractive index \mathbf{n} can be obtained using

$$E(\omega)/E_0(\omega) = \exp[-i(\mathbf{n}(\omega) - 1)L\omega/c], \quad (11.120)$$

where L is the sample thickness and $E(\omega)$ and $E_0(\omega)$ are Fourier transformations of the transmitted and incident waveform, respectively. Thus the real and imaginary parts are determined simultaneously without complex analyses such as the Kramers–Kronig transformation or the ellipsometry introduced in Sect. 11.1.4.

THz waves penetrate dry materials such as paper, ceramics and plastics but are strongly absorbed in water. Recently *terahertz imaging* has been used for drug detection, luggage inspection and integrated circuit inspection [11.67].

11.5 Fiber Optics

Optical fiber technology has developed rapidly during the last 30 years under the demands of the telecommunication network. Today a variety of commercial and laboratory applications of fiber optics are going on because of the excellent properties of optical fiber, e.g. flexibility and compactness. This section summarizes the unique properties of fibers and their characterization methods.

In its simplest form an optical fiber consists of a central glass core surrounded by a cladding layer whose refractive index n_1 is lower than the core index n_0 .

Figure 11.61 shows schematically the cross section and path of a ray propagating via total internal reflection in a step-index fiber. The critical angle for the total internal reflection at the interface is expressed as

$$\theta_c = \sin^{-1} \left(\frac{n_1}{n_0} \right)$$

The fiber numerical aperture (NA), which is defined as the sine of the half-angle of acceptance, is given by

$$\text{NA} = \sin(\theta_{\max}) = \sqrt{n_0^2 - n_1^2}.$$

Two parameters that characterize the step-index fiber are the normalized core-cladding index difference

$$\Delta = \frac{n_0 - n_1}{n_1}$$

and the so-called V parameter defined as

$$V = \frac{2\pi a}{\lambda} \sqrt{n_0^2 - n_1^2},$$

where a is the radius of core and λ is the wavelength of light.

The V parameter determines the number of modes supported by the fiber. A step-index fiber supports a single mode if $V < 2.405$. Fibers with a value of V greater than this are multimodal. More sophisticated index profiles were developed to modify the mode profile and dispersion. Detailed analysis of fiber modes in various structures is described in the textbook [11.68].

A common material for optical fiber is silica glass synthesized by chemical vapor deposition. The refractive index difference between the core and cladding is introduced by selective doping during the fabrication process. Dopants such as GeO_2 and P_2O_5 increase

Fig. 11.61 Cross section of a step-index fiber and the path of a ray propagating via total internal reflection

the refractive index of silica and are used for the core, while materials such as boron and fluorine decrease the refractive index of silica and are used for the cladding.

The fabrication process for optical fibers involves two stages: the formation of a preform and drawing into a fiber. A cylindrical preform with the desired index profile and relative core-cladding dimensions is fabricated through chemical vapor deposition. The preform is then drawn into a fiber using a precision-feed mechanism into a furnace. The fabrication methods for optical fibers are described in the reference [11.69]

11.5.1 Fiber Dispersion and Attenuation

Chromatic dispersion and attenuation of the optical signal are the most important fiber parameters for telecommunications.

Optical Attenuation in Fibers

If P_i is the incident power introduced into a fiber of length L , the transmitted power P_t is expressed by

$$P_t = P_i \exp(-\alpha L),$$

where α is the conventional attenuation constant. Customarily, α is expressed in the unit of dB/km using the following definition.

$$\alpha_{\text{dB}} = -\frac{10}{L} \log \left(\frac{P_t}{P_i} \right).$$

There are three principal attenuation mechanisms in fibers: absorption, scattering and radiative loss. Radiation losses are generally kept small enough by using thick cladding.

Figure 11.62 shows the measured loss spectrum of a typical low-loss silica fiber [11.69]. Silica suffers from absorption due to electronic transitions in the ultraviolet region below 170 nm and absorption due to vibrational transitions in the infrared beyond 2 μm , but is highly transparent in the visible and near-infrared. In this region the fundamental attenuation mechanism is

Fig. 11.62 Measured loss spectrum of a single-mode silica fiber. The *dashed curve* shows the contribution resulting from Rayleigh scattering. (After [11.69])

Rayleigh scattering due to the irregular glass structure. Intrinsic losses in silica fiber due to Rayleigh scattering is estimated to be

$$\alpha_R = \frac{C_R}{\lambda^4},$$

where the constant C_R is in the range 0.7–0.9 dB/km μm^4 depending on the constituents of the fiber core. Typical losses in modern fibers is around 0.2 dB/km near 1.55 μm . Conventional silica fiber has absorption peaks at 1.4, 2.2 and 2.7 μm due to OH vibration modes and these absorption peaks are sensitive to water contamination.

Attenuation Measurement

There are two general methods for the measurement of fiber loss; the cut-back method and optical time-domain reflectometry (OTDR). In any scheme special attention must be paid to uncertainty arising from the source-to-fiber coupling. The cut-back method is a destructive evaluation which neatly avoids the difficulty [11.70]. It operates in the following way:

- Couple the light from the source into a long length of fiber.
- Measure the light output with a large-area detector.
- Cut the fiber back by a known length and measure the change in the light output.

The change in the output is considered to arise from the attenuation in the cut fiber.

In the case of a single-mode fiber, the fiber may be cut back to a relatively short length (several meters) where the cladding modes are effectively removed. However, if the higher mode is near or just beyond the cut-off, we may need a sufficiently long length of

Fig. 11.63 Typical OTDR signal. OTDR can be used for attenuation measurement, splice and connector loss

fiber to strip off the unfavorable lossy modes [11.71]. In the case of multimode fiber the situation becomes more delicate because the attenuation depends on the modes, i. e. higher-order modes have higher losses. So, we should try to excite modes evenly and wait until the mode equilibrium is established through mode conversion. This may need a considerable length of fiber, typically ≈ 1 km.

Nondestructive loss measurement has now become possible with the technological advancement of low-loss single-mode splices or connectors, simply by assuring that the connector loss is much smaller than the fiber loss.

Optical time-domain reflectometry (OTDR) is another nondestructive evaluation method for attenuation. In this method the fiber is excited with a narrow laser pulse and a continuous backscattering signal from the fiber is recorded as a function of time. Assuming a linear and homogeneous backscattering process the decrease in backscattered light with time reflects the round-trip attenuation as a function of distance.

Figure 11.63 shows a typical OTDR signal. The linear slope yields the fiber attenuation and the sudden drop in intensity represents the splice loss; the narrow peak indicates a reflection. The OTDR method enables the evaluation of the loss distribution along the fiber including splice loss even in the deployed fiber. OTDR is also very sensitive to the excitation condition into the fiber, so control of the launch condition is the key for all attenuation measurement of fibers.

Chromatic Dispersion

The refractive index of every material depends on the optical frequency; this property is referred to as chromatic dispersion. In the spectral region far from absorption the index is well-approximated by the Sellmeier equation. For bulk fused silica $n(\lambda)$ is expressed by the

equation,

$$n(\omega)^2 = 1 + \sum_{j=1}^m \frac{B_j \omega_j^2}{\omega_j^2 - \omega^2},$$

where ω_j is the resonance frequency and B_j is the strength of the j th resonance. For bulk fused silica, these parameters are found to be $B_1 = 0.6961663$, $B_2 = 0.4079426$ and $B_3 = 0.8974794$, $\lambda_1 = 0.0684043 \mu\text{m}$, $\lambda_2 = 0.1162414 \mu\text{m}$, and $\lambda_3 = 9.896161 \mu\text{m}$ [11.72], where $\lambda_j = 2\pi c/\omega_j$ and c is the speed of light.

Dispersion plays a critical role in the propagation of short optical pulses because the different spectral components propagate with different speeds, given by $c/n(\omega)$. This causes dispersion-induced pulse broadening, which is detrimental for optical communication systems. The effect of chromatic dispersion can be analyzed by expanding the propagation constant β in a Taylor series around the optical frequency ω_0 on which the pulse spectrum is centered.

$$\beta(\omega) = n(\omega) \frac{\omega}{c} = \beta_0 + \beta_1(\omega - \omega_0) + \frac{1}{2} \beta_2(\omega - \omega_0)^2 + \dots,$$

where

$$\beta_m = \left(\frac{d^m \beta}{d\omega^m} \right)_{\omega=\omega_0} \quad (m = 0, 1, 2, 3, \dots).$$

The parameter β_1 and β_2 are related to the refractive index n through the relations

$$\beta_1 = \frac{1}{v_g} = \frac{1}{c} \left(n + \omega \frac{dn}{d\omega} \right)$$

$$\beta_2 = \frac{1}{c} \left(2 \frac{dn}{d\omega} + \omega \frac{d^2 n}{d\omega^2} \right)$$

where v_g is the group velocity. The envelope of the optical pulse moves at the group velocity. The parameter β_2 , which is a measure of the dispersion of group velocity, is responsible for the pulse broadening. This phenomenon is known as group velocity dispersion (GVD). In bulk fused silica, the GVD parameter β_2 decreases with increasing wavelength, vanishes for wavelengths of about $1.27 \mu\text{m}$ and becomes negative for longer wavelengths. This wavelength is referred to as the zero-dispersion wavelength, denoted by λ_D .

The dispersion behavior of actual silica fiber deviates from the bulk fused silica case for the following two reasons. First, the fiber core usually has small amounts of

Fig. 11.64 Wavelength dependence of the dispersion parameter D for dispersion-shifted fiber (brown line). Brown curve and dotted line represent D for silica bulk material and wave-guide dispersion, respectively

dopants such as GeO_2 and P_2O_5 . In this case, we should use the Sellmeier equation with parameters appropriate to the amount of doping [11.73]. Second, because of dielectric waveguiding, the effective mode index reflects the field distribution in the core and cladding and is slightly lower than the material index $n(\omega)$ of the core. The field distribution itself depends on ω , and this results in what is commonly termed waveguide dispersion [11.74]. Waveguide dispersion is relatively small except near the zero-dispersion wavelength λ_D , so the main effect of the waveguide contribution is to shift λ_D toward longer wavelengths; $\lambda_D = 1.31 \mu\text{m}$ for standard single-mode fiber.

The dispersion parameter $D(\text{ps}/\text{km} \cdot \text{nm})$ is commonly used in fiber optic literature in place of β_2 . D is related to β_2 by the relation.

$$D = \frac{d\beta_1}{d\lambda} = -\frac{2\pi c}{\lambda^2} \beta_2 \approx \frac{\lambda}{c} \frac{d^2 n}{d\lambda^2}$$

An important aspect of waveguide dispersion is that the contribution to D depends on design parameters such as the core radius a and the core-cladding index difference Δ . As shown in Fig. 11.64 this feature was used to shift the zero-dispersion wavelength λ_D in the vicinity of $1.55 \mu\text{m}$ where the fiber loss is at its minimum [11.74]. Such dispersion-shifted fibers, called zero- and nonzero-dispersion shifted fibers, depending on whether $D = 0$ at $1.55 \mu\text{m}$ or not, play an important role in optical communication network systems.

Dispersion Measurements

Optical pulse method is a simple time-domain measurement. Pulse delay through an optical fiber is directly measured as a function of wavelength [11.75]. This

system usually consists of a fast optical pulse generator with a tunable laser source and a fast waveform monitor system, which are common to instruments characterizing optical transmission lines. However, the accuracy is limited by optical pulse distortion due to dispersion and the time resolution of the waveform monitor.

Phase shift method is the prevailing method because higher time-domain resolution can be obtained with a relatively low frequency modulation ($< 3 \text{ GHz}$) [11.76]. The measurement scheme is shown in Figure 11.65.

A tunable light source like an external cavity laser is usually used as the light source. The light is modulated by a sinusoidal wave at a frequency of f_m with a LiNbO_3 Mach-Zender modulator. The optical signal propagated through a test fiber is converted to an electrical signal and then compared with the reference signal using a phase comparator. The phase difference $\phi(\lambda)$ is measured as a function of the wavelength λ . The group velocity delay $\tau(\lambda)$ (s/km) for an optical fiber of length L (km) is obtained by the equation

$$\tau(\lambda) = \frac{\phi(\lambda)}{f_m L},$$

where $\tau(\lambda)$ is supposed to be approximated by a three-term Sellmeier equation

$$\tau(\lambda) = A\lambda^2 + B + \frac{C}{\lambda^2}.$$

Usually, the A , B and C parameters are determined from the delay data and the GVD value is then obtained by differentiating the curve with respect to λ .

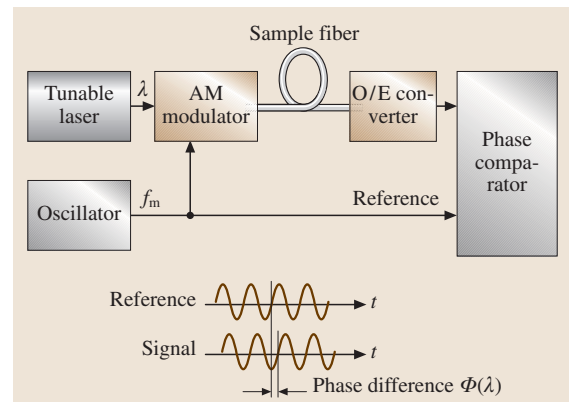

Fig. 11.65 Diagram for dispersion measurement by the phase-shift method

Fig. 11.66 Measurement scheme for the interference measurement method

Interference measurement method is appropriate for short fiber lengths, and allows a detailed and direct comparison of the optical phase shifts between a test fiber and a reference arm. This measurement scheme is illustrated in Figure 11.66 [11.77].

A broadband light source like white light or an LED is used as the light source in order to reduce the coherence length. Typically, a tunable optical filter with a bandwidth of around 10 nm is introduced in front of the interferometer. A free-space delay line or optical fiber of which the GVD is well-known is utilized as the reference arm. By moving the modulated corner cube, the position d corresponding to the zero-pass interference peak is detected. The group velocity delay $\tau(\lambda)$ for the test fiber is expressed by

$$\tau(\lambda) = \frac{2(d - d_0)}{c},$$

where d_0 is the zero-pass difference position at the reference wavelength and c is the velocity of light. The GVD is also estimated by differentiating the smoothed $\tau(\lambda)$ curve with respect to λ .

11.5.2 Nonlinear Optical Properties

This subsection deals with the nonlinear optical properties of fiber. The low loss and long interaction length of optical fibers make nonlinear processes significant. Stimulated Raman and Brillouin scattering limits the power-handling ability of fibers. Four-wave mixing presents an important limit on the channel capacity in wavelength division multiplexing (WDM) systems. Soliton formation and nonlinear polarization evolution are also summarized.

The small cross section and long interaction length of optical fiber make nonlinear optical process significant even at modest power levels. Recent developments

in fiber amplifiers have increased the available power level drastically. Optical nonlinearities are usually detrimental to optical communication networks and put some limits on the power-handling ability of fibers in medical and industrial applications. On the other hand, these optical nonlinearities are utilized in the generation of ultra-short pulse, soliton-based signal transmission, and Raman amplifiers.

As SiO_2 is a symmetric molecule, the second-order nonlinear susceptibility $\chi^{(2)}$ vanishes for silica glasses. So, nonlinear effects in optical fibers originate from the third-order susceptibility $\chi^{(3)}$, which is responsible for phenomena such as third-harmonic generation, four-wave mixing and nonlinear refraction.

In the simplest form, the refractive index can be written as

$$n(\omega, I) = n(\omega) + n_2 I.$$

Self-phase modulation (SPM) is the most important phenomena among the various nonlinear effects arising from the intensity dependence of the refractive index. The self-induced phase shift experienced by an optical field during its propagation is

$$\phi = (n + n_2 I) k_0 L,$$

where $k_0 = 2\pi/\lambda$ and L is the length of the fiber.

The measured n_2 value for bulk silica at $1.06 \mu\text{m}$ is $2.7 \times 10^{-20} \text{ m}^2/\text{W}$ [11.78]. Measured values for various silica optical fibers are found to be in the range $2.2\text{--}3.9 \times 10^{-20} \text{ m}^2/\text{W}$ [11.79]. The scatter of the data may be partly ascribed to the difference of the doping in the core materials of the fibers.

Pulse Compression and Solitons

Figure 11.67 illustrates what happens to an optical pulse which propagates in a nonlinear optical medium. The local index change raises so-called self-phase modulation. Since n_2 is positive, the leading edge of the pulse produces a local increase in refractive index. This results in a red shift in the spontaneous frequency. On the other hand, the pulse experiences a blue shift on the trailing edge.

If the fiber has a normal dispersion at the central wavelength of the optical pulse, the red-shifted edge will advance and the blue-shifted trailing edge will retard, resulting in pulse spreading in addition to the normal chromatic dispersion. However, if fiber exhibits anomalous dispersion, the red-shifted edge will retard and the optical pulse will be compressed. Near the dispersion minimum, the optical pulse is stabilized and propagates

without changing shape at a critical shape. This optical pulse is called a soliton [11.80]. A soliton requires a certain power level in order to maintain the necessary index change. The record for soliton transmission is now well over 10 000 km, which was achieved by utilizing the gain section of a stimulated Raman amplifier or a rare-earth-doped fiber amplifier. In the laboratory, optical fiber nonlinearity is used in the mode-locked femtosecond laser [11.81, 82] and the generation of white continuum [11.83].

Third-harmonic generation and the four-wave mixing effect are based on the same $\chi^{(3)}$ nonlinearity but they are not efficient in optical fibers because of the difficulty in achieving the phase-matching condition. However, WDM signal transmission systems encounter serious cross-talk problems arising from four-wave mixing between the WDM channels near the zero-dispersion wavelength of 1.55 μm [11.85].

The nonlinear optical effects governed by the third-order susceptibility are elastic, so no energy is exchanged between the electromagnetic field and the medium. Another type of nonlinear effect results from stimulated inelastic scattering, in which the optical field transfers part of its energy to the nonlinear medium. Two such scattering processes are important in optical fiber: 1) stimulated Raman scattering (SRS), and 2) stimulated Brillouin scattering (SBS).

The main difference between the two is the phonon participating in the process; optical phonons participate in SRS while acoustic phonons participate in SBS. In optical fiber SBS occurs only in the backward direction while SRS can occur in both directions. The equation governing the growth of the Raman-shifted mode is as follows

$$\frac{dI_S}{dz} = \frac{g_R}{a_{\text{eff}}} I_P - \alpha I_S,$$

where I_S is the Stokes intensity, I_P is the pump intensity and a_{eff} is the effective area of the modes. g_R is Raman gain coefficient. The same equation holds for SBS by replacing g_R with the Brillouin gain coefficient, g_B . The Raman gain spectrum in fused silica is shown in Figure 11.68.

The Raman gain spectrum of silica fiber is broad, extending up to 30 THz [11.84] and the peak gain $g_R = 10^{-13}$ m/W occurs for a Stokes shift of ≈ 13 THz for a pump wavelength near 1.5 μm . In contrast to Raman scattering, Brillouin gain is extremely narrow with a bandwidth < 100 MHz and the Stokes shift is ≈ 1 GHz close to 1.5 μm .

Fig. 11.67 Pulse evolution in a nonlinear medium

Fig. 11.68 Raman gain spectrum in fused silica. (After [11.84])

SRS and SBS exhibit a threshold-like behavior against pump power. Significant conversion of pump energy to Stokes radiation occurs only when the pump intensity exceeds a certain threshold level. For SRS in a single mode fiber with $\alpha L \gg 1$, the threshold pump intensity is given by [11.86]

$$I_P^{\text{th}} = 16\alpha \frac{a_{\text{eff}}}{g_R}.$$

SRS can be observed at a power level of ≈ 1 W. Similarly, the threshold pump intensity for SBS is given by [11.86]

$$I_P^{\text{th}} = 21\alpha \frac{a_{\text{eff}}}{g_R}$$

The Brillouin gain coefficient $g_B = 6 \times 10^{-11}$ m/W and is larger by three orders of magnitude compared with g_R . So, SBR threshold is ≈ 1 mW for CW narrow-bandwidth pumping.

Silica fibers with large effective cross section and short length have a significantly higher power-handling

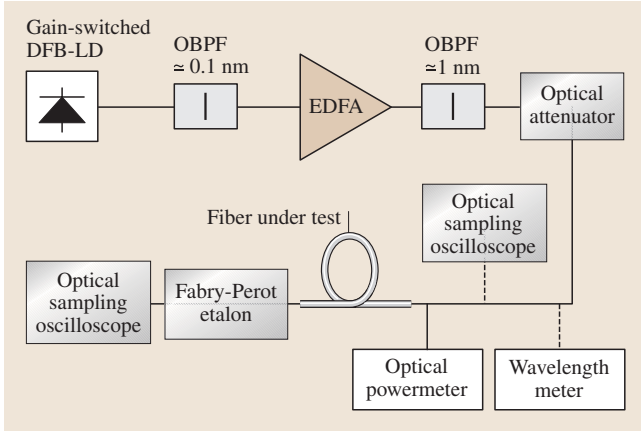

Fig. 11.69 Schematic diagram of the measurement of optical non-linearity of fiber based on the self-phase modulation method

ability and the broad-spectrum operation helps to increase the power-handling ability of the fiber.

Measurement of Nonlinear Refractive Index n_2

The nonlinear refractive index is expressed by the equation,

$$n(\omega, E^2) = n(\omega) + n_2 E^2,$$

In order to characterize the nonlinearity of the fiber, it is more practical to use the following equation.

$$n(\omega, P) = n(\omega) + (n_2/A_{\text{eff}})P$$

where P is the power propagating in the fiber and A_{eff} is the effective area of fiber defined by the equation, [11.80]

$$A_{\text{eff}} = \frac{2\pi \left[\int_0^\infty |E(r)|^2 r dr \right]}{\int_0^\infty |E(r)|^4 r dr},$$

where $E(r)$ presents the field distribution in the fiber; A_{eff} is approximately related to the mode field diameter (MFD) by the following equation

$$A_{\text{eff}} \approx \pi(\text{MFD}/2)^2.$$

For reliable evaluation of the nonlinearity of fiber, a variety of methods have been developed based on self-phase modulation [11.87–89], cross-phase modulation [11.90], four-wave mixing [11.91] and interferometry.

Figure 11.69 shows a measuring system based on self-phase modulation developed by Nami-hira et al. [11.87]. The output of a gain-switched DFB-LD with a pulse width of 26.5 ps is filtered by a narrow-band filter with a bandwidth of 0.1 nm to get

Fig. 11.70 Spectral evolution due to the self-phase modulation as a function of incident power. (After [11.87])

a nearly transformation-limited beam. The beam is amplified by an Er-doped fiber amplifier (EDFA), and is introduced into a test fiber through a variable optical attenuator. The optical spectra of the fiber output are measured by a Fabry–Perot interferometer. The observed output spectra from the fiber for various input powers is shown in Fig. 11.70 [11.87]. The number of observed spectral peaks M is related to the maximum phase shift, Φ_{max} by the equation

$$\Phi_{\text{max}} = \left(M - \frac{1}{2}\right)\pi,$$

Φ_{max} is also related to (n_2/A_{eff}) by the equation

$$\Phi_{\text{max}} = \left(\frac{2\pi}{\lambda}\right) \left(\frac{n_2}{A_{\text{eff}}}\right) L_{\text{eff}} P_0,$$

where P_0 is the incident power into the test fiber and L_{eff} is the effective length of fiber and expressed by the equation,

$$L_{\text{eff}} = \frac{1 - e^{-\alpha L}}{\alpha},$$

where α is the absorption coefficient and L is the length of the test fiber. (n_2/A_{eff}) can be estimated from the slope of Φ_{max} against P_0 .

11.5.3 Fiber Bragg Grating

The photosensitivity of silica fiber was discovered in 1978 by Hill et al. at the Communications Research Center in Canada [11.92]. Fiber Bragg grating (FBG) devices based on these phenomena allow the integration of sophisticated filtering and dispersion functions into

a fiber and have many applications in optical fiber communication and optical sensor systems. This subsection summarizes FBG technology and their properties. More information on FBGs can be found in the following references [11.93–95].

Photosensitivity

When ultraviolet light radiates an optical fiber, the refractive index is changed permanently; this effect is called photosensitivity. The change in refractive index is permanent if the fiber is annealed appropriately. These phenomena were first discovered in a fiber with a germanium-containing core, and have been observed in a variety of different fibers. However, optical fiber with germanium-containing core remains the most important material for FBG devices. 248 nm and 198 nm radiation from KrF and ArF lasers with a pulse width of ≈ 10 ns at a repetition rate of ≈ 100 pps are most commonly used. Typically fibers are exposed to laser light for a few minutes at irradiation levels in the range 100–1000 mJ/cm². Under these conditions, the index change Δn of fibers with germanium-containing cores is in the range between 10^{-5} – 10^{-3} . Irradiation at higher intensities introduces the onset of different kinds of photosensitive processes, leading to a physical damage. The index change can be enhanced by processing fibers prior to irradiation with hydrogen-loading [11.96] and flame-flushing [11.97] techniques. (Photoinduced index changes up to 100 times greater are obtained by hydrogen loading for a Ge-doped core fiber, and a ten times increase in the index change can be achieved using flame brushing.) The physical

process underlying photosensitivity is not completely understood, however it is believed to be related to the bleaching of the color centers in the ultraviolet spectral range.

Fabrication Techniques

Many techniques have been developed for the fabrication of FBG, e.g. the transverse holographic technique [11.98], the phase mask technique [11.99] and the point-by-point technique [11.100]. The phase mask technique is the most common because of its simple manufacturing process, high performance and great flexibility.

Figure 11.71 shows a schematic diagram of the phase mask technique for the manufacture of FBGs. The phase mask is made from a flat silica-glass slab with a one-dimensional periodic structure etched using photolithography techniques.

The phase mask is placed almost in contact with the optical fiber at a right angle to the corrugation and the ultraviolet light is incident normal to the phase mask. Most of the diffracted light is scattered in the +1 and –1 orders because the depth of the corrugation is designed to suppress diffraction into the zeroth order. If the period of the phase mask grating is Λ , the period of the photo-imprinted FBG is $\Lambda/2$, which is independent of the wavelength of the irradiated ultraviolet. The phase mask technique greatly simplifies the manufacturing process and its low coherence requirement on the ultraviolet beam permits the use of a conventional excimer laser. The phase mask technique not only yields high-performance devices, but is very flexible, i. e. apodization and chirping techniques are easily introduced to control the spectral response characteristics of the FBGs [11.101].

Another approach to the manufacture of FDB gratings is the point-by-point technique, in which each index perturbation is written point by point. This technique is useful for making long-period FBG devices that are used for band-rejection filters and fiber-amplifier gain equalizers.

Properties of FBGs

Light propagating in an FBG is backscattered by Fresnel reflection from each successive index change. The back reflections add up coherently in the region of the Bragg wavelength, λ_B and cancel out in the other wavelength regions.

The reflectivity of strong FBGs can approach 100% at the Bragg wavelength, whereas the light in the other spectral region passes through the FBG with negligible

Fig. 11.71 FBG fabrication with phase mask technique

loss. The Bragg wavelength, λ_B , is given by

$$\lambda_B = 2N_{\text{eff}}\Lambda,$$

where N_{eff} is the modal index of the fiber and Λ is the grating period.

The Bragg grating can be described theoretically by using coupled-mode equations [11.102]. Here important properties are summarized for the tightly bound single-mode propagation through a uniform grating. The grating is assumed to have a sinusoidal index profile with amplitude Δn . The reflectivity, R , of the grating at the Bragg wavelength is expressed by the simple equation, $R = \tanh^2(\kappa L)$ where $\kappa = (\pi/\lambda)\Delta n$ is the coupling coefficient and L is the length of the grating. The reflectivity is determined by κL , and a grating with a κL greater than one is termed a strong grating whereas a weak grating has a κL less than one. Figure 11.72 shows the typical reflection spectra for weak and strong gratings.

The other important property of FBGs is the reflection bandwidth. In the case of weak coupling ($\kappa L < 1$), the $\Delta\lambda_{\text{FWHM}}$ is approximated by the spectral distance from the Bragg wavelength, λ_B to the neighboring dip wavelength, λ_D ; $\Delta\lambda_{\text{FWHM}} \approx (\lambda_0 - \lambda_B) = \lambda_B^2/(2N_{\text{eff}}L)$. The bandwidth of a weak grating is inversely proportional to the grating length and can be very narrow for a long grating. On the other hand, in the case of strong coupling ($\kappa L > 1$), $\Delta\lambda_{\text{FWHM}}$ is approximated by the wavelength difference between the

adjacent reflection dips across the Bragg wavelength, $\Delta\lambda_{\text{FWHM}} = 4\lambda_B^2\kappa/(\pi N_{\text{eff}})$. The bandwidth is directly proportional to the coupling coefficient κ .

The bandwidth of the FBG is limited by the attainable values of the index perturbation, Δn , of the photosensitivity, and several nanometers is the actual limit corresponding to $\Delta n \approx 0.001$ at wavelengths used for optical fiber telecommunications, 1.5 μm .

A chirped or aperiodic grating has been introduced in order to broaden the spectral response of FBGs.

The spectral response of a finite-length grating with a uniform index modulation has secondary maxima on either side of the main reflection peak, as shown in Figure 11.72 [11.95]. This kind of response is detrimental to applications such as wavelength division multiplexing. However, if the index modulation profile Δn along the fiber length is apodized, these secondary peaks can be suppressed. Using the apodization technique, the side lobes of the FBG have been suppressed down to $30 \approx 40$ dB.

Another class of grating, termed the long-period grating, was proposed by Vengsarkar et al [11.103]. Gratings with longer periods, ranging into the hundreds of micrometers, involves coupling of a guided mode to forward-propagating cladding modes; the cladding modes are attenuated rapidly due to the lossy cladding coating. FBGs with a long-period grating act as transmission filters with rather broad dips and are utilized as band-rejection filters and fiber amplifier gain equalizers [11.104].

Measurement of FBG Performance

Narrow-band filters with high dynamic range are the key components for dense WDM fiber optic network systems.

However, their characterization was not easy until ultra-high resolution optical spectral analyzers became available. Q8384 (Advantest LTd.) and AQ6328C (Ando Co.) with a folded-beam four-grating configuration have a 0.01-nm resolution and 60-dB dynamic range at 0.2 nm away from the central wavelength. By using such a high-performance spectrometer together with a fiber-coupled broadband light source, characterization of FBGs is no longer difficult.

Applications of FBGs

Many potential applications of FBGs in optical fiber communication and optical sensor systems are reviewed in the reference [11.102]. FBG devices have many excellent properties for fiber optic communication systems, i. e., narrow-band and high-dynamic-range filtering, low

Fig. 11.72 Typical reflection spectra of weak and strong FBGs. (After [11.95])

insertion loss, low back reflection and so on. So, FBG devices acquired a lot of applications in the fiber optic communication system in a short period, e.g., add-drop filtering devices, dispersion-compensation devices, gain-equalizing filters in fiber amplifiers, and wavelength locking of pump lasers.

Figure 11.73 shows some examples of FBG applications in optical fiber communication network systems. Figure 11.73a presents a schematic diagram of a multi-channel dispersion compensator. FBG devices are inherently reflection filtering function whereas a transmission device is usually desired. A narrow-band transmission filtering function is commonly realized with the aid of an optical circulator. Figure 11.74b shows the wavelength locking of pump lasers for Er-doped optical amplifiers. Feedback of the weakly reflected light from FBG locks the lasing wavelength of diodes to λ_B . The temperature coefficient of the fractional change of Bragg wavelength, $\Delta\lambda_B/\lambda_B$ is $\approx 10^{-5}$ due to the very stable thermal properties of silica glass. This value is one order of magnitude lower than the temperature stability of the wavelength of DFB lasers, and is two orders of magnitude smaller than the gain peak shift of conventional laser diodes. So, wavelength locking of the pump laser stabilizes the properties of Er-doped fiber amplifiers against temperature shifts and aging effects.

A change of the in the value of L and N_{eff} causes a shift of the Bragg wavelength, and the fractional change, $\Delta\lambda_B/\lambda_B$ is given by the equation [11.106]

$$\frac{\Delta\lambda_B}{\lambda_B} = \frac{\Delta\lambda}{\lambda} + \frac{\Delta N_{\text{eff}}}{N_{\text{eff}}},$$

where $\Delta\lambda/\lambda$ and $\Delta N_{\text{eff}}/N_{\text{eff}}$ the fractional changes of the period and effective modal index, respectively. An axial change results in a shift of the Bragg wavelength given by the equation

$$\frac{1}{\lambda_B} \left(\frac{\Delta\lambda_B}{\varepsilon} \right) = \frac{1}{\lambda} \frac{\Delta\lambda}{\varepsilon} + \frac{1}{N_{\text{eff}}} \left(\frac{\Delta N_{\text{eff}}}{\varepsilon} \right).$$

The first term on the right is unity by definition and the second term, which is approximately -0.27 for silica fiber, represents the change due to the photo-elastic effect. So, the fractional change of the Bragg wavelength due to axial strain is 0.73ε . This property of FBGs can be used in strain sensors [11.106].

11.5.4 Fiber Amplifiers and Lasers

Fiber amplifiers are key components in the current dense wavelength-division multiplexed (DWDM) telecommunication system. Er-doped fiber amplifiers (EDFA),

Fig. 11.73 Some applications of fibre Bragg gratings

Fig. 11.74 Energy-level diagram for erbium. Optical gain occurs in the vicinity of 1.53 μm under pumping at a wavelength of 0.98 μm or 1.48 μm . (After [11.105])

which have a stimulated emission band in the vicinity of 1.53 μm , are most widely used as repeaters in the optical network. Fiber amplifiers and lasers have many excellent properties, e.g. high efficiency, compactness, thermal and mechanical stability, and so are used in many scientific, medical and industrial applications.

This subsection summarizes Er-doped fiber amplifiers and briefly introduces some recent advancements in femtosecond fiber lasers and high-power fiber lasers with a double-cladding structure.

Er-doped Fiber Amplifiers (EDFAs)

Energy Levels of Er. Figure 11.74 shows an energy diagram for erbium. Gain in EDFAs occurs in the vicinity of 1.53 μm when an inversion population exists between the $^4I_{13/2}$ and $^4I_{15/2}$ states; this is realized by optical pumping at the wavelengths of 0.98 μm (pumping to $^4I_{11/2}$) or 1.48 μm (pumping to $^4I_{13/2}$) [11.105, 107].

When Er ions are incorporated into the fiber core, each ion level, $^{2S+1}I_J$ presents Stark splitting due to

the interaction between the ion and host matrix. Other mechanisms, thermal fluctuation and inhomogeneous environments in the glass matrix further broaden the emission spectrum. Figure 11.75 shows the absorption and emission spectra for erbium in silica with aluminum and phosphorous co-doping [11.108]. The spectrum is constructed from the superposition of the transitions between the Stark levels and is sensitive to the host material. Considerable effort has been devoted to obtaining broadened shapes for the emission spectra for a broadband amplifier. Use of aluminosilicate glass ($\text{SiO}_2\text{--Al}_2\text{O}_3$) results in slight broadening and smoothing over the pure SiO_2 . The use of fluoride-based glasses such as ZBLAN provides significant improvements on spectral width and smoothness [11.109, 110].

EDFA configuration. A general fiber amplifier configuration is shown in Figure 11.76. A typical Er-doped

Fig. 11.75 Absorption and emission spectra for erbium in silica with aluminum and phosphorous co-doping. Spectrum associated with the transition in Fig. 11.74 [11.108]

Fig. 11.76 Er-doped fiber amplifier configuration with bidirectional pumping.

amplifier consists of an Er-doped fiber positioned between optical isolators. Pump light is introduced into the Er-doped fiber through a wavelength-selective coupler, which can be configured for either forward or backward pumping, or for bidirectional pumping. In either case, pump power is absorbed over the amplifier length, such that the population inversion varies with position along the fiber. To get the highest overall effect, the fiber length is chosen so that the length the fiber is transparent to the signal at the point of minimum pump power, i.e., the fiber end opposite to the pump laser for unidirectional pumping and at the midpoint for bidirectional pumping. Other factor like gain saturation and amplified spontaneous emission (ASE) may modifies the optimum length of fiber amplifier [11.111]. Optical isolators are usually positioned at the entrance and exit to avoid gain quenching, noise enhancement or possibly parasitic lasing due to the unfavorable backscattering or reflected light.

Operating regime. There are three operating regimes, which depend on the use intended for the amplifier [11.112]: 1) small-signal, 2) saturation and 3) deep saturation regimes. In the small-signal regime, a low input signal ($<1 \mu\text{W}$) is amplified with negligible saturation. Small-signal gains of EDFAs range between 25 and 35 dB. The gain efficiency is defined as the ratio of the maximum small-signal gain to the input pump power. Gain efficiencies of well-designed EDFA are $\approx 10 \text{ dB/mW}$ for pumping at $0.98 \mu\text{m}$ and $\approx 5 \text{ dB/mW}$ for pumping at $1.48 \mu\text{m}$. In the saturation regime, the output power is reduced significantly from the power expected in the small-signal regime. Input saturation power is defined as the input signal power required to reduce the amplifier gain by 3 dB. Alternatively, saturation output power is defined as the amplifier output when the gain is reduced by 3 dB. For the power amplifier applications, where the amplifiers operate in the deep saturation regime, the power conversion efficiency between pump and signal is important.

However, to achieve deep saturation the input signal must be high enough, so the more important situation is the saturation regime, where the choice of pumping configuration and pump power can substantially influence the performance [11.112].

Noise and gain flattening. Noise is a very important factor in telecommunication applications and is quantified using the noise figure. The noise figure of an EDFA is defined in a manner consistent with the IEEE standard definition for a general amplifier. For a shot-noise-limited input signal, the noise figure is de-

defined as the signal-to-noise ratio of the input divided by the signal-to-noise ratio of the output. The most serious noise source of EDFA is amplified spontaneous emission (ASE), which can be reduced by ensuring that the population inversion is as high as possible. With $0.98\text{ }\mu\text{m}$ pumping theoretically limited noise figures of about 3 dB have been obtained, while the best results for $1.48\text{-}\mu\text{m}$ pumping have been around 4 dB because of the difference in the pump scheme [11.113].

DWDM systems need a flattened gain spectra for all wavelength channels. Gain-flattening techniques are classified into three categories. First, use of aluminosilicate glass or fluoride-based glass with smoother and broader gain spectra. Second, spectral filtering at the output of an amplifier or between the cascaded amplifiers. Third, hybrid amplifiers with different gain media in cascaded and parallel configurations. Flattened gain spectra of EDFA have been extended in the range 12 to 85 nm.

For more details of Er-doped amplifiers, excellent reviews and text books are available [11.111, 112, 115].

Other Fiber Amplifiers

EDFAs have excellent performances within the conventional gain band (1530–1560 nm) and recent efforts have resulted in the extension of EDFA gain into the longer wavelength range (1565–1625 nm). Other rare-earth dopants or dopant combinations have been used to produce fiber amplifiers that have gain at other wavelength region. These include praseodymium-doped fiber amplifiers, which have gain at 1300 nm and are pumped at 1020 nm [11.116]. Thulium-doped fibers have been developed for amplification at 1480 nm [11.117, 118] and 1900 nm [11.119]. Ytterbium-doped fibers amplify radiation in the wavelength range from 975–1150 nm with the pump wavelengths between 910 and 1064 nm. Erbium-ytterbium co-doped fibers provide gain around 1550 nm with the pumping sources, similar to ytterbium-doped fibers [11.120]. Neodymium-doped fiber amplifiers work in the wavelength range 1064–1088 nm under pumping at 810 nm.

Raman amplifiers have also been developed by using the fiber transmission line as a gain media to increase the bandwidth and flexibility of the optical network. Raman amplifiers need multiple high-power pump sources at different wavelengths to realize broadband amplification [11.121].

Fiber Lasers

Fiber lasers are configured by replacing the isolators at both ends of fiber amplifiers by fiber Bragg gratings or

making a closed loop with couplers. In the case of a ring laser one needs a coupler for the output. Fiber lasers are inherently compact, lightweight and maintenance-free, and also do not require any water cooling. So, fiber lasers have already been deployed in some industrial applications.

Er fiber lasers can be pumped with telecom-compatible pump diodes and allow for the straightforward excitation of soliton pulses using standard optical fibers. Figure 11.77 shows a configuration of the passively mode-locked all-fiber laser, which is referred to as a figure-of-eight laser because of its layout [11.114]. Nonlinear all-optical switch including a nonlinear amplifying loop mirror allows self-starting mode-lock operation for femtosecond pulses. Current passive mode-locking lasers are usually based on the nonlinear polarization evolution in a slightly birefringent fiber because they require the least number of optical components [11.122]. Currently, mode-locked fiber lasers which generate pulses with width from 30 fs to 1 ns at repetition rates ranging from 1 MHz to 200 GHz have been developed in a variety of technologies. Details of these ultrafast lasers can be found in the textbook [11.123].

Conventional fiber lasers as well as EDFAs have simple structures with a single core for guiding both the signal and the pumped light, implying that single-mode pump diodes must be used.

The limited available power of single-mode diode-pumped sources has limited the output power to $\approx 1\text{ W}$. Cladding pumping has been developed as a method to overcome this situation using the so-called double-clad fiber shown in Figure 11.78. Double-clad fiber has a rare-earth-doped core for guiding the single-mode output beam, surrounded by a lower-index inner cladding. The inner cladding also forms the core for a secondary waveguide that guides the pumped light. The inner

Fig. 11.77 Set-up of passively mode-locked figure-of-eight laser. (After [11.114])

Fig. 11.78 Schematic drawing of a double-clad fiber

cladding is surrounded by an outer cladding of lower refractive index material to facilitate waveguiding.

Cladding-pumped fiber lasers accommodate high-power multimode pump sources, but can still produce a single-mode output. In the last decade various pumping schemes, such as star-coupler pumping [11.130], V-groove pumping [11.131] and side-coupler pumping [11.132, 133], have been developed to increase the available count of multimode pump sources in addition to the simple end-pumping approach [11.134, 135]. Cladding-pump technology has drastically increased the output power of fiber lasers to well over 100 W even in single-mode operation and seems likely to surpass bulk lasers in many industrial application areas.

11.5.5 Miscellaneous Fibers

In addition to silica-glass-based fibers, many kinds of optical fibers have been developed for various applications, such as local area networks, laser power delivery and optical sensing. In this section, most viable and commercially available fibers are reviewed.

Infrared Fibers

Infrared fibers, defined as fiber optics transmitting radiation with wavelengths greater than $2\text{ }\mu\text{m}$ are divided into three categories, i.e., glass, crystalline, and hollow waveguides. Figure 11.79 shows the optical loss for the most common infrared fibers [11.129]. In general, both the optical and mechanical properties of infrared lasers are inferior to those of silica-based fibers, and the use of infrared fibers is still limited to applications in laser power delivery, thermometry, and chemical sensing.

HMFG Fibers. Heavy-metal fluoride glass (HMFG), most commonly, $\text{ZrF}_4\text{--BaF}_2\text{--LaF}_3\text{--NaF}$ (fluorozirconate, ZBLAN) and $\text{AlF}_3\text{--ZrF}_4\text{--BaF}_2\text{--CaF}_2\text{--YF}_4$ (fluoroaluminate) presents a low optical loss around

$2.5\text{ }\mu\text{m}$ [11.124]. The attenuation in HMFG fiber is predicted to be about ten times less than that for silica fibers based on extrapolations of the intrinsic losses resulting from Rayleigh scattering and multi-phonon absorption [11.136]. ZBLAN is also a candidate host material for various fiber amplifiers because of the smoothed broadened spectra. However, their low durability against moisture attack and poor mechanical strength prevent their widespread use. The losses of fluoroaluminate fibers are not as low as for the ZBLAN, but fluoroaluminate fibers have the advantage of higher glass-transition temperatures and therefore are more promising for the power delivery of Er : YAG laser wavelength of $2.94\text{ }\mu\text{m}$.

Germate fibers. Heavy-metal-oxide glass fibers based on GeO_2 are an alternative candidate to HMFG fibers for $3\text{ }\mu\text{m}$ laser power delivery because of a higher glass-transition temperature (680°C) and excellent durability [11.137]. These fibers have a higher damage threshold and can deliver laser powers over 20 W from Er : YAG lasers.

Chalcogenide fibers. Chalcogenide glass fibers are classified into three categories: sulfide, selenide, and telluride. One or more chalcogen elements are mixed with one or more elements such as As, Ge, P, Sb, Ga to form a glass. Chalcogenide glasses are stable, durable, and insensitive to moisture. Generally, the glasses have a low softening temperature and a rather large value of $d n/dT$. This fact limits their laser power-handling ca-

Fig. 11.79 Loss spectra for some common infrared fiber optics: ZBLAN fluoride glass [11.124], single-crystal sapphire [11.125], chalcogenide glass [11.126], polycrystalline AgBrCl [11.127], and a hollow-glass waveguide [11.128]. After [11.129]

pability, and the fibers are considered to be a promising candidate for evanescent-wave fiber sensors and infrared fiber image bundles. The loss spectra for the most important chalcogenide fibers, AsGeSeTe [11.126] are shown in Fig. 11.79.

Crystalline fibers. Sapphire is an extremely hard, robust and insoluble material with an infrared transmission region from 0.5 to $3.2\text{ }\mu\text{m}$ and a melting point of over 2000° . These superior physical properties make sapphire the ideal infrared fiber candidate for applications at wavelengths less than $3.2\text{ }\mu\text{m}$. The disadvantage of sapphire single-crystal fiber is fabrication difficulties. Fiber diameters range from 100 to $300\text{ }\mu\text{m}$ and lengths are generally less than 2 m. The loss spectra of sapphire fiber [11.125] are shown in Figure 11.79. Fiber loss is less than 0.3 dB/m at the Er:YAG laser wavelength of $2.94\text{ }\mu\text{m}$, and the fibers are used to deliver over 10 W of average power. Sapphire fiber can be used at temperatures up to 1400° without any change in transmission.

Halide crystals have excellent infrared transmission, especially in the longer wavelength region. However, only the silver and thallium halides have been successfully fabricated into fiber optics, using a hot extrusion technique. In the hot extrusion process, a single-crystal perform is placed in a heated chamber at a temperature equal to about half the melting point, and the fiber is extruded to a fiber shape through a diamond or tungsten carbide die. The fibers are usually $900\text{--}500\text{ }\mu\text{m}$ in diameter. The loss spectra of polycrystalline AgBrCl fiber [11.127] are shown in Figure 11.79. The loss at $10.6\text{ }\mu\text{m}$ can be as low as 0.2 dB/m and the transmission band extends up to about $20\text{ }\mu\text{m}$.

Hollow glass waveguides. Previously, hollow waveguides were formed using metallic and plastic tubing. Today, the most popular structure is the hollow glass waveguide (HGW). The advantage of glass tubing is that it is much smoother than either metal or plastic tubing. HGWs are fabricated using a conventional wet process first to deposit a layer of Ag film on the inside of silica glass tubing, and then a dielectric layer of AgI is formed over the metallic film by converting some of the Ag to AgI. The thickness of the AgI is optimized to give high reflectivity at a particular laser wavelength [11.138]. The spectral loss for an HGW with a $530\text{ }\mu\text{m}$ bore, which is optimized for a wavelength of $10\text{ }\mu\text{m}$ [11.128], is shown in Fig. 11.79. HGWs have been used successfully in infrared laser-power delivery and some sensor applications. CO_2 and Er:YAG laser power below about

80 W can be delivered without difficulty. Employment of water-cooling jackets further increased the handleable laser power up to about 1 kW [11.139].

More detailed information on infrared fibers can be found in the literature [11.140].

Plastic optical fiber. Plastic optical fibers are commercially available for local-area networks, sensing use, and illumination. Conventional plastic optical fibers are multimode fibers with a large core diameter of about $1000\text{ }\mu\text{m}$ and are made of polymethyl methacrylate (PMMA). Figure 11.80 shows the transmission loss of the plastic optical fibers as a function of wavelength [11.141]. The transmission loss reaches a minimum value of about 100 dB/km around the spectral region between 500 and 600 nm . Usually, signal transmission lines of plastic optical fibers use 650 nm light-emitting diodes and the transmission distance is limited to 50 m because of the relatively high transmission loss, 160 dB/km .

Recent development of perfluorinated plastic optical fibers significantly improved the transmission characteristics of plastic optical fibers in the spectral region from visible to 1300 nm because the perfluorinated polymer has no C–H bond in its chemical structure. The specific loss at a wavelength of 850 nm is 17 dB/km . Signal transmission at 2.5 Gb/s was conducted over 144 m perfluorinated graded-index plastic optical fiber with an 850 nm vertical-cavity surface-emitting laser (VCSEL) transceiver [11.142].

Photonic Crystal Fibers

The photonic band gap concept triggered the development of photonic crystal fibers [11.143, 144]. Since the first fabrication of photonic crystal fiber (PCF) in 1995 [11.145], a sequence of innovations has been

Fig. 11.80 Transmission loss in plastic optical fiber

achieved in fiber optics technology. The remarkable properties of PCF have overturned many of the key precepts of textbook fiber optics. The enormous potential offered by this new structure may make current fiber optic technology obsolete.

PCFs are optical waveguides in which a microstructured cladding confines light to the fiber core. Unlike conventional all-solid fibers, which guide light by the total internal reflection at the core-clad interface, the new structures provide great freedom to control the characteristics of the fibers.

PCFs are divided into two categories based on the principal mechanism by which light is confined to the core. One of these is a species of total reflection, and the other is a new physical effect—the photonic band gap. Those typical structures are shown in Fig. 11.81.

The first type of PCF usually has a silica core surrounded by the air hole, as shown in Figure 11.81a. Optical confinement is achieved when the effective (area-averaged) refractive index is lower in the cladding region than in the core.

Figure 11.81b shows the structure of the photonic band gap and hollow-core PCF. The guiding mechanism relies on the coherent backscattering of light into the core. This effect, which is based on the photonic band gap (PBG), allows fiber to be made with hollow core.

PCF can be made by stacking tubes and rods of silica glass into a structure that is a macroscopic preform of the pattern of holes required in the final fiber. The typical dimension of this preform is 1 m long and 20 mm in diameter. The preform is then introduced into the furnace of a fiber-drawing tower.

Index-Guiding PCF

Large core. Light can be guided in PCFs by embedding a region of solid glass enclosed by an array of air holes. This approach has several important applications, and an excellent introduction is available in the review [11.146]. Index-guiding PCF provides new opportunities that stem from the special properties of the photonic crystal cladding, which are caused by the large refractive index contrast and the 2D nature of the microstructure. These affect the dispersion, smallest attainable core size, the number of guided mode and the birefringence in a different way to conventional silica fiber.

For example, endlessly single-mode PCF can be made with a very large core area [11.147, 148]. In contrast with conventional fibers, single-mode operation is guaranteed in solid-core PCF whatever the overall size of structure—in particular for large core—provided that

the ratio of hole-diameter to spacing is small enough. Ultra-large mode area PCF may have applications in high-power transmission and high-power lasers and amplifiers [11.149].

Small core. In contrast, if the holes are enlarged and the overall scale of the structure reduced so that the solid core is $\approx 0.8 \mu\text{m}$ in diameter (ultra-small mode), the zero-dispersion wavelength can be 560 nm in the green. This is quite different from the zero-dispersion wavelengths in conventional silica fibers. In fact, the group velocity dispersion can be radically affected by pure waveguide dispersion in fibers with small cores and large air holes in the cladding [11.150]. Another feature of fibers with ultra-small mode area is that the intensity of light attainable for a given launched power is very high, so nonlinear optical effects can be easily obtained. With a fiber with a small core and a zero-dispersion wavelength around 800 nm, femtosecond pulses from a Ti:Sapphire laser was efficiently converted to a single-mode broadband optical continuum [11.151], which is already being used in frequency metrology [11.152], optical coherence tomography [11.153] and spectroscopy. Enormous birefringence that exceeds values attained in conventional fibers by an order of magnitude, have already been achieved in PCFs [11.154].

Hollow-Core Photonic Band Gap Fibers

In 1999, the first hollow-core photonic band gap fiber was drawn from a stack of thin-wall silica capillaries with an extra large hole in the center, which was formed by omitting seven capillaries from the stack [11.155]. The strong wavelength dependence of guiding indicated a photonic band gap effect: only certain wavelength

Fig. 11.81a,b Two different designs of PCF. (a) shows a single-mode fiber with a pure silica core surrounded by a reduced-index photonic-crystal cladding material, (b) is an air-guiding fiber in which the light is confined to a hollow core by the photonic-band-gap effect

ranges fall within the band gaps and are guided, while other light quickly leaks out of the hollow core.

The most important factor for any fiber technology is loss. Loss in conventional fibers has been reduced over the past 30 years and seems to be approaching the material limit. However, losses in hollow-core photonic band gap fibers might be reduced below the levels found in conventional fibers because the majority of the light travels in the hollow core, in which scattering and absorption could be very low. Confinement losses can be eliminated by forming a sufficiently thick cladding. However, increased scattering at the many surfaces is a potential problem. The lowest attenuation reported to date for hollow-core photonic band gap fiber is 1.7 dB/km [OFC-PD] [11.156], and is still an order of magnitude higher than that of conventional state-of-the-art silica fibers, 0.15 dB/km [11.157]. The dramatic reduction of loss over the past few years suggests that it will be reduced still further. Dispersion is far lower than in solid-core fibers. Group velocity dispersion (GVD) in

these fibers—a measure of their tendency to lengthen a short pulse during propagation—crosses zero within the low-loss window, and is anomalous over much of the wavelength band. This implies that these fibers could support short-pulse propagation as optical solitons. The Kerr nonlinearity of the hollow-core fiber was low because it was filled with gas, whereas the effects of Raman scattering were eliminated by filling the fiber with xenon. Hollow-core fibers exhibited a substantially higher damage threshold than conventional fibers [11.158], making them suitable for delivery of high-power beams for laser machining and welding. 200-fs 4-nJ pulses from a Ti : Sapphire laser have been transmitted through 20 m of hollow-core fibers with a zero-GVD wavelength of 850 nm, and the autocorrelation width of the output pulse was broadened to roughly 3.5 times the input pulse, partly due to the modest spectral deformation [11.159]. Further improvement is expected by working away from the zero-GVD wavelength. Hollow-core fibers seem to have massive potential.

11.6 Evaluation Technologies for Optical Disk Memory Materials

Two types of rewritable optical disks are well-known today. One is a phase-change optical disk that utilizes the phenomenon of optical changes that accompany the reversible phase transitions between amorphous and crystalline states. Utilizing phase-change materials, various rewritable optical disks such as DVD-RAM, DVD-RW, CD-RW and Blue-ray discs have been commercialized. The other is a magneto-optical (MO) disk that utilizes the polar Kerr effect. It is known that the polarization plane of linearly polarized light revolves slightly when it is reflected from a perpendicularly magnetized magnetic film. MO disks have also been commercialized as various office tools and as the mini disc (MD) for audio use. In this section, the evaluation technologies for a phase-change material are first explained, and those for an MO material follow. For each case, evaluation technologies are mainly described from two points of view: the material property itself and the device property that uses the memory material. As described below, the properties of the two materials are very different, while the second aspect is generally common. Strictly speaking, various drive technologies such as servo technology and optics etc. are necessary to carry out sufficiently precise evaluations. However, the essence of them will be understood by the descriptions here.

11.6.1 Evaluation Technologies for Phase-Change Materials

To evaluate phase-change memory materials, knowing their thermal and optical characteristics is essential. This is because i) the optical change is dominantly and directly determined by the change of optical properties of the phase-change films, and ii) the phase-change mechanism is typically a thermal process. It is also very important to examine the thermal and optical properties of additional layers such as transparent protection layers composed of dielectric materials and reflection layers composed of metallic materials. The typical layer structure of a phase-change optical disk is shown in Fig. 11.82. Accordingly, practical optical disk characteristics can be estimated by knowing the thermal and optical characteristics of all these films. However, the evaluation technology is limited to the phase-change materials themselves due to space restriction.

Research and Development History of Phase-Change Materials

Today, many phase-change optical disks have been put to practical use. Without exception, they have adopted chalcogenide films for their memory layers. Study of chalcogenide alloys started in Russia in the 1950s.

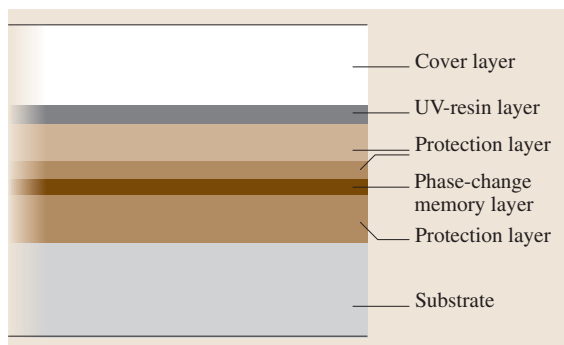

Fig. 11.82 Cross section of a typical layer structure of phase-change optical disk with four layers

Kolomiets et al. found that various chalcogenide alloys, such as Te-Ge and Te-Sb , could be easily vitrified and the obtained glassy substance showed semiconductor properties [11.160]. These new glass materials were named *dark glass* in contrast to the conventional transparent oxide glasses, and they were generically called chalcogenide glass semiconductor in the 1960s.

Ovshinsky's group first demonstrated the great potential of these glass materials as optical memories. In 1971, Feinleib et al. reported that a short laser pulse induced instant and reversible phase changes on a chalcogenide glass semiconductor thin film, representatively $\text{Te}_{81}\text{Ge}_{15}\text{Sb}_2\text{S}_2$ [11.161]. This result aroused large research and development (R&D) activities all over the world at the beginning of the 1980s, and various materials, especially Te-based eutectic alloys, were studied towards the beginning of the 1980s [11.162–165].

However, these Te-based eutectic compositions have not ultimately resulted in practical use, and R&D activities on phase-change optical memories declined in the mid-1980s. This is because conventional chalcogenide glass materials had several fatal problems, such as data rewriting speed and cyclability, for a rewritable optical memory.

Under these circumstances, Yamada et al. proposed the $\text{GeTe-Sb}_2\text{Te}_3$ pseudo-binary material system (hereinafter denoted by GeSbTe) based on a novel concept [11.166]. The largest difference between GeSbTe and the conventional materials is that GeSbTe is no longer a chalcogenide glass but just a chalcogenide while the conventional materials have characteristics suitable for the name of chalcogenide glasses [11.167]. GeSbTe has solved the fundamental problems and realized a very short crystallization time of several tens of nanoseconds, more than 100 000 cycles of data rewriting, and tens of years of estimated life. It can be said

that this material created a new era for the R&D of phase-change optical memories. The basic concept of GeSbTe has been succeeded by other materials such as AgInSbTe and $\text{Ge}(\text{Sb}_{75}\text{Te}_{25})-\text{Sb}$ etc. Those are generically named Sb-Te [11.168, 169]. The latest compositions being studied are Sb-based compositions including Te [11.170].

Principle of Phase-Change Recording

The phase-change principle is explained in Fig. 11.83, which shows the relation between the temperature and free energy of a substance. Molten substance crystallizes at the melting temperature (T_m) when it is gradually cooled down while maintaining thermal equilibrium. However, the molten substance sometimes does not crystallize even though it is cooled below T_m when the cooling speed is sufficiently large. This is a supercooled state and it is frozen into a noncrystalline solid called an amorphous state at a certain temperature (T_g) that is intrinsic to a substance. Conversely, the amorphous solid can be transformed into a crystalline solid by heating it above T_g for a period of time. The amorphous solid then becomes a supercooled liquid and crystallization occurs abruptly.

In order to achieve recording and erasing, it is necessary to undergo the above thermal process on a revolving optical disk. For this requirement, a well-focused laser beam is utilized. Figure 11.84 shows the heat profile of a phase-change recording film of an optical disk while the optical disk is passing through the laser beam. In the figure, two curves show the temperature at the center part of the track. When the laser power is strong enough to melt the phase-change film instantly (a), the temperature increases above T_m as the disk approaches the laser

Fig. 11.83 Thermodynamical explanation of a phase-change process

Fig. 11.84 Schematic view of the thermal profile of a laser-exposed area on an optical disk while it passes through the laser spot

beam, and decreases as the disk goes away from the laser beam. By designing the heat capacity of the recording film to be sufficiently small, and the thermal diffusion rate from the recording film to the adjacent films to be sufficiently large, the molten area can be transformed into an amorphous state. On the contrary, when the laser power is not high enough to elevate the film temperature over T_m but high enough to elevate it over T_g (b), it is seen from the figure that the period when the temperature is between T_g and T_m (t_1) becomes rather longer than the case of (a). Thus, the exposed area is re-transformed into a crystalline state.

Fundamental Properties of Phase-Change Materials

For the recording film of a phase-change optical disk, optical and thermal properties are very important factors. The former is tightly related to the quality of the recording signal itself and the latter relates to the recording sensitivity or thermal reliability. At first, the technologies for obtaining the basic physical properties are described.

Melting Temperature T_m , Glass Transition Temperature T_g , and Crystallization Temperature T_x . It is widely known that the temperatures T_m , T_g , and T_x are measured using differential scanning calorimetry (DSC) or differential thermal analysis (DTA). It is generally said that measurement results by DSC have higher accuracy than with DTA. DTA is suitable for a measurement under rather high-temperature conditions. For a prepara-

tion of the specimens, phase-change films are deposited on a glass substrate, scratched off and powdered. T_m and T_g are observed as endothermic peaks by these machines; however, it is difficult to observe T_g in the case of recent high-speed phase-change materials. It is said that T_g does not appear for those materials since T_g is higher than T_x . T_x is observed as an exothermic peak. Because T_x shows a distinct dependence on the heating rate, the activation energy can be obtained based on Kissinger's equation (11.121) as shown in Fig. 11.85.

$$\ln(\alpha/T_x^2) = \Delta E/R(1/T_x) + \text{const.}, \quad (11.121)$$

where α , R , E and T_x are the heating rate, gas constant, activation energy and crystallization temperature, respectively.

Therefore, by plotting $\ln \alpha/T_x^2$ versus $1/T_x$, an activation energy E can be obtained from the slope of the graph [11.171, 172]. Each value of T_m , T_x , and E closely relates to recording sensitivity, thermal resistance of the amorphous state, and crystallization speed under high-temperature conditions.

There is another, optical method to measure T_x , which is shown in Fig. 11.86. In the case of a phase-change material, phase-change phenomenon naturally accompany distinct optical properties. Accordingly, crystallization temperatures can be measured by detecting the temperature at which the optical properties, such as transmittance and reflectivity, drastically change when elevating the temperature of the film sample at a constant heating rate. Optical changes can be detected for example using a He-Ne laser. The greatest advantage of the optical method is that a film sample can be used instead of a powdered sample. Though it is reported that T_x abruptly increases as the film thickness becomes thinner, practical T_x of an optical disk can be measured by this optical method. Additionally, it is very impor-

Fig. 11.85 Schematic of a Kissinger plot from which the activation energy E can be obtained as the gradient of the line

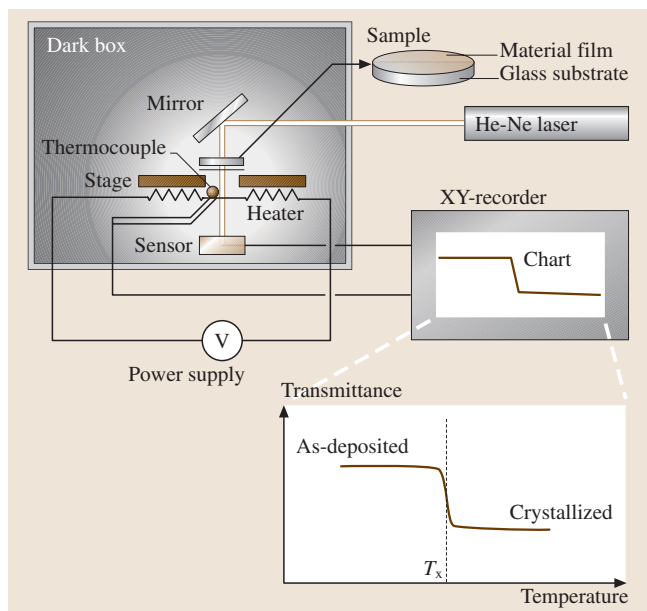

Fig. 11.86 Optical method for evaluating the crystallization temperature T_x of a phase-change thin film. The *upper* figure shows the set-up and the *bottom* shows the obtained chart

tant that this method drastically saves time for a sample preparation.

Optical Constants. It is intrinsically important for phase-change optical materials to obtain their optical constants: n (refractive index) and k (extinction coefficient). Especially, obtaining them for wavelengths λ around 300–1000 nm is very important since laser diodes exist in the range. With the constants both in the amorphous and crystalline states, we can simulate the optical characteristics when the materials are applied as the memory layer of optical disks. They are, for example, reflectivity, absorbance, transmittance and variations of these before and after recording. To obtain these optical constants, we can adopt a commercial ellipsometer. Since it is difficult to obtain a large laser-quenched amorphous film, an as-deposited film is usually substituted for an amorphous sample. A crystalline sample is prepared by annealing the as-deposited film in an Ar or N₂ gas atmosphere.

Optical constants can also be obtained by a calculation method. Firstly, optical reflectivity parameters (from both the film and substrate sides), transmittance and film thickness are experimentally measured using a spectrometer and a step-meter called a DEKTAK or α -step, respectively. Secondary, sets of optical parameters are calculated by assuming values for the optical con-

stants n and k based on the matrix method [11.173]. The measured and the calculated parameters are compared, and the assumed optical constants giving the smallest error are selected as the real values.

Crystallization Speed. Data-rewriting speed is as important a factor as recording capacity for memory devices. In the case of phase-change memory, data-rewriting speed is dominated by the crystallization speed. Since it is difficult to measure the crystallization speed directly, the evaluation of the crystallization speed is usually substituted by the required laser exposure duration that causes crystallization. The laser exposure duration can be calculated from the disk revolving speed v and the laser beam size d (laser wavelength and NA of the objective lens) on a real dynamic tester as d/v ; however, a static tester is applied in order to simulate the response under a wider range of laser exposure conditions.

Figure 11.87 shows a representative set-up of a static tester and a coupon-size specimen [11.174]. On the static tester, laser exposure from a laser diode (LD) is carried out with varying laser power and exposure duration on the coupon specimen. For a detection of the exposure results, a sufficiently weakened laser beam is re-exposed and the variations are observed as the reflectivity changes. Here, it is very important that the specimen has a similar layer structure as the practical optical disks. Accordingly, dynamic properties such as crystallization time and amorphization sensitivity can be simulated on the static tester. For example, we can determine whether the materials are applicable to DVD-RAM by investigating whether their crystallization times are faster than 80 ns. The recording-erasing conditions of DVD-RAM are: revolving speed $v = 8.2$ m/s, laser beam size $d = 0.66 \mu\text{m}(1/e)$, calculated effective exposure duration of $d/v = 80$ ns. In the case of the GeTe–Sb₂Te₃ pseudo-binary system, one of the most well-known materials, the obtained crystallization time is as short as 30 ns, and it is known that this material system can be used as a memory layer for DVD-RAM [11.175].

Instrumental Analyses. For characterization of phase-change materials, various instrumental analyses are utilized. Firstly, averaged film compositions are examined using a X-ray micro analyzer (XMA), an electron-probe micro-analyzer (EPMA) and inductively coupled plasma (ICP). XMA and EPMA can detect the contained elements in a microscopic area on a film sample, although the accuracy is not as high as for ICP. On the other hand, ICP can obtain very precise composition values. The weak points of ICP are that it is not

Fig. 11.87 Optical set-up and a specimen to evaluate phase-change process such as crystallization rate and crystallization-amorphization sensitivity etc.

suitable for detecting light elements such as O and N and for detection on a limited area. In order to detect light elements, Rutherford back scattering (RBS) can be adopted.

When a depth profile of the film composition is necessary, Auger electron spectroscopy (AES) and secondary-ion mass spectrometry (SIMS) are adopted. Quantitative evaluation is not possible for each method, but it is possible by comparison with reference samples whose compositions are known beforehand. To examine chemical bonding between each element, X-ray photoelectron spectroscopy (XPS) has conventionally been adopted. Recently, thermal desorption mass spectrometry (TDS) has also been developed.

For the observation of crystallization condition and shape of recording marks, transmission electron microscope (TEM) has been exclusively utilized; however, some new methods such as the scanning electron microscope (SEM) and surface potential microscope (SPOM) have become important in recent years. This is because the thickness of the memory film has become thinner and observation by TEM is becoming increasingly difficult.

To investigate the structures of memory materials, diffraction studies such as X-ray diffraction (XRD), electron diffraction (ED) and neutron diffraction (ND) are very effective. Precise structure can be obtained, for example, by applying the Riedvelt method to XRD results [11.176].

Dynamic Properties of a Phase-Change Optical Disk

In this part, some dynamic properties of an optical disk will be explained. Though this handbook does

not cover practical devices, it is very important for us to understand how the material characteristics relate to device performance under the practical conditions. Here, carrier-to-noise ratio (C/N), erasability, jitter, and bit error rate (BER) are explained as technologies for evaluating dynamic properties.

C/N and Erasability. C/N and erasability are the most basic items for evaluating the potential of phase-change optical disks. To measure the C/N of an optical disk, a monotone signal with a frequency f_1 is first recorded on an optical disk revolving at a constant linear velocity. Generally, f_1 corresponds to the minimum mark length (i.e., the highest recording density) to evaluate the resolution of the disk. Here, the exposed laser power is modulated between a peak power level P_p for amorphization and a bias power level for crystallization P_b (Fig. 11.88). The DC laser beam is shone on the recorded track at low power to read-out the recorded sig-

Fig. 11.88 Representative laser-modulation scheme for overwriting on a phase-change optical disk using only one laser beam

nal. The reflectivity of the optical disk differs between the amorphous and crystalline portions; accordingly, the recorded signals are detected as the variation of the reflection light intensity from the optical disk. The C/N ratio is determined by the ratio of the averaged signal amplitude and the noise floor at the frequency f_1 , as shown in Fig. 11.89. Usually, the above operations are carried out using a spectrum meter by stepping up the exposed laser powers, and the saturated value is determined as the C/N ratio of the optical disk. It is said that 45 dB is the usual minimum limit for a digital recording. The laser power to achieve saturation is determined by the recording power, as shown. To rewrite the data, another monotone signal with a frequency f_2 is overwritten on the recorded signal track, and the attenuation ratio of the signal amplitude of f_1 is determined to be the erasability. It is generally said that the erasability should be at least 20–26 dB to avoid influencing the quality of the overwritten signal.

The signal amplitude, noise level, and erasability are tightly related to the optical changes of the material, film quality such as surface flatness and grain size, and crystallization properties such as the crystallization rate, respectively.

Jitter and BER. In recent optical disks, signal marks with various lengths, for example from $1.5T$ to $4T$ with a resolution of $0.5T$ (where T is the clock period) are recorded as digital signals on an optical disk, and information is put at every distance from a certain mark-edge to the neighboring mark-edges. Figure 11.90 shows a schematic model of the digital recording signals. As can be seen from the figure, inhibition of the mark-edge deviation is important for increasing signal quality; an error occurs if the deviation becomes over

half of the clock period T . To increase the recording density, the mark length and space length has to be as short as possible. However, this is thermally restricted since the phase-change mechanism is a heat-mode process. This means that the desired thermal conductivity of phase-change films is lower than that of metals. Jitter is measured using a time-interval analyzer.

BER is the most important index to evaluate the disk performance for digital recording. It is measured by comparing the source signal and readout signal one by one. In the case of computer uses, an error rate of 10^{-3} – 10^{-4} is the minimum level.

Reliability

Reliability is naturally one of the most important factors for industrial materials. In particular, the highest level of reliability is intrinsically required for memory devices. In the case of phase-change optical memory, reliability includes the thermal stability of the amorphous state and the chemical stability of the material itself. Both factors are usually evaluated through accelerated environmental tests based on Arrhenius's equation (11.122).

$$K = A \exp(-E/RT) \quad \text{or}$$

$$\ln(k) = -E/R(1/T) + \ln(A), \quad (11.122)$$

where K , A , E , R and T are the reaction rate constant, frequency factor, activation energy, gas constant and environmental temperature, respectively.

The equation gives an estimation of the chemical reaction speed at a certain temperature. It is seen that the rate of chemical reaction becomes large as the temperature increases. The right-hand side of the equation means that the logarithm of K varies lin-

Fig. 11.91 Schematic of Arrhenius plot for obtaining an estimated life at room temperature (r.t.) based on the Arrhenius equation

early with $1/T$ on a logarithmic graph. Accordingly, it is possible to obtain the activation energy for the chemical reaction as the gradient of the straight line. The straight line is drawn based on the least-squares method by plotting the test results at various temperatures. By extrapolating the relation to room temperature, an estimated life under practical conditions can be obtained.

Figure 11.91 shows a schematic example of an Arrhenius plot. In the figure, the vertical axis shows the time for -3 dB of C/N . By extrapolating the straight line to 30°C , the estimated life of this optical disk is determined to be more than 50 years. The vertical axis can be arbitrarily selected to BER, reflectivity, amplitude and noise level etc. as required. The acceleration condition can also be selected in a number of ways. In the case of optical disks, the acceleration test is usually carried out under high-humidity conditions such as 70% RH or 80% RH in order to evaluate moisture resistance.

11.6.2 Evaluation Technologies for MO Materials

To evaluate magneto-optical memory materials, the investigation of their magnetic characteristics is the most important. Of course, thermal and optical properties are not disregarded; however, broadly speaking, these parameters are only important in relation to the magnetic properties. Items that are common to the phase-change technologies are omitted here.

R&D History of MO Materials

Research into MO recording was started by Williams in 1957 [11.177]. He recorded a signal on an MnBi

magnetic film using a magnetic pen and observed the recorded magnetic domain based on the MO effect. The following year, Mayer formed similar magnetic domains using a thermal pen. This fact became the origin of so-called thermal-magnetic recording [11.178]. There was a short break before Chang first reported thermal-magnetic recording using a laser beam in 1965. This became the prototype of present MO recordings [11.179]. From that point, various studies have been carried out to search for memory materials suitable for MO recording. Finally, in 1973, Chaudhari et al. found a good MO material based on the rare-earth-transition metal (RE-TM) system [11.180]. It is known that the RE-TM material system has the following superior characteristics:

1. the film noise is intrinsically low since the film is used in its amorphous state,
2. the perpendicular magnetization is easily formed, and a large MO effect is obtained,
3. a plastic substrate can be adopted since it does not require thermal treatment, and
4. the recording properties can be freely optimized since it is a ferri-magnetic material.

Today, various RE-TM materials are formed combining from heavy-earth elements such as Ge, Tb and Dy and the transition-metal elements Co and Fe. These have been adopted for the memory layer of all the commercialized MO disks without exception. RE-TM materials are characterized by their magnetically continuous structure, as opposed to the gradual structure of usual magnetic materials used in their crystal state.

Evaluation and measurement methods for MO technology are described below, as relevant to their application to RE-TM materials for memory layers.

Principle of MO Recording

The principle of MO recording is explained using Fig. 11.92. Before recording, the direction of the perpendicular magnetization is aligned to one direction by globally applying an intense magnetic field. At this time, the film is instantly heated, which is usually achieved with a flash lamp. The MO film has a large coercive force and a very intense magnetic field is necessary to change the direction of the magnetic field at room temperature. However, the coercive force of a magnetic material is lowered when the film temperature is increased.

Utilizing this phenomenon, we use both a laser beam and an external magnetic field for recording. One method

is optical modulation. Here, the laser power is modulated according to the recording data under a constant magnetic field. Since the laser beam instantly heats the magnetic film to the Curie point, the heated areas change their magnetization direction. When erasing the data, DC laser exposure is applied to align the magnetization in the same direction. A second method is magnetic-field modulation. Here, a magnetic coil is used to make a modulation field while DC laser exposure is applied. In this case, the direction of the magnetization is changed according to the magnetic field formed by the magnetic coil. In this case, recording and erasing is carried out simultaneously and the erase process is not necessary.

For both cases, the Kerr effect is used to read the recorded data. When polarized light is incident on a polarized magnetized film, the polarization plane of the reflected light is slightly revolved from that of the incident light, and the revolution direction changes with the magnetization direction.

Fundamental Magnetic Properties

The most fundamental and important parameters for evaluating MO films are the dependence of the magnetization and magneto-optical effects on the magnetic field. Though the size of the magnetization itself is not a parameter that directly influences the record-reproduce characteristics, the value of the magnetization is indispensable for the analysis of the mechanism of magnetic reversal. On the other hand, the size of the magneto-optical effect, which is the reproducing mechanism itself, directly impacts on the record-reproduce characteristics.

Magnetization. There are various types of magnetometers, a device that measures magnetization directly. For example, i) those that observe the temporal variation of the magnetic flux produced by a magnetic body, ii) those which measure the force applied to a magnetic body placed in a magnetic field gradient, iii) those which measure the alternating force applied to a magnetic body placed in an alternating magnetic field, and iv) vibrating sample magnetometers (VSM), which measure the electromotive force produced in a detection coil placed beside a vibrating sample in a magnetic field. The last of these has become the standard method and almost all magnetic-film institutes provide this measurement equipment. Nowadays, various types are commercially available and the fundamental procedures for gathering data, analysis and the sweeping of the magnetic field are built into a microcomputer as a measuring program and measurements are automated.

Fig. 11.92 Recording (left) and read (right) principle of MO disk

MO Effect and the Curie Point. As described above, the Kerr effect is a very important property for MO recording materials. For the evaluation of the magneto-optical effect, we measure the angle through which the polarization plane of linearly polarized light is turned on vertical incidence to a specimen in a magnetic field. In the practical polar Kerr magnetometer, a hysteresis loop is drawn by sweeping the magnetic field. Various types of this magnetometer have been commercialized, and the fundamental procedures of data gathering, analyses and the sweeping mode of the magnetic field are automatized. It is known that the magneto-optical effect depends strongly on the optical wavelength. For the evaluation of the wavelength dependence, equipment that can cover a wide wavelength range from the ultraviolet to the infrared has been developed and commercialized [11.181].

The Curie point is an important factor that is closely relating to the recording sensitivity of MO disks. This value can be obtained by measuring the thermal dependence of the magnetization and the Kerr rotation angle at temperatures varying from the ferromagnetic to the paramagnetic state. The measurements are carried out using the VSM and a Kerr magnetometer with a heating mechanism and thermal monitoring capability.

Perpendicular Magnetic Anisotropy. It is also important to measure a perpendicular magnetic anisotropy, K_u , in order to discuss the magnetic reversal phenomenon. K_u is calculated from the contortion value of a wire that supports the sample in the revolving magnetic field. The contortion is calibrated to the torque produced in the sample. The torque-meter is usually equipped with an VSM. The fundamental evaluation methods for the magnetic characteristics are overviewed above. However, in recent years, several new technologies

have been proposed. These include, for example, laser-modulation overwrite technologies [11.182, 183] and magnetic super-resolution technologies [11.184–189] utilizing the mutual interaction between a number of magnetic films with deferent thermal properties. In order to evaluate the new technologies, the magnetic cohesion between layers become an important parameter in addition to the aforementioned material properties. An effective method is to compare the hysteresis curves among stacked layers and each layer separately, and observe the magnetic field change required for magnetic reversal [11.188].

Observation of Magnetic Domains. Polarized optical microscopes were used for the observation of magnetic domains until the 1980s, but since then the magneto-force micrometer (MFM) has been used to meet this demand [11.190–197]. This is because the polarized microscope is not good at observing with at higher resolving powers. Additionally, the polarization plane becomes unaccepted as the reflectance of the p-polarized and s-polarized light starts to differ with increasing objective-lens curvature.

Dynamic Recording Properties

The same set-up as a commercial MO disk drive is applied for evaluating the recording–reproducing properties of MO materials. Here, C/N, jitter and BER are measured as for the aforementioned phase-change materials.

11.7 Optical Sensing

11.7.1 Distance Measurement

Distance is defined as “the length of the space between two points” and sometimes means simply “the full length”. The optical distance meter is mainly based on: 1) triangulation measurement, 2) pulse time-of-flight, or 3) amplitude modulation telemetry. The performance of these methods are summarized in Table 11.12.

Triangulation

Let us observe a target from two points that are d apart, as shown in Fig. 11.93. Then the distance L can be calculated as

$$L = \frac{d}{\tan \theta}, \quad (11.123)$$

where θ is the tilt angle. This method has been applied

Reliability

In order to evaluate the lifetime of MO materials, a similar method as for phase-change materials is applicable. Accelerated environmental tests are performed at several temperatures around 60–90 °C, and the lifetime at room temperature can be estimated based on the Arrhenius plot. This method has frequently been used at the first stage of MO disk development, and has resulted in an ideal structure using SiN protective layers on both sides of MO layer. Almost all commercial MO disks have adopted a multilayer structure today. Of course, it is natural that this evaluation procedure should be performed when a new MO disk utilizing new materials is developed.

Another important item is the read-power tolerance. Firstly, this is because the magnetic domain size tends to be smaller in recent high-density MO disks. In addition, new super-resolution technologies such as domain-wall displacement detection (DWDD) [11.198] and the magnetic amplifying magneto-optical system (MAMMOS [11.199]) require high temperatures (i. e., high read powers) to produce the super-resolution mechanism. It is generally known that the coercive force decreases as the magnetic domain size becomes smaller or as the temperature of the magnetic domain becomes higher. To measure the read stability, it is necessary to examine the relation between read laser power and read cycle number and experimentally determine the read power that does not produce degradation. It is said that tolerance to at least one million passes is necessary.

to measurements ranging from millimeters to hundreds of kilometers. Our vision system senses a distance from the body to the target by the same method, where d corresponds to a distance between the two eyeballs. The change of θ is detected by a strain gauge namely the “muscle spindle” that is mounted in the eyeball control muscles, as shown in Fig. 11.94.

Time-of-Flight Measurement

The round-trip transit time (Δt) for a very short high-power pulsed light from a device such as a Q-switched solid-state laser is measured. The distance L from the light source to the target is given by

$$L = \frac{c\Delta t}{2}, \quad (11.124)$$

Table 11.12 Comparison of the performance of triangulation measurements, pulse time-of-flight, and amplitude-modulation telemetry

Method	Typical light source	Typical range	Typical accuracy	Applications
Triangulation	passive light, light source unnecessary	mm to hundreds of kms	10 ⁻⁶	Auto-focusing camera, survey
Time-of-flight	Q-switched laser, pulsed diode laser	mm to kms	10 ⁻⁵	Military range finding, satellite ranging
Amplitude modulation	He-Ne laser, diode laser	sub-mm to kms	10 ⁻⁶	Survey

Fig. 11.93 Triangulation distance measurement

where c is the light speed in the measurement medium. In the actual measurement, the transit time (Δt) is measured with a time-base counter or a time-to-amplitude converter. A time resolution better than 6 ps is required to resolve 1 mm in length. A distance meter that can resolve 1 mm is achieved using a conventional time-base instrument and a pulse-driven diode laser [11.200]. Although the resolution of time-of-flight method is somewhat low, measurement is rapid. Therefore this method is usually applied to military range-finding in combination with a laser radar.

Amplitude Modulation

The amplitude of a stationary light source is sinusoidally modulated by modulation of the driving current with frequency of f (Hz). The wavelength of the modulation (Λ) is

$$\Lambda = \frac{c}{f} . \tag{11.125}$$

The distance L is given by

$$L = \frac{\Lambda}{2} \left(N + \frac{\phi}{2\pi} \right) , \tag{11.126}$$

where ϕ (rad) is the phase difference between the light source and the detected light (see Fig. 11.95), and N is an integer ($N = 0, 1, 2, 3, \dots$). The value of L is simply determined by ϕ when Λ is smaller than $L/2$, but several possible values exist when Λ is larger than $L/2$. In that case, light with different modulation frequencies is additionally used to determine N . An optical laser distance meter using a variable frequency, a sinusoidally modulated He-Ne laser and a precision phasemeter enables measurement distances of as much as 50 km. A portable version with a diode laser and a photodiode as the light source and detector, respectively, can measure distances of up to a few kilometers with an error of 5 mm. Precise distance measurement requires high-frequency no-distortion sinusoidally modulated light. For this purpose, an intermode beat signal of 1 GHz generated in

Fig. 11.94 Triangulation distance sensing by human eyes

Fig. 11.95 Distance measurement by amplitude modulation

a frequency stabilized two-mode He–Ne laser has been utilized [11.201].

11.7.2 Displacement Measurement

A displacement measurement means the measurement of the movement of a point from one position to another, and often requires very accurate length measurement. There are various types of optical instruments, i.e., microscope-based measurement, an optical lever in combination with a mechanical measurement, and triangulation-based methods. In consideration of the very accurate non-contact displacement measurement, a light interferometer is commonly used. A typical set-up called a Michelson interferometer is shown in Fig. 11.96a. Monochromatic light of wavelength λ from a light source such as a laser is collimated onto the beam splitter BS that reflects half of the light towards the flat mirror M and allows transmission of the other half toward the work piece W. Both beams are recombined at BS and transmitted to the screen, resulting in the formation of interference fringes. Fringes appear and disappear when the optical path length of the two beams Δ is an even and odd multiple of $\lambda/2$, respectively, as shown in Fig. 11.96b. There are several variations of the interferometer optics configuration such as the Fizeau interferometer, Twyman–Green interferometer, Kösters interferometer, Mach–Zehnder interferometer, and Dyson interferometer [11.202].

A simple combination of fiber optics and photo-detector depicted in Fig. 11.97 can be applied effectively to displacement measurements from the sub-micrometer range to several tens of centimeters. Such equipment is commercially available, and its typical sensitivity and resolution are 13 nm/mV and tens of nanometers, respectively, up to 60 μm .

11.7.3 3D Shape Measurement

For non-contact profile measurement, photographs using an electric imaging device such as a CCD camera are still

Table 11.13 Comparison of the performance of typical 3D measurement methods

Method	Features	Applications
Stereo-photograph	High accuracy, for large scale object, expensive	Map, Large building, survey
Optical Sectioning	Simple construction, enable from small size to large size object, changeable sensitivity	Car body, industrial parts
Moiré topography	Simple construction, high reliability, moderate sensitivity	car body, human bdy
Holograph	High sensitivity, for small size object	Small parts

dominant. The 3D measurement can be done with the use of two cameras taking stereo images. Accurate 3D measurement is made simply by combination of a light sheet and a CCD camera, as shown in Fig. 11.98. This method is one application of the triangulation measurement and is called optical sectioning. To reconstruct the 3D profile, scanning of the light sheet and/or irradiation of a grating sheet light with an adequate binary (black and white) data treatment by the signal level discrimination are combined. A Moiré topography and holographic technique are also widely applied. The features and typical applications of these methods are summarized in Table 11.13.

11.7.4 Flow Measurement

Flow visualization are based on two basic schemes: a) as-association of tracer particles and b) detection of changes in fluid optical properties caused by flow change.

Fig. 11.98 Optical sectioning by light sheet and CCD camera

Tracer-Particle Image Velocimeter

The flow direction and the velocity of each tracer particle in the liquid can be informed by applying a repetitive stroboscopic light illumination for photographic measurement. Colored dyes and gas bubbles are the common tracers and this technique is known as tracer-particle image velocimetry. When the color of the tracer particle changes with temperature, both temperature and velocity mapping are completed simultaneously. For this purpose, a temperature-sensitive liquid crystal is used as the tracer.

Laser Doppler Velocimeter

For tracer-particle associated flow measurement, a laser Doppler velocimeter (LDV) based on the Doppler shift plays an important role. The frequency of light scattered by a moving object changes depending on the velocity of the object and the scattering geometry. Advantages of LDV are the very high-frequency response (to MHz range) and sensing of very small measurement volumes (smaller than 0.1 mm cubic), while disadvantages are the point nature of the measurement, the requirement for tracer particles, and the high cost and complexity of the apparatus. The particles are not always necessary, because microscopic particles are normally contained in the measurement liquid, e.g., corpuscles in blood. However, gas flow often needs to be seeded. Figure 11.99a shows a popular dual-beam (or differential Doppler) configuration. Though the relationship between the velocity V of the particle moving and the frequency f of the electric signals is introduced by the Doppler shift, the interference fringe explanation depicted in Fig. 11.99b is rather useful in this case. The two crossing light beams form the fringe pattern with a fringe interval of

$$\delta = \frac{\lambda}{2 \sin \left(\frac{\theta}{2} \right)}, \tag{11.127}$$

where λ is the wavelength of the light in the fluid and θ is the angle between the two converging beams. A moving particle crossing the dark and light fringe pattern produces a sinusoidally modulated electric signal with

a modulation frequency f given by

$$f = \frac{V}{\delta} = \frac{2V \sin\left(\frac{\theta}{2}\right)}{\lambda} \quad (11.128)$$

Flow Visualization

The density of the fluid varies with velocity, resulting in a variation in its refractive index. Shadowgraph and schlieren techniques employ this variation in the refractive index. In these methods, light and dark patterns related to the velocity are made by the bending of light rays as they pass through a region of varying density. Because the optical set-ups of these two methods are simple, they are widely utilized for qualitative studies. For quantitative measurement, the Mach–Zehnder interferometer shown in Fig. 11.100a is advantageous. The light and fringe patterns (see Fig. 11.100b) are formed by the interference between the reference beam and the measured beam. The regular light/dark fringes are displayed even for no flow. The fringe profile partially distorts according to the change of the optical length caused by changes in the refractive properties of the fluid medium when appreciable flow occurs. The appearance of fringes on the screen can then be directly related to changes in density in the flow field. The features of these three methods are summarized in Table 11.14.

11.7.5 Temperature Measurement

Temperature measurement is based on the following three methods: 1) blackbody radiation, 2) temperature-dependent-color material, and 3) other spectroscopic methods.

Blackbody Radiation

Any substance at a temperature above 0 K emits radiation. The theory of this radiation is well explained using an ideal emitter called a blackbody. Figure 11.101 shows the change of the emission profile of the blackbody as a function of wavelength λ and temperature T (K). This profile follows the Planck distribution equation,

$$L_{\lambda,T} = \frac{C_1}{\lambda^5} \left(\frac{1}{e^{c_2/\lambda T} - 1} \right), \quad (11.129)$$

where $L_{\lambda,T}$ is the emitted monochromatic blackbody power, and C_1 and C_2 are the Planck emission constants. As one can see, the wavelength corresponding to the maximum energy moves both toward higher energies and shorter wavelengths with increasing temperature.

Fig. 11.99a,b Dual-beam laser Doppler velocimeter: (a) schematic of configuration, (b) interference fringes formed by the two beams

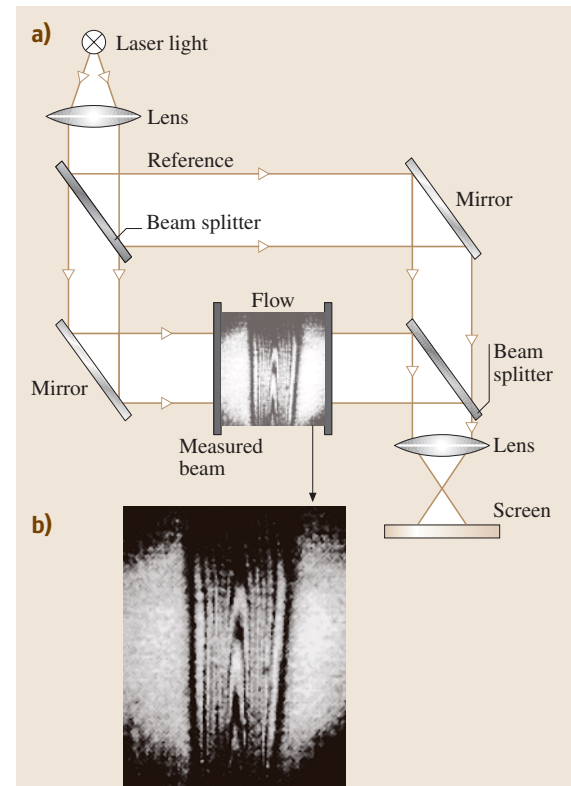

Fig. 11.100a,b Mach–Zehnder interferometer for flow visualization: (a) optics configuration, (b) example of the visualized flow (thanks to Prof. H. Kimoto, Osaka Univ.)

Table 11.14 Comparison of performance of shadowgraph, the schlieren technique and a Mach–Zehnder interferometer for flow visualization

Method	Light source	$\Delta I/I$ is proportional to
Shadowgraph	Continuous wavelength light, CW laser	Gradient of $\frac{dp}{dy}$
Schlieren	Continuous wavelength light, CW laser	Gradient of p
Mach-Zehnder	Monochromatic light is neccessary, e.g., CW laser	Fluid density p

The total thermal radiation power E (W) emitted by a blackbody with unit surface area (1 m^2) at a temperature T is given by the integration of $L_{\lambda,T}$ over λ , resulting in

$$E = \sigma T^4 \text{ ,}$$

(11.130)

where σ is the Stefan–Boltzmann constant ($5.6704 \times 10^{-8}\text{ W/K}^4\text{m}^2$).

The wavelength at the maximum emitted power λ_{max} can be obtained by derivation of $L_{\lambda,T}$ by λ . The relationship between λ_{max} (μm) and T is given by Wien’s law as

$$\lambda_{\text{max}}T = 2897.6\text{ }\mu\text{mK} \text{ .}$$

(11.131)

However, spectral profiles of the actual materials may vary from that of a blackbody (they may exhibit lower emission in some wavelength), and these are called gray-bodies. The temperature of the blackbody can thus be estimated by the measurement of either the total emitted thermal energy, the wavelength of maximum emitted power, or the spectral profile of the emission. Several methods are available to measure the emitted energy and/or spectral profiles with appropriate optical sensors.

Fig. 11.101 Emission profile of a blackbody as a function of wavelength and temperature

These methods are called optical pyrometry. A typical scheme for the pyrometer is shown in Fig. 11.102, where the standard lamp is placed in the optical path of the incident radiation. By adjusting the lamp current, the color of the filament is made the same as that of the incident radiation. Because the temperature is calibrated via the lamp heating current, the temperature of the radiation can then be estimated from the lamp current.

Temperature-Dependent-Color Material
Microcapsules that envelope temperature-depend-color liquid crystals are prepared. Because the color of the capsule changes with temperature, the surrounding temperature can be determined by the color of the capsule. The merit of this method is that it allows the simultaneous determination of both the temperature and its distribution (see the tracer-particle image velocimeter). However, the measurable temperature range is fairly narrow, i.e., from room temperature to 50°C . A laser-induced fluorescence (LIF) method extends the measurable temperature to 1000°C [11.203]. In LIF, an appropriate fluorescent material whose fluorescence intensity and/or fluorescence lifetime change with temperature is used.

Coherent Anti-Stokes Raman Spectroscopy
The infrared light region reflects the state of the molecular vibration energy. Because the population of the molecular vibrational and rotational states depends on

Fig. 11.102 Scheme for optical pyrometer

temperature, the temperature of a gas molecule can be determined directly by appropriate infrared spectroscopy. Among the various spectroscopic techniques, a coherent anti-Stokes Raman spectroscopy (CARS) is attractive and has been applied to gas temperature monitoring [11.204].

Another advantageous application of CARS is the identification of analytical molecules. For this purpose, a CRAS microscope has been proposed [11.205].

11.7.6 Optical Sensing for the Human Body

The important features of the optical method are that it is rapid, non-invasive and safe. These features are useful for measurements in health care and for medical examination of the human body.

Body Temperature and Thermograph

Body temperature monitoring is the most essential examination in health care. It can typically be monitored within 0.1–0.3 s using an infrared ear thermometer, which measures the infrared energy emitted from the eardrum. A short tube with a protective sleeve is inserted into the ear, and a shutter is opened to allow in radiation from the tympanic membrane.

A thermograph is a picture of the heat levels in the body. It is measured with an infrared imaging system that detects infrared radiation from the body's surface. Since some disorders such as breast cancer or soft-tissue injuries have a very high metabolism, they are slightly hotter than the surrounding normal tissues and can therefore be detected by the thermograph. The other technique is based on liquid crystal (LC) technology. It provides a color map of temperature. Spraying or painting the skin with LC materials displays temperature as different color bands.

Body Contours

Optical sectioning and Moiré topography are widely employed to body shape measurement. In clinical applications, spinal faults and progress of their treatment is monitored by so-called Moiré contourography, which highlights body contours [11.206]. The Moiré contours are obtained by passing angled light through a grid onto the surface of the body.

Retina Examination

Optical coherent tomography (OCT) is a non-contact, non-invasive imaging technique used to obtain high-resolution cross-sectional images of optically transparent materials [11.207]. OCT achieves much greater

longitudinal resolution (approximately 10 μm) than ultrasonic examination, and is thus clinically useful for local imaging of selected macular diseases including macular holes, macular edema, age-related macular degeneration, central serous chorioretinopathy, epiretinal membranes, schisis cavities associated with optic disc pits, and retinal inflammatory diseases. In addition, OCT has the capability of measuring the retinal nerve fiber layer thickness in glaucoma and other diseases of the optic nerve. LDV [11.208] (Sect. 11.7) and laser-speckle flowgraphy [11.209] are also applied for blood-flow determination in the retina.

Pulse Oximetry

Pulse oximetry is an optical method to monitor the hemoglobin (Hb) concentration of arterial blood that is saturated with oxygen [11.210]. The absorption profiles of oxy-Hb and deoxy-Hb show absorption peaks at around 920 and 750 nm, respectively. Therefore, the relative amount of oxy-Hb can be determined by measurement of light absorption in the near-infrared region. The pulse oximeter consists of an optical probe attached to the patient's finger or ear lobe which outputs an absorption signal corresponding to Hb and a computerized signal-processing unit. The unit displays the percentage of Hb saturated with oxygen together with an audible signal for each pulse beat. A reflection-type pulse oximeter that increases the flexibility of installation has been developed [11.211].

Brain Optical Topography

As described in the former section, the concentration of Hb in the artery can be determined optically. Since near-infrared light is transmitted through biological tissues including bones easily, local Hb concentration topography has been achieved optically to analyze functions of the brain [11.212]. To achieve brain topography, multiple pairs of light sources and a detector are placed around the head.

Skin Spectroscopy

Skin spectroscopy provides useful information for skin diagnosis. For example, the oxygen saturation of blood and melanin in the skin can be determined by the measurement of a skin spectral reflectance image and the application of component analysis [11.213]. LDV is also applied to skin diagnosis, for example, burn depth has been determined by a laser Doppler imager [11.214]. Second-harmonic generation (SHG) occurs at appreciable levels when collagen is irradiated with intense short-duration pulsed light if the polarization direction of

the incidence light wave is consistent with the collagen fiber orientation [11.215]. This feature has been applied effectively to the determination of collagen fiber orientation in the human dermis [11.216]. The characteristics of a terahertz electromagnetic wave (THz wave) are situated at the boundary between light and radio waves, and these features of THz waves has been applied to the detection of skin cancer and hydration level [11.217]. We recommend the articles on optics of the human skin published in 2004 for further study [11.218].

Glucose Monitoring

Non-invasive, in vivo optical glucose monitoring is one of the most important measurements to be achieved for human health care and diagnosis. However, the analytical probe light is strongly scattered by the skin and blood cells, resulting in a decrease in measurement reliability. This non-invasive measurement is successful at present only when applied to aqueous humor, which the probe light can reach through the cornea without unwanted scattering [11.219].

Corrosion

12. Corrosion

Corrosion is defined as the interaction between a metal and its environment that results in changes in the properties of the metal, and which may lead to significant impairment of the function of the metal. In most cases the interaction between the metal and the environment is an electrochemical reaction where thermodynamic and kinetic considerations apply. Depending on the characteristics of the corrosion system various types of corrosion occur.

In this chapter all test methods available today are described. For scientific purposes as well as investigations in the laboratory so called conventional electrochemical test methods with direct current are primarily used (Sect. 12.1). In addition, newer techniques have been proposed (Sect. 12.1) that are based on dynamic system analysis (Sect. 12.2.1) or that allow study of corrosion processes in situ with spatial resolution down to 20 μm (Sects. 12.2.2 and 12.2.3). In the following sections a distinction has been made between testing for performance of corrosion protection measures such as inhibitors (Sect. 12.8) and testing that focuses on specific types of corrosion. In this context it is advisable to differentiate between corrosion without (Sect. 12.4) and with mechanical loading (Sect. 12.5) including hydrogen-assisted cracking (Sect. 12.6) which has some similarities to stress corrosion. High-temperature oxidation (Sect. 12.6) has a different mechanistic background than electrolytic corrosion because it is an oxidation process at a metal/gas or metal/salt solution interface. Exposure and on-site testing (monitoring) require specific considerations in the design of test facilities, probes and the interpretation of results (Sect. 12.4).

Appendix Part D provides a list of standards related to the various sections of this chapter. Another important source of information regarding corrosion testing is that edited by *Baboian* [12.1].

12.1 Background

According to ISO 8044 [12.2] corrosion is defined as an interaction between a metal and its environment that results in changes in the properties of the metal, and which may lead to significant impairment of the function of the metal, the environment, or the technical system, of which these form a part. This definition has solved a conflict because previously the term corrosion had been used to mean the process, results of the process and damage caused by the process. In most cases the interaction between the metal and the environment is an electrochemical reaction where thermodynamic and kinetic considerations apply. From a thermodynamic point of view the driving force as in any electrochemical reaction is a potential difference between anodes and cathodes in a short-circuited cell.

The result of corrosion is a corrosion effect which is generally detrimental and may lead to loss of material, contamination of the environment with corrosion products or impairment of a technical system. It is important to notice that corrosion damage resulting from an attack to the metal has to be distinguished from corrosion failure which is characterized by the total loss of function of the technical system. Corrosion protection measures are available to influence corrosion process with the objective of avoiding corrosion failures.

Corrosion and protective measures against corrosion result in costs. Many attempts have been made to estimate the financial expenditure to the community caused by corrosion. These include the costs which can arise in the form of corrosion protection measures, through replacement of corrosion-damaged parts or through different effects deriving from corrosion, such as shut-

down of production or accidents which lead to injuries or damage to property. Several estimations have arrived at the conclusion that the total annual corrosion costs in the industrialized countries amount to about 4% of the gross national product. Part of these costs is unavoidable since it would not be economically viable to carry out the necessary precautions to eliminate completely corrosion damage. It is, however, certain that one can reduce losses considerably solely by better exploiting the knowledge we have today and, according to one estimate, about 15% of corrosion costs are of this type [12.3].

Due to the technical, scientific and economic importance of the problem numerous textbooks [12.1, 4–18] and publications in journals or proceedings from conferences are available. As mentioned before the corrosion reaction is in most cases of electrochemical nature. Therefore many of the published information deal with the electrochemical reactions and especially the kinetics of the corrosion process. For the engineer durability aspects in a technical plant or equipment or the safety of a process play a more important role. However, both approaches follow the same route in yielding information about the corrosion rate of a material in a specific environment [12.4].

The schematic diagram in Fig. 12.1 [12.4] shows the various reactions that can occur sequentially and simultaneously in the corrosion process. Material transport and chemical reactions can supply or remove important reaction components. In addition to adsorption or desorption, a phase-boundary reaction occurs which mostly involves electrochemical reactions and which can be affected by external currents. An example is the

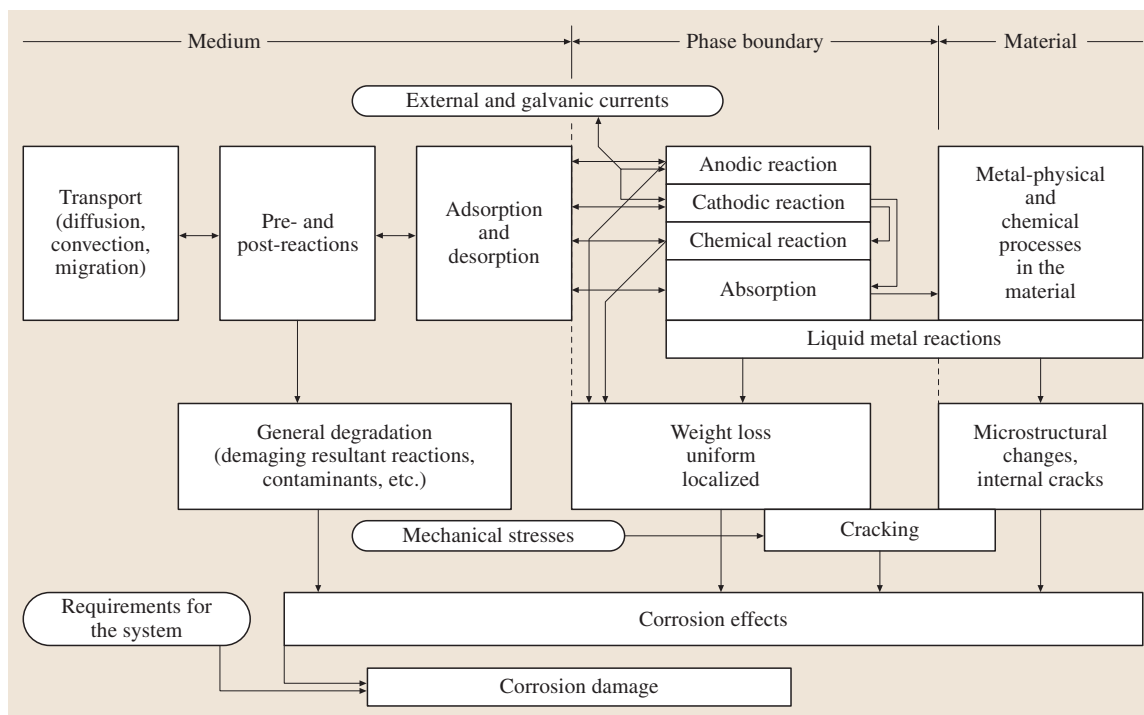

Fig. 12.1 Flow diagram of corrosion processes and types of damage (after [12.4])

formation of hydride on lead where the partner to the hydrogen reaction can arise from the cathodic process. Hydrogen can also penetrate the metal microstructure, where it can have a physical or chemical effect, causing a degradation of the mechanical properties of the material. In this type of corrosion cracks can form during mechanical testing, leading to fracture without the loss of any metal.

12.1.1 Classification of Corrosion

Numerous concepts have been applied to classify corrosion into categories. Due to the complex interaction between a material and its environment different classification schemes have developed to classify corrosion by the type of attack, the rate of attack, the morphology of the attack, or the properties of the environment, which may change in the ongoing corrosion process.

Type of damage have been predominantly used. This can be classified as uniform or localized metal removal, corrosion cracking or detrimental effects to the environment. Local attack can take the form of shallow pits, pitting, selective dissolution of small microstructure regions or cracking. It is usual, where different

results of reactions lead to definite forms of corrosion effects, to classify them as particular types of corrosion. The most important are uniform corrosion, pitting corrosion, crevice corrosion, intergranular corrosion, and those with accompanying mechanical-stress corrosion and corrosion fatigue. The two latter are most feared. Most failures arise from pitting corrosion. Uniform corrosion almost always occurs in practice but seldom leads to failure.

From [12.19] it can be taken that there are generally eight forms of corrosion:

1. General (uniform) corrosion;
2. Localized corrosion;
3. Galvanic corrosion;
4. Cracking phenomena;
5. Intergranular corrosion;
6. Dealloying;
7. High-temperature corrosion.

The eight forms of corrosion can be divided into three categories:

Group I Those readily identified by visual examination (forms 1, 2 and 3);

- Group II Those which may require supplementary means of examination (forms 5, 6 and 7);
- Group III Those which usually should be verified by microscopy, optical or scanning electron microscope, although they are sometimes apparent to the naked eye.

The individual phenomena are illustrated in Fig. 12.2.

12.1.2 Corrosion Testing

The safe use of materials in technical plants, structures or equipment requires sufficient information for assessing corrosion risks – especially if mechanical stresses are superimposed on the electrolytic load and failure of components due to stress corrosion cracking (SCC) cannot

be excluded. If sufficient knowledge about the corrosion behavior is not available then tests to determine this under practical conditions will be required. In this context a distinction must be made between the terms corrosion investigation and corrosion test. According to the International Standards Organization (ISO) standard ISO 8044 [12.2] a corrosion investigation includes corrosion tests and their evaluation and is directed towards the following objectives:

- the explanation of corrosion reactions,
- obtaining knowledge on corrosion behavior of materials under corrosion load,
- selecting measures for corrosion protection.

This enables statements about the properties of a corrosion system to be made. A corrosion test is a special case

Fig. 12.2 Types of corrosion

of a corrosion investigation; the corrosion load and the assessment of the results being prescribed by certain regulations (standards, test sheet) and/or agreements such as, for example, delivery conditions.

Corrosion tests mainly help in quality control during production and further treatment of materials as well as for the assessment of corrosion protection measures. The significance of the corrosion tests selected for an investigation differs. While corrosion tests under loads that are characteristic of service conditions give the best

estimation of the real corrosion behavior, tests with increased corrosion load or accelerated corrosion tests are less suitable to give a reliable prognosis of behavior in practice as the corrosion mechanism could differ from that under practical conditions. Nevertheless, accelerated corrosion tests are more suitable for determining certain material properties (e.g. resistance to intergranular corrosion or stress corrosion cracking) although they can be reliably used only if sufficient experience exists for the transfer of the test results to practical situations.

12.2 Conventional Electrochemical Test Methods

Corrosion is the degradation of materials by gaseous or liquid environments. Atmospheric corrosion involves the influence of both media on the surface of a solid, often with alternating wet and dry periods. Any kind of materials may be attacked, including metals, semiconductors and insulators as well as organic polymers. This chapter describes corrosion of metals in electrolytes and therefore some fundamentals of electrochemistry and related test methods are discussed.

Large losses are caused by corrosion in modern industrial societies. One estimate is that 4.0% of the gross national product is lost by corrosion, a third of which may be avoided if all knowledge is taken into account. Traditionally corrosion is subdivided into attack by dry and hot gases and by electrolytes. In this section corrosion in aqueous electrolytes only is described, although solutions with organic solvents may play an important role in praxis. Corrosion is a reaction at the metal/electrolyte phase boundary. Although the bulk properties of the solid and the solution may play an important role for the degradation of the materials, the properties of the metal surface and the reactions at the solid/electrolyte interface are most important. Therefore corrosion science and corrosion engineering apply the concepts of electrochemistry and electrode kinetics. In Sect. 12.2.1 a basic introduction to the equipment and experimental procedures is given. Corrosion involves electrode processes which are ruled by the electrode potential and thermodynamic and kinetic factors. For this reason the equilibria and the related thermodynamic properties of the metal/electrolyte interface and their electrode kinetics are discussed. In Sect. 12.2.3 a short introduction to electrochemical thermodynamics and equilibrium is given followed by an introduction to electrode kinetics in Sect. 12.2.5. Finally this chapter is completed by a description of the application

of electrochemical transient measurements and some electroanalytical methods.

12.2.1 Principles of Electrochemical Measurements and Definitions

Electrochemical measurements are performed in an electrochemical cell, which contains a three-electrode arrangement in its most simple form Fig. 12.3. The

Fig. 12.3 Standard electrochemical cell with working electrode (WE), counter-electrode (CE), reference electrode (RE), Haber-Luggin capillary (HL), magnetic stirring (MS), water jacket with thermostat water (TW) and nitrogen inlet

Table 12.1 Some commonly used reference electrodes and their related standard potential E^0 from [12.20]

Electrode	E^0 / V	Nernst equation
Calomel electrode: $\text{Hg}/\text{Hg}_2\text{Cl}_2/\text{Cl}^-$	0.268	$E = E^0 - 0.059 \log [\text{Cl}^-]$
Hg_2SO_4 electrode: $\text{Hg}/\text{Hg}_2\text{SO}_4/\text{SO}_4^{2-}$	0.615	$E = E^0 - 0.059 \log [\text{SO}_4^{2-}]$
HgO electrode: $\text{Hg}/\text{HgO}/\text{OH}^-$	0.926	$E = E^0 - 0.059 \log [\text{OH}^-]$
AgCl electrode: $\text{Ag}/\text{AgCl}/\text{Cl}^-$	0.222	$E = E^0 - 0.059 \log [\text{Cl}^-]$
PbSO_4 electrode: $\text{Pb}/\text{PbSO}_4/\text{SO}_4^{2-}$	-0.276	$E = E^0 - 0.029 \log [\text{SO}_4^{2-}]$

working electrode (WE) of the material under study, the counter electrode (CE) of a metal which is not attacked by the electrolyte, in most cases a platinum or gold electrode, and finally the reference electrode (RE) with an electrolytic contact to the bulk electrolyte via the Haber–Luggin (HL) capillary. Usually such an electrochemical cell contains an inlet for protective gases such as nitrogen or argon, a stirrer for the electrolyte and a water jacket to keep the electrolyte at the desired temperature using a thermostat. Numerous special designs for electrochemical cells have been applied depending on the special problem under study. In some cases small electrolyte vessels are used as e.g. for microscopic in situ investigations or in situ measurements with a scanning tunneling microscope (STM). Another approach is cells that restrict the investigated surface area to the size of droplets in the μm range. In all these cases a three-electrode set up is used with the exception of in situ STM investigations. Here two working electrodes are required, the material under study and the STM tip. The potentials of both electrodes have to be set independently and therefore a bipotentiostat is required. A similar situation with two or even more working electrodes exists for a rotating ring-disc electrode. This analytical method will be described in Sect. 12.2.11. The reference electrode is usually an electrode of the second kind. Its potential is fixed by a weakly soluble compound of the metal and an anion of the solution. Table 12.1 gives some examples of mercury and silver

electrodes [12.20]. These reference electrodes are easy to prepare and to handle and their electrode potential is very stable.

For most experiments the electrode potential is fixed by an electronic potentiostat and the current is measured. Potentiodynamic polarization curves involve a linear change of the electrode potential with time. Potentiostatic measurements keep the potential constant. Potentiostatic transients require its rapid change. With a fast potentiostat and some precautions a potential change can be achieved in a few microseconds so that fast electrode processes can be followed with a high time resolution starting in the μs range. In most cases of corrosion studies a ms resolution of the current measurement is sufficiently fast.

Figure 12.4 explains with a simple block diagram the characteristics of a potentiostat built with an operational amplifier (OA). The reference electrode, RE, is given directly to the inverting input of OA and the desired electrode potential is determined by the setting of the voltage ΔU from a power source fed into the noninverting input. The working electrode WE is set to common. The high gain of the operational amplifier (factor 10^5) ensures a negligibly small deviation of both inputs. Thus RE has a potential difference ΔE to WE equal to ΔU . The input resistance is very high ($10^7 \Omega$) so that almost no current flow occurs into the OA. Its output resistance is very low so that it may supply a sufficiently high current I_C to WE via CE and the electrolyte which may be required for the rate of the electrode processes related to the chosen potential. I_C is measured via its ohmic drop RI_C at the resistor R . This simple electronic circuit stabilizes the chosen electrode potential automatically, independent of the required current density I_C . However, a good potentiostat contains additional booster units to provide high currents and to improve the setting of potential changes with a fast response. Usually potentiostats contain additional circuits built with operational amplifiers for necessary options such as, e.g., an adder which permits the addition of various potentials forming a potential program with ramps and pulses for potentiostatic transients. A special circuit compensates

Fig. 12.4 Block diagram of potentiostat with operational amplifier (OA), potential setting ΔU , resistance R for current measurement I_C as RI_C and connections to working electrode (WE), counter-electrode (CE) and reference electrode (RE)

for ohmic drops within the electrolyte between WE and HL which may occur in the case of high-current densities and electrolytes with low conductivity.

Galvanostatic measurements require the setting of a current I_C while the change of the electrode potential ΔE is followed with time. This is achieved by a galvanostat (constant-current source) depicted as a simple block diagram in Fig. 12.5. I_C is set via a proportional voltage ΔU from a built-in power source. ΔU is given to the noninverting input of the operational amplifier OA, which is compared to the ohmic drop RI_C across the resistor R at the output. This voltage drop passes a differential amplifier (DA), which avoids the setting of a second point of the circuit to common. As both inputs of OA have to be at the same potential as a consequence of its high magnification, I_C is adjusted to the desired value $RI_C = \Delta U$. Usually galvanostats are built in to potentiostats. Appropriate voltages ΔU may be given to the input with specific time characteristics to permit also galvanodynamic measurements including galvanostatic transients controlled by appropriate voltage pulses given to OA.

12.2.2 Some Definitions

An electrochemical cell usually consists of two electrodes. Figure 12.6 gives as an example an iron electrode in a Fe^{2+} solution in contact with a hydrogen electrode via a diaphragm. The H^+/H_2 electrode consists of a platinum electrode in a solution of a given pH with the introduction of pure hydrogen. If the solution is 1 M for the H^+ concentration, i.e. if pH is 0, and the gas pressure of H_2 is 1 atm = 1.013 bar, this is the standard hydrogen electrode (SHE). Potential drops at the electrode–electrolyte interface cannot be measured separately in principle. The contact of a voltmeter to the electrolyte introduces automatically a second interface so that the measured voltage necessarily includes the potential drop of two electrodes. The potentials of any electrode is therefore given relative to the SHE. The electrode potential of the standard hydrogen electrode is thus set to 0 V by definition. Its value relative to the zero point of the potential scale in physics, i.e. the charge-free vacuum level, has been determined to -4.6 V [12.21, 22], so that both scales may be converted to each other.

There are two main kinds of electrodes, metal/metal-ion electrodes and redox electrodes. For the first case the electrode reaction requires the transfer of metal ions across the electrode–electrolyte interface. The Fe/Fe^{2+} electrode is an example. Redox electrodes involve the

Fig. 12.5 Block diagram for galvanostat with operational amplifier (OA), differential amplifier (DA), voltage supply ΔU for current setting I_C and connections to working electrode (WE), counter-electrode (CE) and reference electrode (RE)

transfer of electrons, which is the case for the hydrogen electrode. A Pt electrode within a solution of Fe^{2+} and Fe^{3+} ions or $\text{Fe}(\text{CN})_6^{4-}$ and $\text{Fe}(\text{CN})_6^{3-}$ are other examples. If no reaction occurs, the electrode is in electrochemical equilibrium, i.e. both reactions – Fe^{2+} dissolution or Fe deposition – compensate each other. The same is the case for the redox reaction.

One has to distinguish anodic and cathodic processes. An anodic process involves the transfer of positive charge from the electrode to the electrolyte, such as Fe dissolution to Fe^{2+} , or the transfer of negative charge in the opposite direction, e.g. the oxidation of Fe^{2+} to Fe^{3+} . A cathodic process involves the transfer of positive charge from the electrolyte to the electrode, such as the deposition of Fe^{2+} from the solution as Fe metal or the transfer of negative charge in the opposite direction, e.g. the reduction of Fe^{3+} to Fe^{2+} . The currents of anodic processes get a positive sign, those

Fig. 12.6 Electrochemical cell with an Fe/Fe^{2+} and H_2/H^+ electrode

for cathodic reactions a negative sign. In conclusion, it is the kind of process which determines whether an electrode acts as an anode or a cathode. Depending on the applied electrode potential and further electrochemical conditions an electrode may be either an anode or a cathode.

If anodic and cathodic currents of a redox or a metal/metal-ion electrode compensate each other the electrochemical equilibrium is established at the equilibrium potential E_0 . A positive deviation $\eta = E - E_0$ leads to an anodic current. η is called the overvoltage. A deviation in the negative direction with a negative overvoltage $\eta = E - E_0 < 0$ causes a cathodic reaction. If two *different* electrode processes compensate each other, such as an anodic Fe dissolution and cathodic hydrogen evolution with vanishing current in the external circuit, the electrode is at its rest potential E_R . A positive deviation $\pi = E - E_R > 0$ is called a positive polarization and $\pi = E - E_R < 0$ a negative polarization.

12.2.3 Electrochemical Thermodynamics

The equilibrium potential E_0 is related to the change of the Gibbs free energy for standard conditions ΔG_0 of the related electrode process, i. e. for activities of solutes of $a = 1$ M and gas pressures of $p = 1.013$ bar. As all electrode potentials are referred to the standard hydrogen electrode its reaction has been chosen as a compensating process for thermodynamic calculations. Equations (12.1, 12.2) describe the process of an electrochemical cell with the Fe/Fe²⁺ and the H₂/H⁺ electrode; (12.3) describes their combination. ΔG_0 for the electrode process of interest has to be calculated for the cathodic direction and the compensating process of the reference electrode in the anodic direction to avoid mistakes in the sign (12.4). The relation between ΔG_0 and the electrode potential is given by (12.5). The concentration dependence of the equilibrium potential E_0 is given by the Nernst equation (12.6, 12.7) for both electrodes. Equation (12.7) describes the pH dependence of the hydrogen electrode:

$$\Delta G_{298}^0 = \sum_i \nu_i G_{i,i}^0 = -G_{\text{Fe}^{2+}}^0 = 78.9 \text{ kJmol}^{-1}, \quad (12.4)$$

$$\Delta G_{298}^0 = -nFE_0, \quad (12.5)$$

$$E^0 = -\frac{\Delta G_{298}^0}{2F} = -\frac{78.94 \times 10^3}{2F} = -0.409 \text{ V}, \quad (12.6)$$

$$E_0 = E^0 + \frac{RT}{nF} \ln a(\text{Fe}^{2+}) = -0.409 + \frac{0.059}{2} \lg a(\text{Fe}^{2+})/\text{V}, \quad (12.7)$$

$$E_0 = 0 + \frac{RT}{2F} \ln \left(\frac{a(\text{H}^+)^2}{p(\text{H}_2)} \right) = -0.059 \text{ pH}/\text{V}, \quad (12.8)$$

$$\text{with } \text{pH} = -\lg [a(\text{H}^+)]. \quad (12.9)$$

Electrode reactions that involve solid compounds are treated in a similar way. As an example the equilibrium of Fe with Fe₃O₄ is given in (12.10–12.13). This equilibrium describes the electrochemical formation of an oxide layer at the metal surface. These equilibria are important for the calculation of potential–pH diagrams, so called Pourbaix diagrams, which will be discussed in the next section.

$$\Delta G_{298}^0 = 1013.23 - 4(237.13) = 64.71 \text{ kJ/mol}, \quad (12.11)$$

$$E^0 = -\frac{64.71 \times 10^3}{8F} = -0.084 \text{ V}, \quad (12.12)$$

$$E_0 = -0.084 + \frac{0.059}{8} \lg [a(\text{H}^+)^8] = -0.084 - 0.059 \text{ pH}/\text{V}. \quad (12.13)$$

Thermodynamic data and especially standard Gibbs free energies ΔG_f^0 for the formation of compounds from the elements are listed in special publications for $T = 298$ K, but also for other temperatures [12.23, 24]. They permit the calculate of data for electrochemical equilibria as shown for (12.1–12.13). For most equilibria the standard electrode potentials E^0 are listed. Their dependence on the concentrations of the reacting species, i. e. their Nernst equations, are used to calculate potential–pH diagrams [12.25]. Figure 12.7 shows the diagram for iron, which is a very important example in corrosion. The horizontal line (1) at $E = -0.589$ V describes the pH-independent Fe/Fe²⁺ equilibrium with a 10^{−6} M, i. e. a negligibly small concentration of Fe²⁺. At $E = 0.771$ V the Fe²⁺/Fe³⁺ equilibrium is given as a further horizontal line (2). Line (3) depicts the pH-dependent formation of Fe₃O₄ according to (12.10–12.13). Line (4) corresponds to the Fe₃O₄/Fe₂O₃ equilibrium. Lines (5) and (6) refer to

Fig. 12.7 Potential–pH diagram of Fe with equilibria (1–7) and (a) and (b) and domains of corrosion, immunity and passivation, as described in the text, Flade potential describing passivation in acidic electrolytes

the oxidation of soluble Fe^{2+} to Fe_3O_4 and Fe_2O_3 respectively. The vertical line (7) describes the potential-independent dissolution equilibrium of $\text{Fe}_2\text{O}_3/\text{Fe}^{3+}$ that is related to a specific pH. According to this diagram one has to distinguish three main fields. Corrosion, i. e. metal dissolution, should occur where soluble products are stable, i. e. at the upper left end of the diagram Fig. 12.7. At the lower end of the diagram one has the field of immunity where Fe is the stable species. In the upper right part the surface should be protected by anodic oxide layers. Here thin anodic films should form at the metal surface, which block further oxidation and lead to passivity. The lines (a) and (b) describe the equilibrium potential of the hydrogen and oxygen electrode, which are important redox systems for aqueous corrosion. These diagrams have been calculated at 298 K for all elements, metals, semiconductors and elements with insulating properties [12.26, 27]. More recently they have also been calculated for elevated temperatures. They provide an excellent possibility to get a first

idea of the corrosion properties of a metal. However, one should always keep in mind that they are calculated on the basis of thermodynamic data only. Any kinetic properties are not included. This means that conclusions on the basis of these diagrams may be misleading. Pourbaix diagrams tell us whether a reaction may occur or not. Whether the predictions really happen or not depends on the kinetic parameters of the related reactions. A typical exception is the passive behavior of iron in strongly acidic electrolytes such as 0.5 M H_2SO_4 or 1 M HClO_4 . Iron should dissolve at potentials above $E = -0.409$ V. However, passivation occurs when the potential gets above $E = 0.58 - 0.059 \text{ pH[V]}$. This condition is depicted as a dashed line in Fig. 12.7. Surface analytical investigations have shown that Fe forms a poreless few-nm-thick layer of Fe_2O_3 a spinell-type oxide which is very slowly dissolving in these acidic electrolytes. Detailed electrochemical studies come to the conclusion that the transfer of Fe^{3+} cations from the oxide surface to the electrolyte is an extremely slow process, although the oxide layer is far from its dissolution equilibrium. As a consequence this surface film passivates the metal underneath. It has been shown that the passivation potential may be explained by the thermodynamic data for the anodic oxidation of Fe_3O_4 to Fe_2O_3 [12.28] Apparently the structure and the electrochemical properties of Fe_2O_3 provide sufficient stability for dissolution, i. e. the activation energy to transfer Fe^{3+} ions from the potential well of the O^{2-} matrix of an oxide is very high. Similar arguments hold for passive layers on Cr. Here a Cr_2O_3 film of only 1–2 nm thickness dissolves in acidic solutions so extremely slowly that Cr is protected very effectively against corrosion in strongly acidic electrolytes [12.29–31]. This is also the case for Cr-containing alloys, such as Ni/Cr or Fe/Cr. The strong bonds between Cr^{3+} ions and its ligands in its complexes are well known from inorganic chemistry. The exchange of ligands is so slow that many of these Cr^{3+} compounds are almost insoluble, although this description is misleading; they dissolve extremely slowly, which has the same effect. As an example the extremely slow dissolution of CrCl_3 should be mentioned, which leads to its description as an insoluble compound. However, this behavior is only caused by an extremely slow dissolution rate [12.31]. This becomes faster at elevated temperatures when the related high activation energy for the exchange of ligands has been overcome.

In conclusion the Pourbaix diagrams provide excellent initial information on the corrosion behavior of metals on the basis of thermodynamic data. However, a reliable discussion has to include kinetic parameters

12.2.4 Complex Formation

The formation of strong complexes of dissolved cations with anions has an important influence on the dissolution of metals; they shift the concentration of free cations to very small values and thereby shift the equilibrium potential of the related metal/metal-ion electrode to very negative values [12.20,32,33] (Fig. 12.8). A well-known effect is the strong complexation of Au^{3+} by Cl^- or of Au^+ by CN^- as depicted in (12.14, 12.15). The standard potential of Au dissolution is shifted by Cl^- from 1.42 V to 0.994 V or by CN^- from 1.68 V to -0.60 V, which is a consequence of the small value of the dissociation constant $K_D = 2.2 \times 10^{-22}$ of the AuCl_4^- and $K_D = 2.3 \times 10^{-39}$ for the Au(CN)_2^- complex. Therefore Au dissolution occurs in a 1:3 mixture of HCl and HNO_3 (aqua regia) whereas pure HNO_3 does not attack. Similarly Au may be dissolved in CN^- -containing solution by air oxidation (Fig. 12.8). The latter example is shown by (12.16, 12.17) in detail, and has been applied for extraction of Au from minerals.

$$a(\text{Au}^+) = K_D \frac{a(\text{Au(CN)}_2^-)}{a^2(\text{CN}^-)} ,$$

(12.16)

$$E = E_{\text{Au}}^0 + \frac{RT}{F} \ln a(\text{Au}^+) \\ = 1.68 + 0.059 \log K_D \\ + 0.059 \log \frac{a[\text{Au(CN)}_2^-]}{a^2(\text{CN}^-)} ,$$

(12.17)

$$E_{\text{AuCN}}^0 = 1.68 - 0.059 \log 2.3 \times 10^{-39} \\ = 1.68 - 2.28 = -0.60 \text{ V} .$$

(12.17a)

Complexation of cations also plays a role in the enhanced dissolution of passivating layers. The formation of complexes of cations with halides has been proposed as a mechanism for the breakdown of passivity and localized corrosion [12.29–31].

12.2.5 Electrochemical Kinetics

The kinetics of electrode processes influence decisively corrosion phenomena. As usual in kinetics the rate of a chemical reaction at the electrode surface is ruled by the activation energy of the slowest of a sequence of elementary reaction steps. This could be the charge-transfer process or any preceding or following reaction step. Any electrode process requires the transport of the reacting species to the electrode surface, a possible chemical reaction within the solution in front of the electrode, the charge-transfer process, a possible following chemical reaction and finally the transport of the product from the electrode to the bulk electrolyte. In addition adsorption and desorption processes may be involved. Any of those steps may be the slowest and thus may be rate-determining for the overall reaction. Figure 12.9 describes the sequence of elementary reaction steps, including the charge-transfer reaction, that together form the overall reaction. Each of these steps may contribute with its special overvoltage η_i to the total overvoltage $\eta = \sum \eta_i$ of the whole reaction (Fig. 12.9). Usually one reaction step is the slowest and thus rate-determining for the overall reaction. Its overvoltage η_i dominates η .

12.2.6 The Charge-Transfer Overvoltage

If the charge transfer is rate-determining the related current density follows an exponential relationship, the Butler–Volmer equation. As mentioned earlier an ion or

an electron may be the transferred species. This process occurs within the Helmholtz layer, i. e. within a distance of the radius of solvated ions of typically less than 1 nm. The charge transfer of (12.18) occurs via a tunneling process that is seriously influenced by the potential drop $\Delta\phi = \phi_M - \phi_S$ within this layer. Combining the usual rate equation with Faraday's law one obtains a redox process (12.19) which includes the two opposite parts due to the anodic and the cathodic reactions. At the equilibrium potential these are equal and compensate each other. F is the Faraday constant and n is the number of charges transferred for this reaction, which is usually 1 and may be larger if several one-electron processes occur in a sequence, k_+ and k_- are the rate constants for the anodic and cathodic reaction steps and $c(\text{Red})$ and $c(\text{Ox})$ are the concentrations of the oxidized and reduced species of the redox system involved. For metal dissolution equivalent (12.20, 12.21) hold where Θ_{Me} is the surface coverage for metal atoms which is proportional to their surface concentration, and $c(\text{Me}^{z+})$ is the concentration of the cations within the electrolyte. One has to distinguish in general between the charges n which are involved in the total electrode reaction of (12.18, 12.20), and the charge z of the species which is transferred across the electrode–electrolyte interface during the charge-transfer process. In the case of a simple metal dissolution, according to (12.20) n equals z . If the dissolving cation forms a complex with anions from the solution in a reaction before the charge-transfer step these number may be quite different. For a redox reaction z equals 1. If however, more than one electron is transferred in a fast sequence of several steps, i. e. in the case of a charge-transfer reaction with more electrons n will be larger:

$$i = nF \left(\frac{-dc(\text{Red})}{dt} - \frac{-dc(\text{Ox})}{dt} \right) \\ = nF [k_+c(\text{Red}) - k_-c(\text{Ox})], \quad (12.19)$$

$$i = nFk_+\Theta_{\text{Me}} - nFk_-c(\text{Me}^{z+}). \quad (12.21)$$

The rate equations of both types of charge-transfer processes may contain the concentration of additional species that are involved in their mechanisms. An example is the catalysis of active Fe dissolution by OH^- ions. The exponent of the concentrations of OH^- , i. e. its electrochemical reaction order, is 1.5 [12.34]. Reaction orders may be any number for a given reaction depending on the details of its mechanism.

Fig. 12.10 Activation energy $\Delta E_{0,A}$ and its change to ΔE_A for the anodic (+) and cathodic reaction (−) due to the potential drop $\Delta\phi$ across the electrode–electrolyte interface

As usual, both rate constants k_+ and k_- depend exponentially on their activation energy $\Delta E_{0,A+}$ and $\Delta E_{0,A-}$ (12.22, 12.23). According to Fig. 12.10 the activation energies $\Delta E_{A,+}$ and $\Delta E_{A,-}$ for the transfer of charged species across the electrode–electrolyte interface are influenced by the potential drop $\Delta\phi$. However, only a fraction of $\Delta\phi$ will modify $\Delta E_{0,A+}$. The part α takes into account the fraction of $\Delta\phi$ which is kinetically effective, i. e. which part will act on the species up to the maximum of the energy–distance curve; α usually has a value of 0.2–0.8. If α refers to the anodic process $1 - \alpha$ will hold for the cathodic reaction. Thus the activation energy $\Delta E_{A,+}$ will change by $-\alpha z F \Delta\phi$ for the anodic and $\Delta E_{A,-}$ by $+(1 - \alpha) z F \Delta\phi$ for the cathodic process, respectively; z is the charge of the species which is transferred across the double layer, where $z = 1$ for electrons, i. e. for charge-transfer processes, and z may be larger for metal ions, e.g. $z = 2$ for Fe^{2+} . Equations (12.22, 12.23) describe the influence of $\Delta\phi$ on the rate constants of both processes and (12.24) gives the full kinetic equation for a redox reaction. An equivalent equation is obtained for a metal/metal-ion electrode. The unknown potential drop $\Delta\phi$ within the double layer is replaced by the electrode potential E and the drop $\Delta\phi_H$ within the double layer of the SHE ($\Delta\phi = E - \Delta\phi_H$). As $\Delta\phi_H$ is constant, any changes of $\Delta\phi$ will equal that of the

electrode potential E :

$$\begin{aligned}
 k_+ &= k_{0+} \exp \frac{-(E_{0,A+} - \alpha z F \Delta \phi)}{RT} \\
 &= k'_{0+} \exp \frac{\alpha z F \Delta \phi}{RT} \\
 &= k'_{0+} \exp \frac{-\alpha z F \Delta \phi_H}{RT} \exp \frac{\alpha z F E}{RT}, \quad (12.22) \\
 k_- &= k_{0-} \exp \frac{-[E_{0,A-} + (1-\alpha)z F \Delta \phi]}{RT} \\
 &= k'_{0-} \exp \frac{-(1-\alpha)z F \Delta \phi}{RT} \\
 &= k'_{0-} \exp \frac{-(1-\alpha)z F \Delta \phi_H}{RT} \exp \frac{-(1-\alpha)z F E}{RT}. \quad (12.23)
 \end{aligned}$$

The introduction of (12.22, 12.23) into (12.19) yields (12.24). For the conditions of electrochemical equilibrium, i.e. for $E = E_0$ and $i = 0$, one obtains the expression for the exchange current density i_0 of (12.25). Introducing the overpotential $\eta = E - E_0$ and (12.25) for i_0 in (12.24) one obtains the Butler–Volmer equation (12.26):

$$\begin{aligned}
 i &= n F k'_{0+} c(\text{Red}) \exp \left(\frac{\alpha z F (E + \Delta \phi_H)}{RT} \right) \\
 &\quad - n F k'_{0-} c(\text{Ox}) \exp \left(-\frac{(1-\alpha)z F (E + \Delta \phi_H)}{RT} \right) \quad (12.24)
 \end{aligned}$$

for $E = E_0, i = 0$,

$$\begin{aligned}
 i_0 &= n F k'_{0+} c(\text{Red}) \exp \left(\frac{\alpha z F (E_0 + \Delta \phi_H)}{RT} \right) \\
 i_0 &= n F k'_{0-} c(\text{Ox}) \exp \left(-\frac{(1-\alpha)z F (E_0 + \Delta \phi_H)}{RT} \right), \quad (12.25)
 \end{aligned}$$

$$\begin{aligned}
 i &= i_+ + i_- = i_0 \left[\exp \left(\frac{\alpha z F \eta}{RT} \right) \right. \\
 &\quad \left. - \exp \left(\frac{-(1-\alpha)z F \eta}{RT} \right) \right]. \quad (12.26)
 \end{aligned}$$

For large positive overpotentials $\eta \gg RT/F$ the cathodic current density may be neglected and for large negative overpotentials with $\eta \ll RT/F$ the anodic current density is vanishingly small. Taking the logarithm of (12.26) one obtains the η -log i equations, (12.27) and (12.28), for both cases. The appropriate semi-logarithmic presentation yields the so-called Tafel

plot

$$\eta = -\frac{RT}{\alpha z F} \ln i_0 - \frac{RT}{\alpha z F} \ln i_+ = a + b \log i_+, \quad (12.27)$$

$$\begin{aligned}
 \eta &= \frac{RT}{(1-\alpha)z F} \ln i_0 - \frac{RT}{(1-\alpha)z F} \ln |i_-| \\
 &= a + b \log |i_-|. \quad (12.28)
 \end{aligned}$$

Figure 12.11 gives an example of a dimensionless $\log |i|/i_0 - \eta$ presentation for different charge-transfer coefficients α with an anodic and a cathodic branch. For $\alpha = 0.5$ both branches are symmetrical to each other and for $\alpha \neq 0.5$ they are asymmetric. The measured current densities i deviate from the Tafel lines for $\eta \leq 0.1$ V and $\eta \geq -0.1$ V due to the influence of the corresponding counter-reaction. Extrapolation of the Tafel lines meet at the equilibrium potentials with $\eta = 0$, $i = i_0$ and $\log |i|/i_0 = 0$. The constants a and b of a Tafel plot are important kinetic parameters for an electrode process. The b factor contains the value of α and constant a the exchange current density i_0 . According to (12.22–12.25) i_0 depends on the activation energy and the electrochemical reaction order for those species that influence the rate law. The same equations (12.22–12.28) hold for redox reactions as well as for anodic metal dissolution and cathodic metal deposition, when the concentrations of the cations are introduced. The evaluation of the kinetics of a redox process or metal dissolution requires Tafel plots, which then yield data from the slope and the intersection with the ordinate.

An alternative approach requires the determination of the slope of the polarization curve at $E = E_0$ only. For small overpotentials the development of the i - η relation (12.26) in a MacLaurin series with only the linear terms for η yields (12.29). Its reverse slope for $\eta \rightarrow 0$ V yields the charge-transfer resistance R_T of (12.30). According to this equation only the reciprocal slope of the polarization curve has to be determined for $\eta \rightarrow 0$ to get the exchange current density i_0 . Thus the determination of the total polarization curve is not required. A similar situation holds for the rest potential E_R when two different reactions compensate each other, as will be shown in the following section (12.36, 12.37):

$$i = i_0 \left(1 + \frac{\alpha z F \eta}{RT} - \frac{[(1-\alpha)z F \eta]}{RT} \right) = \frac{i_0 z F \eta}{RT}, \quad (12.29)$$

$$R_T = \left(\frac{d\eta}{di} \right)_{\eta \rightarrow 0} = \frac{RT}{z F i_0}. \quad (12.30)$$

12.2.7 Elementary Reaction Steps in Sequence, the Hydrogen Evolution Reaction

Electrochemical processes often consist of a sequence of elementary reaction steps. This situation is treated similarly to the general rules of chemical kinetics. The slowest step in a sequence determines the total rate. Any preceding process is submitted to stationary conditions or chemical equilibrium may even be established. Any fast following step does not affect the rate of the overall process. In this section the possible mechanisms of cathodic hydrogen evolution and its influence on the rate equation and cathodic current density are described. This relatively complicated electrochemical process is presented as an example for the treatment of a sequence of elementary reaction steps. Furthermore it is a very important reaction for corrosion processes.

Two possible reaction paths are discussed, the Volmer–Tafel and the Volmer–Heyrovski mechanism. In both cases the process starts with the oxidation of hydrogen ions to atoms H_{ad} adsorbed at the electrode surface according to the Volmer reaction of (12.31). The

following Tafel reaction (12.32a) involves the combination of two H_{ad} to $H_{2,ad}$, which is then finally transferred to the electrolyte by desorption and diffusion to the bulk electrolyte. At high negative overvoltages hydrogen formation is fast enough to form gas bubbles. An alternative is the Heyrovski reaction (12.32b), a second charge-transfer step which involves the reduction of a hydrogen ion in the vicinity of H_{ad} to form $H_{2,ad}$ that then again desorbs and diffuses to the bulk.

With the Volmer reaction as a rate-determining step one obtains for the cathodic current density of hydrogen evolution i_H the Butler–Volmer equation as described by (12.26). For sufficiently large cathodic overvoltages i_H is described by (12.28). A Tafel plot of (12.28) yields, with $z = 1$ and $\alpha = 0.5$, a slope $b = \frac{d\eta}{d \log |i_H|} = \frac{RT2.303}{(1-\alpha)F} = \frac{0.059}{0.5} = -0.120 \text{ V}$. Figure 12.12 presents the Tafel plot for cathodic hydrogen evolution at various metals [12.35]. From the slope $1/b$ of this $\log |i_H| - \eta$ presentation one obtains for most metals a factor $b = -0.12 \text{ V}$. The Tafel lines for the metals are shifted relative to each other, which proves the strong influence of the kind and surface condition of the electrode materials on the electrode kinetics. The parallel shift of these lines is caused by the specific values of the exchange current density $i_{H,0}$ for the different metals, i. e. of the constant a of (12.28). Pt is a metal with a small overvoltage whereas Pb and Hg have large overvoltages. The very fast kinetics on Pt are very useful for water electrolysis to produce hydrogen as fuel with optimized energy input. On the contrary Pb and Hg electrodes are well suited to the suppression of hydrogen evolution when other cathodic reactions are of interest, such as the reduction of organic compounds or electrolysis of NaCl or KCl solutions, which yield Cl_2 gas at the anode and K or Na amalgam at the cathode. Hg electrodes are also well suited for polarography. Here again the large overvoltage suppresses hydrogen evolution and permits the analysis of cations of very reactive metals such as Zn^{2+} and Cd^{2+} by their cathodic reduction.

If the Heyrovski reaction of (12.32b) is the rate-determining step it will lead to the kinetic equation (12.34). Here Θ_H is the surface coverage of hydrogen atoms which is proportional to their surface concentration. Assuming electrochemical equilibrium for the preceding

Fig. 12.11 Tafel plot for a charge-transfer-controlled reaction and its dependence on the charge-transfer coefficient α (after [12.35])

Fig. 12.12 Tafel plot of cathodic hydrogen evolution for different electrode metals (after [12.35])

Volmer reaction one obtains from the related Nernst equation (12.35) which allows the replacement of Θ_H with (12.36) in (12.34). Equation (12.37) then contains $c^2(H^+)$, i. e. the electrochemical reaction order of H^+ is 2. It also contains a modified exponential term. Replacing $E = E^0 + \eta$ one obtains the related Tafel (12.38) which yields with $\alpha = 0.5$ a slope $b = 0.40$

$$i_H = -k_- \Theta_{Hc} (H^+) \exp \left(-\frac{(1-\alpha) F}{RT} E \right), \quad (12.34)$$

$$E = \text{const}' + \frac{RT}{F} \ln \frac{c(H^+)}{\Theta_H}, \quad (12.35)$$

$$\Theta_H = \text{constc} (H^+) \exp \left(-\frac{F}{RT} E \right), \quad (12.36)$$

$$\begin{aligned} i_H &= -k_- c^2 (H^+) \exp \left(-\frac{(2-\alpha) F}{RT} E \right) \\ &= -k_- c^2 (H^+) \exp \left[-\frac{(2-\alpha) F}{RT} (E^0 + \eta) \right], \end{aligned} \quad (12.37)$$

$$\begin{aligned} \eta &= \frac{RT2.303}{(2-\alpha) F} \log |i_{0,H}| - \frac{RT2.303}{(2-\alpha) F} \log |i_H| \\ &= a + b \log |i_H|. \end{aligned} \quad (12.38)$$

If the Tafel reaction (12.32a) is the rate-determining step one starts with (12.39) and (12.40) for i_H and Θ_H and $i_{0,H}$ and $\Theta_{H,eq}$ respectively. Assuming electrochemical equilibrium for the Volmer reaction (12.31) yields the Nernst equation for this charge-transfer step and consequently (12.41a) for the electrode potential E and for the over-voltage η . η is thus a consequence of the varying surface coverage Θ_H with i_H . For this discussion diffusion control of H^+ ions from the bulk to the electrode surface is excluded and therefore the same concentration $c(H^+)$ is present within the bulk and at the electrode–electrolyte interface. In consequence the Tafel plot according to (12.40) yields a slope $d\eta/d \log i_H = b = -0.29$ V if the Tafel reaction is the rate-determining step

$$|i_H| = kF\Theta_H^2, \quad \Theta_H = \sqrt{\frac{|i_H|}{kF}}, \quad (12.39)$$

$$|i_{H,0}| = kF\Theta_{H,eq}^2, \quad \Theta_{H,eq} = \sqrt{\frac{|i_{H,0}|}{kF}}, \quad (12.40)$$

$$E - E_0 = \eta = \frac{RT}{F} \ln \frac{\Theta_{H,eq}}{\Theta_H} = \frac{RT}{F} \ln \sqrt{\frac{|i_{H,0}|}{|i_H|}}; \quad (12.41a)$$

$$\begin{aligned} \eta &= \frac{0.059}{2} \log |i_{H,0}| - \frac{0.059}{2} \log |i_H| \\ &= a + b \log i_H. \end{aligned} \quad (12.41b)$$

12.2.8 Two Different Reactions at one Electrode Surface

The corrosion rate may be ruled by metal dissolution or by a compensating cathodic reaction of a redox system. Metal dissolution by hydrogen evolution or oxygen reduction are important examples. In acidic electrolytes hydrogen evolution is the favored counter-reaction for dissolution of reactive metals such as iron and will be discussed as an example. The equilibrium potential of the hydrogen electrode $E_0 = -0.059 \text{ pH}$ is much more positive than the standard potential $E^0 = -0.409$ V for the Fe/Fe^{2+} electrode, which is a necessary requirement for an efficient metal dissolution. However in addition the kinetics of both processes determine the shape of their polarization curves and thus have a strong influence on the overall process. Figure 12.13 presents schematically the anodic and cathodic reactions of both electrodes in the vicinity of their equilibrium potentials $E_0(\text{Me}/\text{Me}^{z+})$ and $E_0(\text{H}_2/\text{H}^+)$. The rest potential E_R is found between both values where anodic metal dissolution and cathodic hydrogen evolution compensate each other. E_R is sufficiently distant from both equilib-

Fig. 12.13 Schematic diagram of metal dissolution and hydrogen evolution as cathodic counter-reaction with rest potential E_R

rium potentials so that only Fe dissolution and hydrogen evolution have to be taken into account. For a positive polarization $\pi = E - E_R > 0$ metal dissolution exceeds hydrogen evolution with a total anodic current i and for the opposite case hydrogen evolution is larger with a total cathodic current i . Both partial reactions may be described by a Butler–Volmer equation and their sum leads to a similar expression (12.42) as discussed before when opposite partial reactions of the same electrode process compensate each other as described by (12.26). For a vanishing total current density i , i. e. for $\pi = 0$, one obtains (12.43) for the corrosion current density i_C . Its application to (12.42) yields (12.44) which has a similar form as (12.26)

$$\begin{aligned} i &= i_{\text{Me}} + i_{\text{H}} = i_{0,\text{Me}} \exp\left(\frac{\alpha_{\text{Me}} z_{\text{Me}} F (E - E_{0,\text{Me}})}{RT}\right) \\ &\quad - i_{0,\text{H}} \exp\left(-\frac{(1 - \alpha_{\text{H}}) F (E - E_{0,\text{H}})}{RT}\right), \end{aligned} \quad (12.42)$$

$$\begin{aligned} i_C &= i_{0,\text{Me}} \exp\left(\frac{\alpha_{\text{Me}} z_{\text{Me}} F (E_R - E_{0,\text{Me}})}{RT}\right) \\ &= i_{0,\text{H}} \exp\left[-\frac{(1 - \alpha_{\text{H}}) F (E_R - E_{0,\text{H}})}{RT}\right], \end{aligned} \quad (12.43)$$

$$\begin{aligned} i &= i_C \left[\exp\left(\frac{\alpha_{\text{Me}} z_{\text{Me}} F \pi}{RT}\right) \right. \\ &\quad \left. - \exp\left(-\frac{(1 - \alpha_{\text{H}}) F \pi}{RT}\right) \right]. \end{aligned} \quad (12.44)$$

Fig. 12.14 Tafel plot for Fe^{2+} dissolution and hydrogen evolution of an Fe electrode in solutions of $\text{H}_2\text{SO}_4/\text{Na}_2\text{SO}_4$ mixtures: 0.482 M/1 M pH 4.0, 0.00482 M / 1 M, pH 2.95, 0.0965 M / 0.9 M, pH 1.63, 0.75 M / 0.75 M, pH 0.40, 2 M / 0, pH -0.23, 5 M / 0 M, pH -0.90 (after [12.36])

For large polarizations i. e. $\pi \gg RT/\alpha_{\text{Me}}z_{\text{Me}}F$ or $\pi \ll RT/(1 - \alpha_{\text{H}})F$ the anodic or cathodic current density dominates the overall process, so that i equals the first or second term of (12.44), respectively. These conditions yield (12.45) and (12.46), which describe Tafel plots for metal dissolution and hydrogen evolution. The extrapolation of the lines intersect at $\pi = 0$ and $E = E_{\text{R}}$ with $i = i_{\text{C}}$. An example for iron dissolution and hydrogen evolution is presented in Fig. 12.14 as a function of pH [12.36]. With increasing pH the Tafel lines of hydrogen evolution are shifted to negative potentials. This is a consequence of the -0.059pH dependence of the equilibrium potential of the H^+/H_2 electrode, but also of the decrease of the kinetics of H_2 evolution. At pH 4.0 and 3.0 the start of diffusion control may be seen by the deviation of the current density from the Tafel line for large cathodic overvoltages. In addition Fe dissolution is pH-dependent; its Tafel lines shift to more negative potentials with increasing pH. This is a consequence of the aforementioned OH catalysis of iron dissolution [12.34]. Iron dissolution occurs with a dissolution current density $\log i \propto 1.5 \log c(\text{O}^-)$. Thus the electrochemical reaction order for OH^- ions is 1.5, i. e. $\log i$ increases by 1.5 or

ders when the pH increases by one unit. Both effects lead to the observed negative shift of E_{R} with increasing pH but they compensate each other partially with an only moderate decrease of the corrosion current density i_{C} at the rest potential. i_{C} may be determined by the evaluation of the Tafel lines but also by a direct measurement of metal dissolution. The related data may be obtained by analysis of the concentration of metal ions within the electrolyte but also by the weight loss of metal specimens. These independent data should match each other

$$\log i = \log i_{\text{C}} + \frac{\alpha_{\text{Me}}z_{\text{Me}}F}{RT}\pi \quad \text{for } \pi > 0, \quad (12.45)$$

$$\log i = \log i_{\text{C}} - \frac{(1 - \alpha_{\text{H}})F}{RT}\pi \quad \text{for } \pi < 0. \quad (12.46)$$

A third possibility uses the inverse polarization resistance $1/R_{\text{p}} = (di/d\pi)_{\pi \rightarrow 0}$ similar to the discussion of the charge-transfer resistance of (12.30). The development of (12.44) by a MacLaurin series for $\pi \rightarrow 0$ yields (12.47) and (12.48) which may serve to determine the missing kinetic parameters α_{Me} and α_{H} . With known charge-transfer coefficients α_{Me} one may determine i_{C} . Similar relations hold with z_{Red} as a factor of the second term of (12.47) for the case of other redox systems such as the reduction of dissolved oxygen or Fe^{3+} ions taking over the counter-reaction for metal dissolution:

$$i = i_{\text{C}} \left(\frac{\alpha_{\text{Me}}z_{\text{Me}}F\pi}{RT} + \frac{(1 - \alpha_{\text{H}})F\pi}{RT} \right), \quad (12.47)$$

$$\left(\frac{di}{d\pi} \right)_{\pi \rightarrow 0} = \frac{i_{\text{C}}F}{RT} [\alpha_{\text{Me}}z_{\text{Me}} + (1 - \alpha_{\text{H}})]. \quad (12.48)$$

Hydrogen evolution by water decomposition is an important cathodic process for neutral and alkaline solutions. In these cases the concentration of H^+ ions is too small to contribute to the cathodic reduction. Hydrogen evolution by water reduction has a large overpotential and thus relatively negative potentials are required to start this reaction. The cathodic polarization curves for different pH merge at very negative potentials all in one line because it is not the H^+ but the high and pH-independent water concentration that enters the rate equation for these conditions. Figure 12.15 compares the hydrogen evolution on Fe in HCl solution with 4% NaCl [12.37, 38]. In acidic electrolytes a linear part for $\log i/E$ is found, corresponding to charge-transfer control of H^+ reduction. The deviation in the vicinity of E_{R} is caused by compensating Fe dissolution. At large cathodic polarization the current density enters a plateau

Fig. 12.15 Hydrogen evolution on Fe in HCl + 4% with pH as indicated (after [12.37, 38])

which is caused by diffusion control. Its value is proportional to $c(\text{H}^+)$. This situation with dominating diffusion overvoltage will be discussed in Sect. 12.2.11. Finally all cathodic current densities merge in one line corresponding to hydrogen evolution by water decomposition. No limiting current is achieved for very high cathodic overvoltages due to the high water concentration as reacting species of 55.56 M. For $\text{pH} > 4$ no hydrogen evolution by H^+ reduction is possible due to its very small bulk concentration and the plateau of a diffusion-limited process of H^+ reduction is missing.

12.2.9 Local elements

The above discussion assumes a homogeneous electrode with the same reactivity all over the surface. If an electrode is composed of physically or chemically different areas A and B with varying electrochemical activity their cathodic and anodic reaction rates and related current densities i_A and i_B will follow the same behavior as described above. i_A and i_B are the polarization curves that could be measured for the pure surfaces A and B. They differ from each other in shape and position on the potential scale and thus have different rest potentials $E_{R,A}$ and $E_{R,B}$. The combination of A and B in one surface causes a potential shift of A and B to a new value $E_{R,AB}$ in between both. At $E_{R,AB}$ the

anodic current i_A on A and a cathodic current i_B on B will compensate each other. As a consequence a net current $|i_A(E_{R,AB})| = |i_B(E_{R,AB})|$ will flow from A to B within the electrolyte and thus will lead to local elements at the metal surface. If the electrolyte in front of the electrode is sufficiently conductive and does not allow an ohmic drop, A and B will assume the same electrode potential Fig. 12.16. In the example of Fig. 12.16, A will be dissolved at a higher rate than B and the reduction of hydrogen will occur at a higher rate on B. Therefore the A sites are the local anodes and the B sites are the local cathodes. The application of a polarization $\pi = E - E_{R,AB}$ via an external supply, such as a potentiostat, allows the determination of the polarization curve. One measures the current density $i = i_A + i_B$ as a function of the polarization π of a metal surface with local anodes A and cathodes B. Low conductivity of the electrolyte may cause a potential drop in front of the electrode between sites A and B due to the local current densities between both. This situation will be discussed in Sects. 12.2.12 and 12.2.13.

These local elements frequently lead to a pronounced increase of the corrosion rate. A well-known example is the increase of Zn dissolution by small deposits of copper at its surface for open-circuit conditions. Hy-

Fig. 12.16 Polarization curve of a metal surface with sites A and B with different electrochemical properties. Rest potentials $E_{R,A}$ and $E_{R,B}$ of pure sites and $E_{R,AB}$ of mixed electrode. Polarization π for the sites A and B and mixed surface AB. i_A , i_B are current densities of sites A and B which compensate each other at $E_{R,AB}$. Inset shows local elements with current flow from A to B at rest potentials $E_{R,AB}$

Fig. 12.17 Concentration profile in front of an electrode with Nernst diffusion layer of thickness δ , maximum current density i_D for $c = 0$

drogen evolution on the Cu deposits occurs at much higher rates, thus promoting zinc dissolution. The common rest potential is positive when compared to that of pure zinc. These local elements often cause serious corrosion damage. Another well-known example is the corrosion of Cu-containing commercial aluminium. Cu inclusions prevent the total protection of the Al surface by a passivating Al_2O_3 film. Cu acts as a local cathode, which compensates the dissolution of Al by local oxygen reduction. Well-passivated Al does not permit the reduction of redox systems such as oxygen due to the isolating electronic properties of the pure protecting Al_2O_3 film. For similar reasons one should not combine reactive metals such as Fe with Cu in water-containing supplies. The close vicinity of both metals and some Cu dissolution and its redeposition on a reactive metal surface will cause local elements. Effective oxygen reduction at these Cu deposits causes increased Fe dissolution, as described above.

12.2.10 Diffusion Control of Electrode Processes

In many cases metal corrosion and the compensating redox process may be under diffusion control, which leads to a diffusion overvoltage η_D . Diffusion of H^+ ions in weakly acidic electrolytes during Fe dissolution is one example that was discussed in the last section. Oxygen diffusion within electrolytes is another. Low oxygen concentration in solution and thick layers of electrolyte are a frequent situation that causes diffusion overvoltage. In all these cases the concentration of the oxidizing species reduces at the metal surface due to its intense consumption by the reduction process, lead-

Fig. 12.18 i/η dependence for a cathodic reaction under diffusion control without (solid) and with additional charge-transfer control (dashed line)

ing to a concentration profile. Similarly high dissolution rates of a metal cause the accumulation of its cations at the metal surface and a related increase of its concentration. As a consequence a concentration profile builds up

Fig. 12.19a,b Cross section of a convex hemispherical electrode/electrolyte combination (a) and a concave hemisphere (b) with diffusion lines or current lines (solid) and curves of equal concentration or potential (dashed) respectively; a is the radius of the electrode

which may cause locally saturated or supersaturated solutions and even the precipitation of corrosion products, such as the formation of salt films.

Figure 12.17 presents the concentration profile of the oxidized component Ox in front of an electrode within the Nernst diffusion layer of thickness δ . The dashed line refers to the maximal concentration gradient when the concentration of Ox at the surface approaches zero. For a diffusion-controlled electrode process the transfer of Ox equals the current density i according to (12.49) which is a combination of Fick's first diffusion equation and Faraday's law with Faraday's constant F , the diffusion constant D , the concentration of Ox at the surface c_S and within the bulk c_B , the thickness of the diffusion layer δ and the number of electrons for the charge-transfer process n . For vanishing concentration $c_S = 0$ one obtains the maximum diffusion current density i_D according to (12.50). The combination of (12.49) and (12.50) yields (12.51). If the charge-transfer reaction is fast with respect to diffusion the electrochemical equilibrium is established with an electrode potential $E = E_0 + \eta_D$. η_D is given by the difference of the electrode potentials for the concentrations c_S and c_B according to the Nernst equation, which yields (12.52). Introducing the current densities i and i_D with (12.49) and (12.50) one obtains (12.53). Figure 12.20 depicts the change of the current density with η for a cathodic process which approaches i_D for large overvoltages. For small η the reaction becomes charge-transfer controlled,

which results in the dashed curve of Fig. 12.18. Similarly metal dissolution for large positive polarizations becomes diffusion controlled and the current density becomes independent of the electrode potential. For large positive overvoltages the accumulation of cations at the electrode surface yields precipitation of corrosion products and salt films may form, which slow down the metal dissolution rate. In many cases the growth of oxides films at the metal surface causes a much more pronounced decrease of its dissolution current density. These processes may lead to thin passive layers that act as a barrier to the transfer of cations from the metal to the electrolyte, thus effectively protecting even very reactive metals against corrosion.

$$i = - \frac{(c_B - c_S) n F D}{\delta}, \quad (12.49)$$

$$i_D = - \frac{n F D c_B}{\delta}, \quad (12.50)$$

$$i = i_D - \frac{n F D c_S}{\delta}, \quad (12.51)$$

$$\eta_D = \frac{RT}{nF} \ln \left(\frac{c_S}{c_B} \right), \quad (12.52)$$

$$\eta_D = \frac{RT}{nF} \ln \left(\frac{i_D - i}{i_D} \right). \quad (12.53)$$

Diffusion of oxygen to a corroding metal surface is frequently the rate-determining step for corrosion processes. This is a consequence of its limited dissolution in water and the presence of thick water layers, which act as a diffusion barrier. For very thin water layers the access of oxygen is less hindered and sufficiently fast, yielding high corrosion rates. This is often the case under atmospheric corrosion. As an estimate i_D of oxygen reduction is calculated using the first diffusion law according to (12.50) with $n = 4$ for oxygen reduction to H_2O . With a diffusion constant $D_{O_2} = 10^{-5} \text{ cm}^2/\text{s}$ the thickness of the Nernst diffusion layer $\delta = 5 \times 10^{-3} \text{ cm}$ and a concentration of saturation for oxygen at 25 °C $c_B = 2 \times 10^{-4} \text{ M} = 2 \times 10^{-7} \text{ mole/cm}^3$, a value of $i_D = 1.6 \times 10^{-4} \text{ A/cm}^2 = 0.16 \text{ mA/cm}^2$ is obtained. This value is relatively large and will also disturb electrochemical studies in the laboratory as a cathodic background current. It may be suppressed effectively by purging of electrolytes with nitrogen or argon.

Diffusion may be enhanced by microelectrodes with a small radius a . According to Fig. 12.19 the diffusion in front of a hemispherical electrode follows the current lines, which follow the direction of its radius. The concentration gradient is given by the density of the hemispheres of constant concentration surrounding the electrode surface (dashed circles). Most variation is lo-

Fig. 12.20 Rotating disc electrode with electrolyte convection in front

Fig. 12.21 Disc rotator with an exchangeable RRDE with a split ring

cated close to the surface due to the divergence of the current lines. According to the hemispherical shape of this transport the current density $i(r)$ decreases with the distance $a + r$ from the surface according to (12.54) with the radius a for the metal electrode and the current density $i(a)$ at its surface. Integration of the first diffusion law (12.55) for these conditions in the range $r = 0$ to $r = \infty$ yields (12.56) for i and the limiting current density i_D

$$i(r) = i(a) \frac{a^2}{(a+r)^2}, \quad (12.54)$$

$$i = nFD \frac{(a+r)^2}{a^2} \frac{dc}{dr}, \quad (12.55)$$

$$i = nFD \frac{c_S - c_B}{a}; \quad i_D = -nFD \frac{c_B}{a}. \quad (12.56)$$

If the radius a becomes small, i_D may achieve large values. For $c_B = 1 \text{ M} = 10^{-3} \text{ mol/cm}^3$, $n = 1$ and $D = 5 \times 10^{-6} \text{ cm}^2/\text{s}$ and an ultra-microelectrode with a radius $a = 1 \text{ }\mu\text{m} = 10^{-4} \text{ cm}$ one obtains $i_D = 5 \text{ A/cm}^2$. This value will be even higher for electrodes of nm dimensions. In contrast using (12.50) for a planar electrode with a well-stirred electrolyte and a diffusion-layer thickness of $\delta = 5 \times 10^{-3} \text{ cm}$, one obtains $i_D = 0.1 \text{ A/cm}^2$. This is one reason why such small electrodes are used for electroanalytical purposes. For similar reasons a small radius leads to small ohmic voltage drops in front of an ultra-microelectrode which will be discussed in the next section.

Small active areas on a metal surface of this size may occur during localized corrosion of a passivated metal surface. In these cases extremely high local corrosion current densities may be measured within corrosion pits of up to several 10 A/cm^2 , whereas the rest of the surface shows extremely small dissolution currents in the range of $\mu\text{A/cm}^2$. The concentration gradient is about three times larger in this case due to the concave geometry when compared to a convex hemisphere (Fig. 12.21b) [12.39]. This more complicated transport problem has been solved numerically [12.40]. An analytical solution does not exist. Effective hemispherical transport will delay the accumulation of corrosion products for high dissolution rates, at least for some time before they precipitate. The precipitation of salt films will decrease the local current density and change the shape of growing pits from a polygonal shape to hemispheres due to the electropolishing effect of the precipitates [12.29, 30, 39].

12.2.11 Rotating Disc Electrode (RDE) and Rotating Ring-Disc Electrode (RRDE)

Diffusion control of electrode processes has been applied to various polarographic methods to analyze qualitatively and quantitatively the composition of electrolytes or the products formed at an electrode surface. The rotating disc electrode (RDE) and rotating ring-disc electrode (RRDE) are special arrangements to measure qualitatively and quantitatively the amount and composition of corrosion products. A disc that rotates with moderate speed has a laminar flow of the front electrolyte. Its flow is perpendicular and parallel to the rotating disc, as shown in Fig. 12.20. On one hand metal dissolution causes an increase of the concentration of the corrosion products during the outward flow of the electrolyte film parallel to the surface. On the other hand the income of fresh electrolyte from the bulk

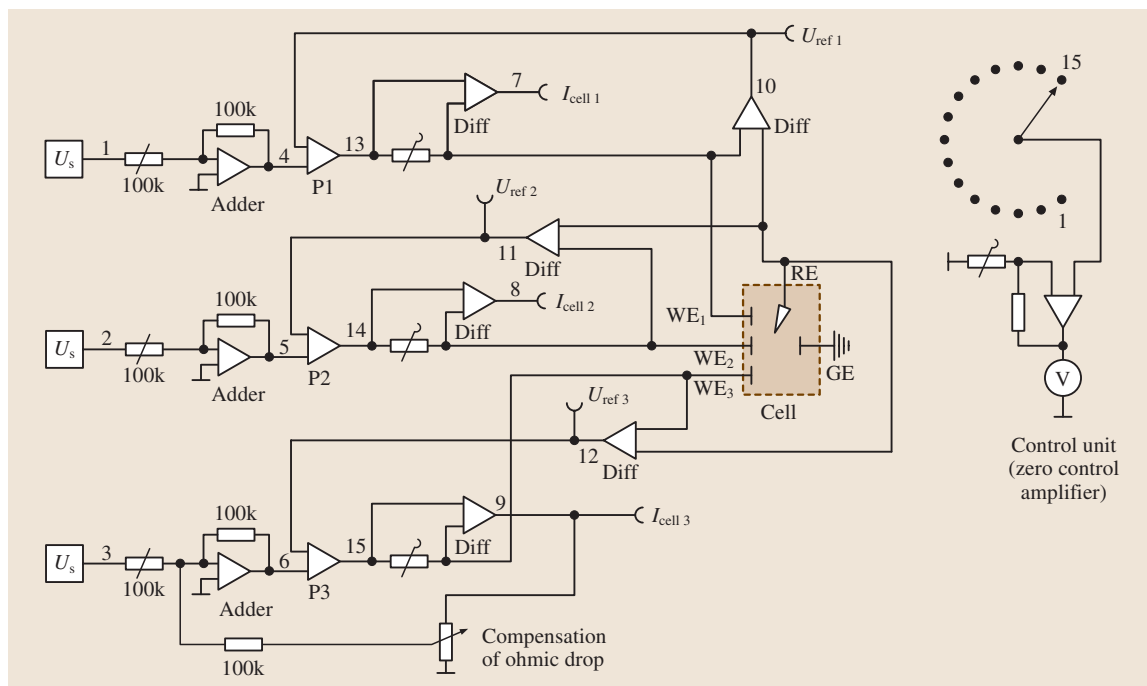

Fig. 12.22 Tripotentiostat for potentiostatic RRDE studies

perpendicular to the surface yields a decrease of the concentration. Both effects compensate each other, so that one may calculate diffusion to the bulk with a constant thickness of the Nernst diffusion layer and a constant concentration profile independent of the location at the disc surface. The quantitative treatment of this problem yields the Levich equation (12.57) [12.41] for the thickness of the diffusion layer δ , with the rotation speed $\omega = 2\pi f$, the frequency f , $\nu = \nu'/\rho$, i.e. the viscosity ν' divided by the density ρ of the electrolyte and the diffusion coefficient D . With $\nu = 10^{-2} \text{ cm}^2/\text{s}$ for water, $D = 5 \times 10^{-6} \text{ cm}^2/\text{s}$ and $\omega = 63 \text{ s}^{-1}$ one obtains $\delta = 1.6 \times 10^{-3} \text{ cm}$. Introducing this value in (12.50) yields with $n = 1$ and $c_B = 10^{-3} \text{ M}$ for the limiting disc current density of a species which is consumed at the disc surface $i_D = 300 \mu\text{A}/\text{cm}^2$. Another example is i_D of a rotating iron disc in $0.5 \text{ M H}_2\text{SO}_4$. With a saturation concentration of $c = 0.56 \text{ M}$ for FeSO_4 and its bulk concentration $c_B = 0$ one calculates, for all other conditions the same, $i_D = 0.336 \text{ A}/\text{cm}^2$. Continued Fe dissolution causes accumulation of corrosion products and leads finally to a precipitated salt film which restricts the dissolution to the calculated value. This is close to the experimental maximum $i_D = 200 \text{ mA}/\text{cm}^2$ of dissolution of a flat iron electrode with moderate agitation of

the electrolyte. A better coincidence cannot be expected due to the difference in hydrodynamic flow between the two electrodes

$$\delta = 1.61 \omega^{-1/2} \nu^{1/6} D^{1/3} \quad (12.57)$$

The RRDE consist of a central disc with a surrounding analytical ring electrode, usually made of a noble metal such as gold or platinum (Fig. 12.21). The products of the central disc are transported parallel to the electrode surface and finally pass the ring surface where they undergo an electrochemical process with a diffusion-limited maximum current density. The transfer efficiency N from the disc to the ring may be calculated from the dimensions of both electrodes [12.42] or may be determined experimentally. Values of $N > 30\%$ may be achieved easily. The disc current I_D and the ring current I_R are correlated by (12.58), which takes into account the number of exchanged charges n_D and n_R at both electrodes. With (12.58) one may calculate I_D and the formation of soluble products at the ring from measured I_R values. A reaction well suited to the experimental calibration of a RRDE and the determination of N is the redox reaction of $[\text{Fe}(\text{CN})_6]^{3-/4-}$ with an oxidation of $[\text{Fe}(\text{CN})_6]^{4-}$ at the disc and the related reduction of

$[\text{Fe}(\text{CN})_6]^{3-}$ at the ring or vice versa

$$N = \frac{n_{\text{Di}} I_{\text{R}}}{I_{\text{Di}} n_{\text{R}}} \quad (12.58)$$

RRDE with different metal discs and even brittle semiconductor electrodes have been formed. Usually the disc is embedded in a thin layer of resin with a cylinder of Au or Pt glued by resin to its surface. The total set is then surrounded by resin within a cylinder of a polymer and the electrodes are contacted from the rear side. This exchangeable **RRDE** may then be attached to a disc rotator with rotating contacts for a reliable connection of the rotating electrodes to a potentiostat (Fig. 12.22) [12.43]. Frequently two isolated half cylinders are used instead of a full cylinder, which opens the possibility to mea-

Fig. 12.23 Current of a copper disc I_{Di} and ring currents I_{R1} and I_{R2} of a split **RRDE** in 0.1 M KOH for a potentiodynamic scan of the disc potential $dE_{\text{Di}}/dt = 10 \text{ mV/s}$

Fig. 12.24 Current densities i_A and i_B of two surface sites A and B with an ohmic drop ΔU_{Ω} within the electrolyte in front and related rest potentials E'_{RA} and E'_{RB}

sure the formation of two products simultaneously at the split ring. The **RRDE** requires a bipotentiostat to set the potential of two working electrodes independently from each other. An **RRDE** with a split ring needs a tripotentiostat. The related block diagram is depicted in Fig. 12.22. The three working electrodes WE_1 , WE_2 and WE_3 (disc, ring 1 and ring 2) are connected via a differential amplifier to avoid grounding problems. The three circuits have one common reference electrode, **RE**, and one counter-electrode, **CE**, which is grounded. Further details are similar to those discussed for the block diagram of Fig. 12.4. Figure 12.23 presents as an example the I_{D} of the polarization curve of a Cu disc in

Fig. 12.25 (a) Current lines (arrows) and curves of equal potential in the presence of local elements with surface sites A and B. (b) potential profile with very low (1), low (2), and very high conductivity (3) of the electrolyte

0.1 M KOH. Cu forms a passivating oxide layer at sufficiently positive potentials at the anodic peaks A1 and A2. Figure 12.23 depicts I_{R1} and I_{R2} of the two analytical ring electrodes, which are set to appropriate potentials $E_{R1} = 0.6$ V and $E_{R2} = -0.23$ V, respectively. These potentials are suited to oxidize soluble Cu(I) ions to Cu(II) ions and to reduce Cu(II) to Cu(I) ions respectively. Thus the measured analytical ring currents permit the determination of the kind and the amount of soluble corrosion products from the disc. The calculation of the related disc currents $I_{Di}(\text{CuI})$ and $I_{Di}(\text{CuII})$ of soluble products with (12.58) and their comparison with the measured total current I_{Di} allow the determination of the charge which is stored as a passivating oxide film on the copper electrode. Thus these measurements with RRDE allow the determination of the efficiency of layer formation and dissolution. Figure 12.23 shows the close relation of the current peaks A1 and A2 of I_{Di} for Cu(I) oxide and Cu(II) oxide formation and the dissolution of the related ions. Even the dissolution of weakly soluble Cu(I) ions may be detected by I_{R1} in 0.1 M KOH.

A further development of the RRDE is its hydrodynamical modulation of the rotation speed ω . Here the thickness δ of the Nernst diffusion layer is modulated according to (12.57) and thus the diffusion of corrosion products and their transfer to the rings. With a hydrodynamical square-wave modulation one may even distinguish quantitatively between species of the same kind from the bulk electrolyte and those formed at the disc. A detailed description of this method and its application to corrosion is beyond the scope of this chapter and the reader is referred to the literature. An example of its application to the dissolution and film formation has been described for Fe in 1 M NaOH [12.44]. The agreement of experiments and calculation is shown in [12.45].

12.2.12 Ohmic Drops

High current densities cause ohmic drops within the electrolyte. For a planar electrode with a current density i the voltage drop ΔU_{Ω} changes according to (12.59) with the electrolyte resistance R_{Ω} , the specific conductivity κ of the electrolyte, and the distance d from the electrode surface. The ohmic drop ΔU_{Ω} in front of a hemispherical electrode of radius a at distance r is given by (12.60). For $r \rightarrow \infty$, ΔU_{Ω} obtains a maximum value $\Delta U_{\Omega, \max}$ related to the maximum ohmic resistance $R_{\Omega, \max}$. Similar to the concentration gradient related to diffusion in front of a hemispherical electrode a small radius a reduces $R_{\Omega, \max}$ and $\Delta U_{\Omega, \max}$

to very small values. For $i = 1 \text{ A cm}^{-2}$ a distance of $d = 5$ mm, and $\kappa = 22 \Omega^{-1} \text{ cm}^{-1}$ for an electrolyte with good conductivity such as 0.5 M H_2SO_4 , one obtains for a planar electrode at a distance $d = 0.5$ cm, a value of $\Delta U_{\Omega} = 0.023 \text{ V} = 23 \text{ mV}$ (12.59). ΔU_{Ω} will be much larger for less-conducting electrolytes and higher current densities. These values are characteristic of the ohmic drop between the Haber-Luggin capillary of a reference electrode and the working electrode of a potentiostatic circuit. It may be compensated automatically to about 90% by an electronic feedback loop, a unit built into potentiostats. However, this may still be a problem for electrochemical measurements at very high current densities of $i \geq 10 \text{ A/cm}^2$ or electrolytes with low conductivity. Large electrodes will also be submitted to a nonhomogeneous potential distribution due to the presence of large local differences of the ohmic drops.

In the case of a microelectrode with a radius of $a = 10^{-4}$ cm one obtains $\Delta U_{\Omega, \max} = 4.5 \times 10^{-3} \text{ mV}$ for conditions otherwise the same as given above (12.60). Furthermore the potential will be uniform in front of its surface even for high current densities. Similar conditions will hold for concave hemispherical surfaces such as small corrosion pits with μm dimensions. Here again the potential drop will be three times larger, i. e. $13.5 \times 10^{-3} \text{ mV}$ for $a = 1 \mu\text{m}$, due to the concave geometry

$$\Delta U_{\Omega} = i R_{\Omega} \quad \text{with} \quad R_{\Omega} = \frac{d}{\kappa}, \quad (12.59)$$

$$\Delta U_{\Omega} = i R_{\Omega}, \quad R_{\Omega} = \frac{ra}{\kappa(r+a)};$$

$$R_{\Omega, \max} = \frac{a}{\kappa} \quad \text{for} \quad r \rightarrow \infty. \quad (12.60)$$

Microelectrodes are of increasing interest. Many processes occur on a very small scale so that micro- and nano-electrochemistry are actively developing branches in electrochemistry. These fields are also important for corrosion studies. Many corrosion processes occur on a small scale and still cause huge damage. Mechanistic studies of localized corrosion of passive metal electrodes may follow the formation and growth of corrosion pits to micrometer and nanometer scales with appropriate methods such as scanning force microscopy (SFM) and scanning tunneling microscopy (STM). These methods use very sharp tips that may also be seen as ultra-microelectrodes. Another important example is corrosion of integrated circuits, which is a serious problem for their life time and reliability. There are always electrolyte residues on metallic

connections on chips and the encapsulant gives imperfect protection against the ingress of moisture. The voltage supply of 5 or 15 V is large for any electrochemical process and thus dissolution of metal at positive potentials and its redeposition at negative potential causes disconnection of vapor-deposited metal connections with μm dimensions and short circuits by the deposition of dendrites. The investigation of biological processes and the development of sensors also need electrochemistry on a micrometer scale. Further miniaturization pushes electrochemistry to a nanometer scale. Thus micro- and nanotechnology require studies of electrochemical processes with the help of micro- and ultra-microelectrodes. Corrosion research necessarily has to address these small and extremely small scales. Modern electroanalytical chemistry uses these micro and ultra-microelectrodes for scanning electrochemical microscopes (SECM). It should also be mentioned that the tip of an STM or an SFM may be used for highly localized electrochemical studies and surface structuring in combination with the imaging of the electrode surface with mesoscopic and atomic resolution. One possible application of these ultra-microelectrodes is the structuring of metal surfaces by dissolution and deposition of metal on a sub-micrometer and nanometer scale.

12.2.13 Measurement of Ohmic Drops and Potential Profiles Within Electrolytes

The ohmic drop in front of an electrode may be used as a measure of localized electrochemical processes, as e.g. in the case of local elements and other localized corrosion phenomena. For an electrolyte with good conductivity the potential in front of an electrode does not change if the current densities assume moderate values, although the rate of electrode reactions change locally with the surface sites A and B due to their physical or chemical differences. This leads to local anodes A and cathodes B as discussed in Sect. 12.2.9 with no potential drop between them (Fig. 12.16). However for a low-conductivity electrolyte large potential drops ΔU_Ω may occur, which shift the rest potentials of these sites to the values E'_{RA} and E'_{RB} apart from each other (Fig. 12.24). For a vanishingly small conductivity κ the potential profile parallel to the electrode surface within the electrolyte follows the shape of the related areas A and B with steep changes at their contact Fig. 12.25. For $0 < \kappa < \infty$ a smoothed profile is found which disappears for $\kappa \rightarrow \infty$. Thus the potential in close vicinity to the electrode surface will change within the electrolyte with location. However, these differences will smear out

Fig. 12.26 Measurement of the potential profile ΔU_Ω within the electrolyte with two reference electrodes RE_I and RE_II

with increasing distance from the electrode due to the spread of the current lines.

The related ohmic potential drop ΔU_Ω may be measured with two reference electrodes, e.g. two calomel electrodes, one close to the surface moving to the locations of interest (RE_I) and the other at large distance within the bulk electrolyte (RE_II). This arrangement measures the total drop ΔU_Ω with superimposed changes when moving the sampling electrode parallel to the surface (Fig. 12.26). More sensitive measurements of small changes of ΔU_Ω are performed when two reference electrodes are fixed with their Haber-Luggin capillaries close to each other (Fig. 12.27). If they are moved together across the metal surface one measures the potential difference referring to their close distance as a function of position. Their potential dif-

Fig. 12.27 Measurement of the profile of the potential gradient $d(\Delta U_\Omega)/dx$ within the electrolyte with two close reference electrodes RE_I and RE_II

ference changes with their common position in front of the electrode surface and thus samples local potential gradients without a large background voltage. In conclusion, with the second electrode separation within the bulk electrolyte one measures the integral potential drop ΔU_{Ω} whereas with two closely interconnected reference electrodes, i. e. with the so called scanning reference electrode technique (SRET) [12.46–48], the local potential gradient $d\Delta U_{\Omega}/dx$ is obtained. One may improve the spatial resolution with two small platinum tips that are isolated at their sides and which may be arranged closer to each other.

An even better arrangement works with a vibrating reference electrode, i. e. the scanning vibrating electrode technique (SVET) [12.46, 47]. Here one uses a small vibrating metal tip and a second reference electrode far away in the bulk electrolyte. The small amplitude of vibration measures the related local potential gradient corresponding to the small local changes during vibration. The measurement of the related small potential changes may be improved by a lock-in technique that separates the signal from the background and disturbing signals of different frequencies from other sources. With an applied scan of the vibrating electrode parallel to the electrode surface one samples the related potential profile and thus images the sites of different electrochemical activity. The potential change may also be investigated perpendicular to the surface and thus three-dimensional potential profiles may be obtained. Useful SVET equipment is available commercially. One may even calculate from these potential gradients the local current densities when the size of the surface sites of different activity and a possible change of the conductivity of the electrolyte in front are taken into account. At present the vibrating electrode is used mainly to map surface sites of different activity. Examples of frequent interest are local elements on a corroding metal surface with cathodic and anodic areas, inclusions at a metal surface causing localized corrosion or corrosion pits with high metal dissolution rates within a passivated metal surface.

In industry the investigation of local corrosion damage by potential measurements is a very important

Fig. 12.28 Detection of localized corrosion sites on under ground pipelines by measurement of potential profiles with two reference electrodes (RE)

Fig. 12.29 Equivalent circuit of a Kelvin probe with the capacity C of the vibrating tip/specimen combination, the compensation voltage ΔU and current measurement A

method. Corrosion damage of metal constructions under ground may be detected by screening with two reference electrodes (Fig. 12.28). Similarly to the above discussion, localized corrosion of a pipeline will cause a spread of currents and related potential drops within the ground. The center of the damage may be found by two references which are in contact with the ground. One of these will be placed at different sites, thus measuring the potential difference as a function of location. The position of large potential differences should be close to the site of active corrosion damage.

The scanning Kelvin probe provides another possibility to investigate surface sites with varying elec-

Fig. 12.30a,b Contact of specimen W and tip T with work functions $e\phi_W$ and $e\phi_T$ and (a) the resulting contact potential difference $e(\phi_W - \phi_T)$, (b) compensation of $e(\phi_W - \phi_T)$ by $e\Delta U$. E_{FW} and E_{FT} are the Fermi levels of the specimen and the tip

trochemical activity. Its application to surface studies is complementary to the two aforementioned methods for corrosion studies. Its advantage is that it enables a potential measurement without direct contact with the medium of interest. Two different metals, the working electrode W and a vibrating tip T in its vicinity, form a condenser (Fig. 12.29). Their direct contact in the outer circuit produces a contact potential difference which equals the difference of the work functions $e_0(\Phi_W - \Phi_T) = e_0\Delta\Phi$ of both metals (Fig. 12.30a). This potential difference $\Delta\Phi$ causes a small alternating current during the vibration of the tip to the surface of the working electrode due to the change of the capacity $C = \frac{\varepsilon\varepsilon_0 A}{d}$ with distance d according to (12.62). This current disappears when an externally applied voltage ΔU compensates $\Delta\Phi = (\Phi_W - \Phi_T)$ [(12.61), Figs. 12.29, 12.30b]. Thus the difference of the work functions is measured by a disappearing current density i of a Kelvin probe. The work function is closely related to the energy of the Fermi level of a metal, which changes with the potential drop within the electrolyte in front of an electrode, i. e. due to charging of its double layer. Any change of the potential across the

electrode–electrolyte interface affects the work function and thus the compensating voltage of the Kelvin probe. With a vibrating small metal electrode T one may scan the electrode surface and thus measure the changes of the difference of the work functions of W and T as a function of its position and consequently the potential distribution in front of a corroding metal. The main advantage is the measurement of potential differences without making contact with the electrolyte in front of the electrode. This may be very important when the electrode–electrolyte interface is buried below a layer of polymer. For these cases the Kelvin probe allows one to follow electrochemical reactions and corrosion processes, including the delamination of polymer layers on metals via potential measurements that otherwise would not be accessible [12.49, 50]. Another example is atmospheric corrosion when only a very thin film of electrolyte covers the surface, to which one cannot easily make a conducting contact via the Haber–Luggin capillary of a reference electrode.

$$\Delta U_{\text{tot}} = e_0\Delta\Phi - \Delta U = e_0(\Phi_W - \Phi_T) - \Delta U = 0, \quad (12.61)$$

$$\frac{dC}{dt} = \frac{\varepsilon\varepsilon_0 A}{dd} = \frac{\frac{dQ}{dt}}{\Delta U_{\text{tot}}} = \frac{i}{\Delta U_{\text{tot}}}, \quad (12.61a)$$

$$i = \frac{dC}{dt} \Delta U_{\text{tot}} = \frac{\varepsilon\varepsilon_0 A}{dd} \Delta U_{\text{tot}} = 0. \quad (12.62)$$

12.2.14 Non-stationary Methods, Pulse Measurements

The sequence of several elementary reaction steps and their influence on the overall electrochemical corrosion process requires their separation. This could be done by electrochemical transient measurements. A very rapid change of the electrode potential leads to a sequence of reaction steps (Fig. 12.31) that may be separated in the time domain. The ohmic drop within the electrolyte between the reference electrode and the working electrode is established within less than a microsecond. This may be measured with fast galvanostatic transients. For this discussion a useful equivalent circuit for an electrode within the electrolyte consists of a capacity C in parallel to a charge-transfer resistance R_{CT} . A resistance R_Ω in series to this combination takes care of the electrolyte resistance between the Haber–Luggin capillary and the working electrode (Fig. 12.31). A galvanostatic pulse with a rise time in the range of about 100 ns may easily be applied between working and

Fig. 12.31 (a) Equivalent circuit of an electrode surface with a double-layer capacity $C = 10\ \mu\text{F}$, a charge-transfer resistance $R_{CT} = 1\ \text{k}\Omega$ and an ohmic resistance $R_\Omega = 10\ \Omega$ within the electrolyte. (b) Bode diagram of the impedance Z in dependence on the frequency of the added alternating voltage (*solid*) and the related phase shift $\Delta\Phi$ (*dashed*)

counter-electrode. As a consequence the ohmic drop will be detected immediately, within less than 1 μs . The subsequent charging of the double layer, i. e. of the capacity C with time causes an increase of the measured voltage across the equivalent circuit. Extrapolation of this voltage increase back to $t = 0$ yields at the intersection the ohmic drop ΔU_{Ω} , which should increase linearly with the galvanostatically applied current density i . The thus measured ohmic drop $\Delta U_{\Omega} = R_{\Omega}i$ may be used for an appropriate setting of the resistance R_{Ω} at the compensation unit of a potentiostat. Thus one may compensate ΔU_{Ω} automatically during potentiostatic transients, which increase proportionally to the current density i .

The electronic properties of the electrode–electrolyte interface and its related equivalent circuit may be determined by measurement of the impedance and its dependence on frequency, which is presented in Fig. 12.31 as a so-called Bode plot. For impedance measurements the electrode potential is varied by a small superimposed amplitude of a few mV in order to justify the approximation of the electrochemical system by the proposed equivalent circuit. A linear i – E relation in the sense of Ohm's law is valid for small potential changes only. In general the i – E relation is exponential according to the Butler–Volmer equation of (12.26). Figure 12.31 also contains the phase shift $\Delta\Phi$. For the presented example $R_{CT} = 1 \text{ k}\Omega$, $R_{\Omega} = 10 \text{ }\Omega$ and $C = 10 \text{ }\mu\text{F}$ are chosen. These values are reasonable for the electrode–electrolyte interface. At low frequency ($\omega = 2\pi f$), i. e. below 1 Hz, the current passes the ohmic resistances leading to approximately $Z = R_{CT} + R_{\Omega}$ because the parallel capacitive resistance $1/\omega C$ becomes very large. The phase shift is vanishingly small. At very high frequencies of $f = 100 \text{ kHz}$ the capacitive resistance is very low with a short circuit across C . In this case the impedance equals R_{Ω} with $\Delta\Phi = 0$. At intermediate frequencies of $f = 100 \text{ Hz}$, $Z = 1/\omega C$ will hold approximately with a maximum of $\Delta\Phi$. In the example of Fig. 12.31a,b one obtains $1/\omega C = 100 \text{ }\Omega$ for $f = 158 \text{ Hz}$, which refers to the maximum of the phase shift $\Delta\Phi$.

For potentiostatic transients one has to discuss a sequence of time ranges. Figure 12.32 presents an example for a rotating Au disc electrode in a solution of $0.5 \times 10^{-3} \text{ M}$, $\text{K}_3[\text{Fe}(\text{CN})_6]$ and $\text{K}_4[\text{Fe}(\text{CN})_6]$, which are dominated by the following processes: (1) charging of the double layer, (2) charge-transfer control of the electrode process (3) increasing diffusion control and (4) full diffusion control. This charge-transfer process of a redox system does not involve complicating chemical reaction steps within the electrolyte and adsorption

and desorption at the electrode surface (Fig. 12.11). Therefore it is still a relatively simple situation.

1. The charging of the double layer via the R_{Ω} – C combination in series occurs according to (12.63, 12.64). The total applied voltage is the sum of the potential drop at the ohmic resistance R_{Ω} and the capacity C of the double layer i. e. $\Delta U = \Delta U_{\Omega} + \Delta E$. With a typical capacity of $20 \text{ }\mu\text{F}/\text{cm}^2$ for a free metal surface and a resistance of $R_{\Omega} = 0.1 \text{ }\Omega\text{cm}^2$ for a well conducting electrolyte at the short distance between the metal surface and the Haber–Luggin capillary of the reference electrode the charging of the double layer occurs with a time constant of $R_{\Omega}C = 2 \times 10^{-6} \text{ s} = 2 \text{ }\mu\text{s}$. For potentiostatic transients the measured current density drops according to (12.63) and the voltage across the double layer, i. e. across the capacitance C , increases according to (12.64). After about $8 \text{ }\mu\text{s}$ the electrode potential ΔE should be fully established. A larger R_{Ω} value will increase the time constant. This is the case for low-conductivity electrolytes. However in most cases the charging time for the double layer is short enough to follow corrosion processes with a sufficient time resolution

$$i = \frac{\Delta U}{R_{\Omega}} \exp\left(-\frac{t}{R_{\Omega}C}\right), \quad (12.63)$$

$$\Delta E = \Delta U \left[1 - \exp\left(-\frac{t}{R_{\Omega}C}\right)\right]. \quad (12.64)$$

2. After about $10 \text{ }\mu\text{s}$ of double-layer charging one may measure the electrode reaction under charge-transfer control with the related charge-transfer overvoltage η_a . For these conditions the electrode process is ruled by the Butler–Volmer equation (12.26). If the current density is small enough no further complications are involved. This situation refers to the plateau currents in time range 2 of Fig. 12.32. The current density assumes a constant value of $10^{-2} \text{ A}/\text{cm}^2$ for about 0.3 ms , which corresponds to a charge of $3 \text{ }\mu\text{C}/\text{cm}^2$ and thus to $3 \times 10^{-11} \text{ mole}/\text{cm}^2$ of $\text{K}_3[\text{Fe}(\text{CN})_6]$. For the $5 \times 10^{-4} \text{ M}$ solution this amount of reacting ions is within a layer of 600 nm . This distance is close to the mean diffusion path $\bar{x} = \sqrt{2Dt} = \sqrt{2 \times 5 \times 10^{-6} \times 3 \times 10^{-4}} = \sqrt{30 \times 10^{-10}} = 5.5 \times 10^{-5} \text{ cm} = 550 \text{ nm}$ of dissolved ions within the electrolytes.
3. If diffusion becomes rate-determining for a sufficiently large current density the change of the electrolyte composition immediately at the electrode surface leads to a diffusion overvoltage η_D . Con-

Fig. 12.32 Potentiostatic transient for an Au RDE, with the different time domains, change of i with the frequency of rotation $\omega = 2\pi f/(\text{min}^{-1})$

sequently the reaction rate becomes determined by the diffusion overvoltage after some time when the concentrations of the reacting species at the electrode surface deviate from their bulk values. If only the diffusion overvoltage is effective, *Cottrell* derived the current density as a function of time, as shown in (12.65) [12.51]. i depends exponentially on the diffusion overvoltage η_d and (12.65) is similar to (12.53), which holds for stationary conditions. For a potentiostatic transient i also depends on time with $1/\sqrt{t}$. The bulk concentration c_B and the diffusion constant D refer to a species that is involved in the electrode process and which causes diffusion overvoltage by its limited transport. It could be a reduced or oxidized species and the current density then refers to the anodic or cathodic process, respectively. Equation (12.65) is not valid for $t = 0$ because i goes to infinity for this condition. However, charge-transfer overvoltage cannot be excluded, which limits the current density for short times. This however, is not included in this treatment.

$$i = nF\sqrt{\frac{D}{\pi}}c_B \left[\exp\left(\frac{nF}{RT}\eta_D\right) - 1 \right] \sqrt{\frac{1}{t}}. \quad (12.65)$$

If both, charge transfer and diffusion are rate-determining the total overvoltage equals $\eta = \eta_d + \eta_D$.

For these conditions the change of the current density for potentiostatic transients has been deduced as (12.66) [12.52, 53]. $i(0)$ is the current density for $t \rightarrow 0$ when the double-layer charging is finished and the concentration of any reacting species is still unchanged. This corresponds to (12.26) when diffusion control is still not effective. For short times, i.e. for $\lambda\sqrt{t} \ll 1$, the approximation of (12.67) has been derived which may be used to determine $i(0)$ from $i-\sqrt{t}$ plots of the current values of potentiostatic transients. Thus $i(0)$ is obtained by extrapolation of $i-\sqrt{t}$ plots to $\sqrt{t} \rightarrow 0$ for each electrode potential. The $i(0)$ values may then be compared to the polarization curve for pure charge-transfer control. For $\lambda\sqrt{t} \gg 1$ the approximation of (12.68) has been derived with a $t^{-0.5}$ dependence of i . This condition corresponds to dominant diffusion control. The double logarithmic plot of the current transient of Fig. 12.32 shows a slope $d \log i / d \log t = -0.5$. This result is expected for the $t^{-0.5}$ dependence of (12.65). A slope of -0.5 is also expected from the approximation of (12.68) for $\lambda\sqrt{t} \gg 1$

$$i = i(0) \exp(\lambda^2 t) \operatorname{erfc}(\lambda\sqrt{t}), \quad (12.66)$$

$$\lambda = \frac{i_0}{zF} \left[\frac{1}{c_{B,\text{Red}}\sqrt{D_{\text{Red}}}} \exp\left(\frac{\alpha z F}{RT}\eta\right) + \frac{1}{c_{B,\text{Ox}}\sqrt{D_{\text{Ox}}}} \exp\left(-\frac{(1-\alpha)zF}{RT}\eta\right) \right], \quad (12.66a)$$

$$i(0) = i_+ + i_- = i_0 \left[\exp\left(\frac{\alpha z F \eta}{RT}\right) - \exp\left(\frac{-(1-\alpha)zF\eta}{RT}\right) \right], \quad (12.26)$$

$$i = i(0) \left(1 - \frac{2}{\sqrt{\pi}} \lambda\sqrt{t} \right) \quad (\text{for } \lambda\sqrt{t} \ll 1), \quad (12.67)$$

$$i = i(0) \frac{1}{\sqrt{\pi} \lambda\sqrt{t}} \quad (\text{for } \lambda\sqrt{t} \gg 1). \quad (12.68)$$

- For times longer than 0.5 s the transients of Fig. 12.32 are in the regime of total diffusion control with a current density which depends on the rotation speed of the RDE. In this time range the current densities follow the $\sqrt{\omega}$ dependence according to the Levich equation (12.57) demonstrating the full diffusion control of the process.

12.2.15 Concluding Remarks

Corrosion within electrolytes or under the influence of thin electrolyte films is an electrochemical process. For an understanding of its leading mechanisms the application of electrochemical methods is a necessary requirement. They allow the simulation of corrosion phenomena under well-controlled electrochemical conditions with a systematic variation of the related parameters. For a detailed understanding of the mechanisms and the condition of the metal surfaces one needs additional information, which is obtained through the application of surface analytical methods. For a chemical analysis of corroding surfaces and surface films methods working in the ultra-high vacuum such as X-ray photoelectron spectroscopy (XPS) [12.54, 55] or Auger electron spectroscopy (AES) [12.56] are valuable analytical tools that provide qualitative and quantitative information. The structure of surfaces and surface layers may be investigated with synchrotron methods such as X-ray diffraction (XRD) and X-ray absorption spec-

troscopy (XAS), which yield the parameters of the long- or short-range order of surfaces or surface films, respectively [12.57]. A direct image of surface structures even down to atomic resolution is obtained by the in situ application of scanning methods such as scanning force microscopy (SFM) and scanning tunneling microscopy (STM). There are numerous other in situ methods such as infrared (IR) or laser Raman spectroscopy, each of them having its specific advantages and providing some insight into a corroding system. All these methods together give information on the chemical composition, structure and the properties of surfaces and surface films. Electrochemistry remains incomplete and rather arbitrary without the surface methods, whereas these analytical tools without a detailed understanding of the electrochemical reactions and a well-controlled electrochemical specimen preparation give no reliable results. One therefore has to apply many of these methods in combination in order to get reliable results without too much speculation for the usually complicated systems in corrosion, whether in theory or practice.

12.3 Novel Electrochemical Test Methods

During the last 30 years new electrochemical techniques have arisen which give more and faster information about corrosion reactions and also provide data on corrosion in geometric orders at the nanoscale. Analyzing the dynamic behavior of a corrosion system requires special techniques, which are essentially different from conventional direct-current (DC) techniques (Sect. 12.1), such as measurement of the open-circuit potential, polarization curves, weight loss, or other physicochemical parameters. Based on linear system theory (LST), electrochemical impedance spectroscopy (EIS) is one of the most powerful techniques.

Electrochemical noise analysis (ENA) is a relatively new method. Stochastic fluctuations of the electrode potential or the cell current are often referred to as electrochemical noise, analogous to the word *noise*, indicating random fluctuations of incoherent acoustic or electrical signals. Noise analysis is a well-developed technique in many fields, and it is being applied increasingly to electrochemical systems, in particular in corrosion science and engineering.

Another important and widely used tool for corrosion investigations is the scanning electrode technique. The inherent advantage of scanning reference electrodes is the possibility to measure the initiation, distribution,

and rate of local corrosion processes in situ with spatial resolution down to 20 μm .

12.3.1 Electrochemical Noise Analysis

Within corrosion research, the analysis of electrochemical noise offers a simple, sensitive and virtually nondestructive measuring technique for assessment of the corrosion susceptibility of metallic materials and for the investigation of corrosion processes. The present status of knowledge concerning noise diagnostics in corrosion processes permits the application of this method not only to experimental tasks in the laboratory, but also to special problems in the context of practical corrosion monitoring. Furthermore, specific advantages of the technique enable its use to an increasing extent in supporting or improving conventional corrosion testing. The advantages here include obtaining additional information and shortening testing times, thus resulting in state-of-the-art corrosion testing.

ENA is an electrochemical method that offers great potential for measuring and monitoring localized corrosion. This technique needs no external signal to obtain corrosion data. The principle is based on the fact that two identical electrodes exposed to the same medium

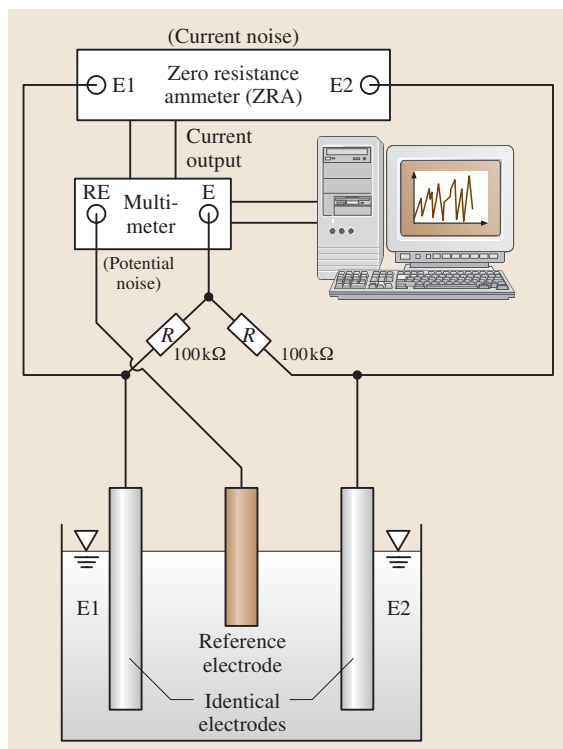

Fig. 12.33 Experimental set up for potential and current noise measurements

(environment) under free corrosion conditions show stochastic fluctuations of the open-circuit potential in the μV range and of the galvanic coupling current in the nA range, generated by corrosion reactions on the electrode surfaces [12.58–61]. These potential and current fluctuations are known as electrochemical noise.

The experimental set up for measuring electrochemical noise is relatively simple (Fig. 12.33). The two identical electrodes (made, e.g., from mild steel) are connected over a zero-resistance ammeter (ZRA), which feeds the current output (current noise) via a multimeter into a computer. The two electrodes can be connected over two ultra-accurate metal resistors ($100\text{ k}\Omega$ each) in series to provide an average potential point: since the resistance of the two resistors is much larger than the solution resistance (generally not more than 100Ω) no measurable disturbance is introduced into the system by the potential and current measurements. The potential between this average point and the reference electrode [e.g. Saturated Calomel Electrode (SCE)] is sampled. For potential and current measurements a 2 points/s sampling rate for 500 s (8.3 min) of measuring time is

sufficient. For corrosion monitoring this procedure will be repeated in appropriate time intervals.

Figure 12.34 shows potential and current noise versus time plots of mild steel in two cooling waters with different salt concentration [12.61]. Cooling water 2 contained higher chloride and sulfate levels, which obviously resulted in a significantly different fluctuation pattern of the electrochemical noise at mild steel in these two waters. The electrochemical noise signals can be processed in a digital or analogue manner. The digital signal-processing technique involves the acquisition of raw data and their subsequent numerical analysis, while the analog processing method produces an output signal proportional to the root mean square (RMS) of the noise using electronic filters and amplifiers. From these data the noise resistance R_n can be defined as

$$R_n = \delta V / \delta I, \quad (12.69)$$

where δV is the RMS of the corrosion potential fluctuation and δI is the RMS of the current fluctuation [12.62, 63].

Data processing can also include transformation in the frequency-domain (spectral density) curves using the maximum-entropy method (MEM) or fast Fourier transformation (FFT). The MEM inherently produces smoother spectra without apparent loss of information [12.64] and is simpler to use when the number of data points is not a power of two. Analysis in the frequency domain needs simultaneous collection of potential and current noise data.

With FFT the spectral noise response $R_{sn}(f)$ can be calculated at each frequency f by

$$R(f) = V(f)/I(f) \quad \text{and} \quad (12.70)$$

$$R_{sn} = |R(f)| = \left[R(f)_{re}^2 + R(f)_{im}^2 \right]^{1/2}, \quad (12.71)$$

where $V(f)$ and $I(f)$ are complex numbers obtained from the FFT. The spectral noise resistance R_{sn} is defined as the value of

$$R_{sn}(f) \quad \text{at} \quad f = 0, \quad (12.72)$$

$$R_{sn}^0 = \lim_{f \rightarrow 0} [R_{sn}(f)]. \quad (12.73)$$

An analysis in the frequency domain can yield information on the type of corrosion at the electrodes.

The electrochemical current-noise power-spectral density [PSD(I)] at high frequencies (100–1000 MHz) can be indicative for general corrosion while the shape and the repetition rate of transients of the electrochemical potential and current determine the type of corrosion [12.61]. The slope of the power-spectrum

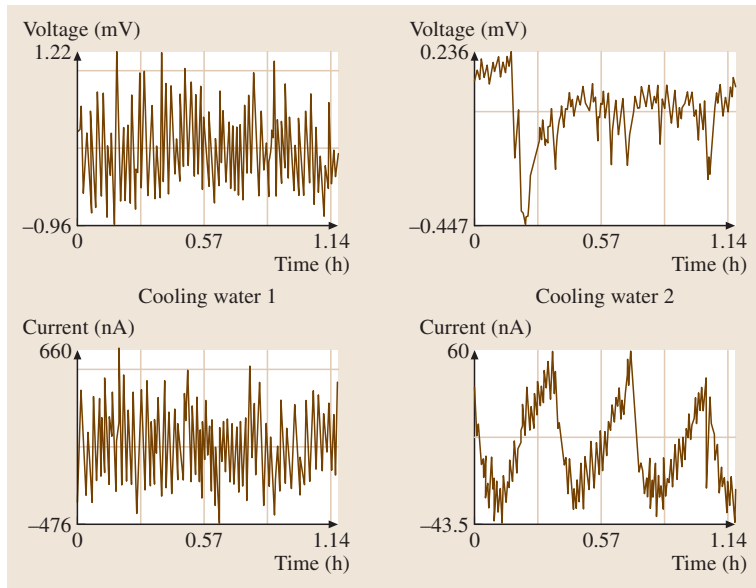

Fig. 12.34 Potential and current noise at mild steel in different cooling waters (after [12.61])

density of the electrochemical voltage-noise relationship [PSD(U)] after the removal of the linear trend was recognized as a significant parameter for distinguishing between uniform and local corrosion. The electrochemical noise generated by uniform corrosion is, white noise, and therefore the slope is close to zero. Electrochemical noise generated by localized corrosion consists of

exponentially decreasing transients and the slope of the PSD(U) curve is higher ($> 12 \text{ dB(V}^2\text{Hz}^{-1}) \text{ decade}^{-1}$). Figure 12.35 shows PSD(U) graphs that, for the uniformly corroding steel in cooling water 1, the slope is $6.3 \text{ dB(V}^2\text{Hz}^{-1}) \text{ decade}^{-1}$, while the slope is $15.3 \text{ dB(V}^2\text{Hz}^{-1}) \text{ decade}^{-1}$ at the locally corroding steel in cooling water 2.

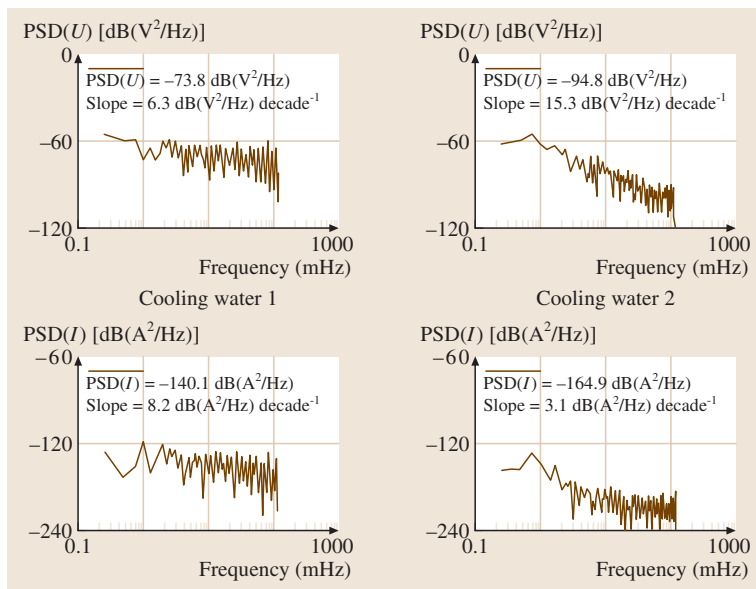

Fig. 12.35 Power-spectral density (PSD) for potential and current noise at mild steel in different cooling waters (after [12.61])

Fig. 12.36 Current noise plot of mild steel in air saturated 1 mass % NaCl solution. Effect of NaNO₂ concentration

Similar results were obtained with Admiralty brass, which generally showed only localized corrosion but with a higher initiation rate of pits in cooling water 2.

These and other results reported in the literature allow one to conclude that ENA can be used for corrosion monitoring with the possibility of distinguishing between uniform and local corrosion.

However, it has been shown [12.65–67] that measuring only potential noise can be misleading in cases where small fluctuations in mass-transport control can produce large changes in the corrosion potential U . Such is the case for metals and alloys that are immune to corrosion such as Pt or are passive, such as stainless steel in neutral, aerated aqueous solutions; e.g. it was found that potential noise plots, as analyzed with the use of power-spectral density (PSD), were similar for Pt and for an Al/SiC metal matrix composite, which pits severely in aerated 0.5 N NaCl. However, the current-noise PSD plots were very different for the two materials. The explanation is that mass transport of oxygen can play a large role in potential noise.

For corrosion monitoring, specifically large-scale corrosion monitoring and field testing, the statistical analysis of noise data resulting in RMS values has many advantages over spectral analysis by FFT or MEM which requires expensive equipment and/or complicated analysis programs. It was shown [12.65] that the noise resistance R_n and the polarization resistance R_p have similar values and trends; therefore theoretical relationships between R_n and R_p are currently investigated. Thus for cases where only qualitative results are needed in a fast, simple and inexpensive way, collection and evaluation of R_n data is sufficient. However, a quan-

titative understanding of electrochemical noise and its relationship to corrosion, specifically to localized corrosion phenomena, can only be achieved through spectral analysis of noise data, leading to the determination of the spectral noise resistance R_{Sn} which shows very strong relations between R_n and R_p [12.66, 67]. The pitting index (PI) defined as

$$PI = \delta I / I_{\text{mean}}, \quad (12.74)$$

where δI is the RMS current noise and I_{mean} the mean coupling current [12.63], appeared not to be applicable for all corrosion systems for the determination of the nature of the corrosion mechanism, specifically localized corrosion; e.g. for the system steel/aqueous salt solution the PI gave misleading results [12.66, 67]. This can be understood considering that I_{mean} in the above definition equation should be close to zero for all cases of uniform corrosion. PI can therefore show large fluctuations independent of the actual corrosion mechanism.

ENA seems to be very useful for investigation of corrosion-inhibitor performance. The great advantage is that only two metal electrodes are necessary to measure a current signal, which indicates high or low general corrosion rates and susceptibility to pitting and other localized corrosion. Figure 12.36 gives an example how in a very short time the critical concentration of a dangerous anodic inhibitor (NaNO₂) for steel corrosion in aerated 1% NaCl solution can be evaluated. In this example two identical mild-steel electrodes were placed in the inhibitor free brine. In the first 20 min considerable current fluctuation indicates typical oxygen corrosion of the steel electrodes. Addition of 2×10^{-3} mol/l NaNO₂ reduces the noise, however, the noise level indicates insufficient inhibition. After another 20 min more NaNO₂ is added to make a NaNO₂ concentration of 4.2×10^{-2} mol/l, which is above the critical concentration of NaNO₂. Consequently the current noise ceases nearly completely, indicating complete inhibition. ENA technology today is advanced enough to be used as a monitoring device for critical inhibitor concentration and the start of localized corrosion.

ENA can also be applied in media with low conductivity and also in multiphase media because, in contrast to other electrochemical methods, it needs no reference electrode which could give measuring problems due to high IR drops and – specifically in oil/water mixtures – plugging or sealing of the diaphragm. In technical systems the life of the reference electrode is also determined by the tendency of the test media to contaminate the electrolyte in the electrode.

12.4 Exposure and On-Site Testing

There is a considerable number of sources of material testing data that have been accumulated over the years and are available to process plant designers to assess the most suitable materials selection for a particular plant and operating conditions. However, many of the factors involved in the selection of an optimum choice are subject to variability, and this makes the choices more complex.

The ranking of the most valuable corrosion data for plant designers is generally understood to be as follows:

1. Operating experience on full-scale equipment under the actual process environment.
2. Operating experience on a pilot plant with similar feedstock and operating conditions.
3. Sample tests in the field, coupons, electrical resistance (ER) probes, or stressed samples exposed to the process environment.
4. Laboratory evaluations on actual plant fluids, or simulated environments.
5. Materials and corrosion database.

It should also be recognized that the economics of the various material selection choices is not constant. A decision that makes economic sense at the design time, or at the materials selection time, may not make sense by the time the plant is actually built or operating. In addition, the economics of plant shutdowns due to failure can depend on the market for the product being generated by the plant, although these costs are generally always upward.

The balance between choice of a more-expensive corrosion-resistant alloy versus the cost of subsequent chemical treatment costs to inhibit corrosion is also subject to change, due to changes in the raw material costs of chromium, nickel, and other constituents in corrosion-resistant alloys. Sometimes a less-expensive material

that would otherwise be unacceptable due to low corrosion resistance can still be the best choice when used with chemical corrosion inhibitors.

Corrosion testing may be conducted in the laboratory, pilot plant, or field. Systems that are either in the design phase or operating benefit from laboratory and pilot plant testing. In situ testing is useful for pilot plant testing and for providing information for systems that are currently operating.

Laboratory tests should simulate the water chemistry and operating conditions of the freshwater system. A sample of water from the system may be used if it is available. Immersion testing and electrochemical testing (Sect. 12.1) are commonly used for laboratory tests.

In situ testing is commonly conducted in pilot plants. This testing is useful in evaluating or monitoring a water-treatment system or the effects of varying operating parameters such as flow rate and temperature. In addition, the performance of different alloys in a system may be studied by in situ testing. In situ testing provides information on uniform corrosion rate, types of corrosion, and pitting tendencies (Sect. 12.4).

In situ testing is also performed in the field to determine the effectiveness of a water treatment system, the performance of difference alloys, and the effects of varying operating parameters such as flow rate and temperature. Uniform corrosion rates, types of corrosion, and pitting tendencies are identified with in situ testing.

Another form of testing the corrosion behavior especially for coatings is atmospheric exposure under various climatic conditions. This type of testing yields more reliable information on the corrosion behavior than testing in climatic chambers. A disadvantage is the long duration of such tests. For reasons of practicability a mixture of laboratory testing and exposure under natural environmental conditions is recommended.

12.5 Corrosion Without Mechanical Loading

By taking into consideration the different causes of corrosion and their mechanisms, as well as the appearance of the attack, one can differentiate between several types of corrosion. A common approach is to distinguish between corrosion systems with or without mechanical loading. In the latter case the result of corrosion is the initiation and propagation of cracks. If only corrosion takes place and there is

no conjoint action of mechanical loading the various forms of corrosion occurring in such systems can either be described as local or uniform. Also corrosion testing is different if mechanical loads have to be included in the test set up. Therefore this section is specifically dedicated to types of corrosion where mechanical loading is unavailable in the system.

Table 12.2 Corrosion rate conversion

	mA cm ⁻²	mm year ⁻¹	mpy	g m ⁻² day ⁻¹
mA cm ⁻²	1	3.28 <i>M/nd</i>	129 <i>M/nd</i>	8.95 <i>M/n</i>
mm year ⁻¹	0.306 <i>nd/M</i>	1	39.4	2.74 <i>d</i>
mpy	0.00777 <i>nd/M</i>	0.0254	1	0.0694 <i>d</i>
g m ⁻² day ⁻¹	0.112 <i>n/M</i>	0.365 <i>/d</i>	14.4 <i>/d</i>	1

where: mpy = milli-inch per year
n = number of electrons freed by the corrosion reaction
M = atomic mass
d = density
Note: you should read the Table from left to right, i. e.:
1 mA cm² = (3.28 *M/nd*) mm y⁻¹ = (129 *M/nd*) mpy = (8.95 *M/n*) g m⁻² day⁻¹
For example, if the metal is steel or iron (Fe), *n* = 2, *M* = 55.85 g and *d* = 7.88 g cm⁻³ and the Table of conversion becomes:

	mA cm ⁻²	mm year ⁻¹	mpy	g m ⁻² day ⁻¹
mA cm ⁻²	1	11.6	456	249
mm year ⁻¹	0.0863	1	39.4	21.6
mpy	0.00219	0.0254	1	0.547
g m ⁻² day ⁻¹	0.00401	0.0463	1.83	1

Note: you should read the table from left to right, i. e.: 1 mA cm² = 11.6 mm y⁻¹ = 456 mpy = 249 g m⁻² day⁻¹

12.5.1 Uniform Corrosion

Uniform corrosion is given when a metal is corroding with the same rate over the whole surface of the metal exposed to the corrosive environment. The extent can be given by the weight loss per unit area or the average penetration, which is the average of the corrosion depth. This can be determined by direct measurement or by calculation from the weight loss per unit area when the density of the material is known. Uniform corrosion takes place as a rule via the effect of corrosion cells without clearly defined anode and cathode surfaces. A prominent case for uniform corrosion is the rusting of railways due to atmospheric exposure. From a technical standpoint uniform corrosion is quite easy to handle because the design engineer must only include an additional thickness to the material which equals the loss due to corrosion over the life time of the structure.

Uniform corrosion rates may be determined by weight loss or electrochemical methods. Both methods average a specimen's corrosion rate over its surface area. Corrosion rates calculated from weight-loss data also average the loss over the exposure period. Electrochemical methods may yield instantaneous or time-averaged corrosion rates. Weight-loss testing is performed by immersing a coupon in a test solution either in the laboratory or in situ. Another method is exposing a metal

or a coated specimen to a specific environment (atmosphere) or a climatic chamber and measure the corrosion loss over a certain period of time. It should be noted that measurements carried out in climatic chambers very rarely correspond to the behavior of a material under practical conditions. Therefore investigations in the laboratory are mostly advisable for comparing different materials and give a ranking on their sensitivity to corrosion in a laboratory environment than to get reliable information on their performance in service.

There is a correlation between the electrical parameters and the weight loss of the material. Table 12.2 yields information how the values correspond. The following charts provide a simple way to convert data between the most common corrosion units in usage, i. e. corrosion current (mA/cm²), mass loss [g/(m² · day)] and penetration rates (mm/y or mpy) for all metals or for steel.

Another important factor for determining uniform corrosion and its rate of corrosion is the removal of corrosion products from the surface to measure the corrosion loss in weight units.

There are a large number of chemical solutions available for the different materials used in practice to remove oxide layers from surfaces. Table 12.3 yields information on typical solutions for various materials.

Table 12.3 Some solutions used to remove corrosion products from metals

Metal	Corrosion products	Reagents and temperature

12.5.2 Nonuniform and Localized Corrosion

In contrast to uniform corrosion nonuniform or localized corrosion is corrosion attack that is preferentially concentrated on discrete sites of the metal surface exposed to the corrosive environment. Localized corrosion can result in, for example, pits, cracks, grooves or scars. In any case it is the occurrence of a local nonuniform attack due to the build up of corrosion cells over the metal, which means a local and uneven distribution of anodic and cathodic sites over the metal surface. What makes the case worse is the comparatively high corrosion rate at the anodic sites and, especially in pitting or crevice corrosion, self-accelerating processes occur in the course of the corrosion process. Therefore pitting and crevice corrosion are the most prominent and dangerous forms of corrosion attack as well as intercrystalline corrosion which can be encountered along or in the vicinity of grain boundaries.

Pitting

Pitting is localized corrosion which results in pits in the metal surface (Fig. 12.37). This type of corrosion gener-

ally takes place in corrosion cells with clearly separated anode and cathode surfaces. The anode is situated in the pit and the cathode usually on the surrounding surface (Fig. 12.38). Pitting usually results in worse damage than uniform corrosion because it can lead to perforation in a very short period of time.

When evaluating attack caused by pitting the following should be taken into account:

- the number of pits per unit area,
- the diameter of the pits, and
- the depth of the pits.

The number of pits per unit area and the pit diameter are easily determined by comparison with a pictorial standard. In the case of pit depth it is usually the maximum depth that is determined. In some cases this means the depth of the deepest pit observed on the sample examined, but in others the mean value of, for example, the five deepest pits. The depth of the pits can be measured with a microscope by focusing first on the bottom of the pit and then on the surface of the uncorroded metal. In this way the distance between the two focusing levels is obtained. The depth of pitting can also be determined

Fig. 12.37 Pitting in stainless steel

Fig. 12.38 Principle of pitting corrosion

with a micrometer or by cutting a cross section through the pit followed by direct measurement – possibly with the aid of a microscope.

The ratio of the maximum pit depth (P_{\max}) and the average penetration (P_{aver}) is called the *pitting factor* (F) (Fig. 12.39)

$$F = \frac{P_{\max}}{P_{\text{aver}}} \quad (12.75)$$

Pitting can occur in most metals. Amongst passivated metals this type of corrosion is initiated only above a certain electrode potential, the *pitting potential*.

Especially stainless steels where the protective effect results from passivation of the steel are prone to pitting under certain environmental conditions. Stainless steels are iron-based alloys in which chromium is the main alloying additive at a concentration of at least

Fig. 12.39 Pitting factor $F = P_{\max}/P_{\text{aver}}$ (after [12.10])

12%. Because of the chromium content, stainless steels are easily passivated and hence have good corrosion resistance in many of the more common environments. In unfavorable conditions, however, even stainless steels can be subject to, for example, uniform corrosion, pitting, crevice corrosion, intergranular corrosion or stress corrosion cracking.

One can distinguish between different types of stainless steels depending on their structure, e.g. ferritic, austenitic and ferritic–austenitic steels. Differences in structure convey differences in corrosion characteristics and even differences in weldability, hardening capacity and magnetic properties. Ferritic and ferritic–austenitic steels are magnetic in contrast to pure austenitic steels.

The Active and Passive States

The conditions for passivation are shown in the anodic polarization curves of the steels. If, in the case of a stainless steel in sulphuric acid solution, the electrode potential is increased then the current density rises to a maximum, with dissolution of the metal taking place in the *active state*; the current density is an expression of the dissolution rate. At a certain potential, the *passivation potential*, the corrosion current density is drastically reduced and the metal surface becomes *passivated*. Passivation is associated with the formation of a thin, protective coating which largely consists of a mixed iron–chromium oxide and hydroxide. If the potential is further increased to very high values the current density will increase again as a result of, so-called, *transpassive corrosion*.

Mechanism of Pitting and Crevice Corrosion

When using stainless steel in an environment with a high chloride content, such as sea water or the bleaching liquors used in the pulp industry, *localized corrosion* will often occur in the form of pitting – which can some-

times result in perforation of pipe walls – or in the form of *crevice corrosion*, e.g. in flanged joints. These two corrosion types are related.

Stainless steels are sensitive to localized corrosion, especially in the presence of halogen ions. Amongst these the chloride ion is the most corrosive and also of greatest practical importance.

Addition of sulphide considerably increases the corrosiveness of the environment and may take place, e.g. due to the dissolution of sulphide inclusions in the steel surface.

Pitting in stainless steel also affects the shape of the anodic polarization curve. Thus, if the potential is increased above a certain critical value, referred to as the breakdown potential, the current density will begin to increase and the curve often shows thereafter a series of current peaks. Since this rise marks the beginning of pitting the breakdown potential is in this case called the *pitting potential*. If the potential is then decreased, passivation is achieved again, but only when a *protection potential*, which is a little below the pitting potential, is reached. A similar development occurs with corrosion in crevices or under surface deposits. The existence and value of the pitting potential can be demonstrated by using an auxiliary electrode and an applied voltage. In practice, the presence of an oxidizing agent, e.g., oxygen, chlorine or peroxide, in the solution is often sufficient to raise the potential to the pitting value with consequent attack. The breakdown potential is not a well-defined constant but depends to a large extent on conditions such as chloride concentration, temperature and the method of measurement.

Localized corrosion is observed only after a certain incubation time during which the initiation of the attack takes place. This is followed by the propagation stage and the growth of the pit. Both initiation and propagation take place by a mechanism which involves electrochemical corrosion cells.

Many mechanisms have been proposed for the *initiation stage*. In some the initiation can consist of a new, unpassivated metal surface being created as a result of the dissolution of sulphide or sulphide/oxide inclusions in the surface. This could then lead to an acidic solution containing a high sulphide content developing in the incipient cavities; these conditions would not allow passivation of the stainless-steel surface to occur at these sites. In other cases, initiation can be associated with depletion of oxygen in a crevice or under a deposit. This would give rise to an oxygen concentration cell with the anode in the crevice or under the deposit, and the cathode outside these regions. Hydrolysis of anodically

dissolved metal ions in the various situations gives rise to acidic, unpassivating conditions at anodes.

When localized attack has been initiated and the growth has reached steady-state conditions then the process can be said to have reached the *propagation stage*. Certain characteristic conditions now prevail in the pit, as detailed below.

The pH value is lower than in the bulk of the solution because anodically dissolved metal ions, such as Fe^{2+} and Cr^{3+} have been hydrolyzed with the formation of oxides, hydroxides or hydroxide salts, thus releasing hydrogen ions. The actual pH value will depend on the composition of the steel and will be lower the more corrosion resistant the steel. Often a pH value of 0–1 can arise.

The solution in the pit has a higher chloride concentration than the bulk of the solution. This is because chloride ions migrate against the electric current in through the mouth of the pit. In practice a chloride concentration as high as 5 M can occur in the pit.

The resistance of stainless steels towards localized corrosion can be *evaluated* by:

- determination of the breakdown potential, i.e. the pitting potential or crevice corrosion potential; this can be done by recording the anodic polarization curve in a solution of chloride [American Society for Testing and Materials (ASTM) G 61],
- determination of the critical pitting temperature (c.p.t.) and the critical crevice corrosion temperature (c.c.t.); the c.p.t. or c.c.t., is the lowest temperature at which attack takes place, while maintaining the stainless steel at a constant potential.
- total immersion testing in a suitable corrosive agent, e.g. ferric chloride solution (ASTM G 48), followed by measurement of the maximum pit depth; in this type of test an elastic string or plastic disc is pressed against the test piece and the depth of attack is measured at the points of contact after the exposure period.

Crevice Corrosion

Corrosion which is associated with a crevice and which takes place in or immediately around the crevice, is called *crevice corrosion*. In some cases crevice corrosion can simply be caused by corrosive liquid being held in the crevice, while surrounding surfaces dry out. If the crevice and the surrounding metal surfaces are in a solution, the liquid in the crevice can be almost stagnant. As a result of corrosion in the crevice the conditions there can be changed; for example, the pH value can decrease

Fig. 12.40 Principle of crevice corrosion

and the concentration of chloride increase, and as a consequence the corrosiveness can be higher in the crevice than outside (Fig. 12.40).

When stationary conditions have been established, anodic attack of the metal usually takes place near the mouth of the crevice, while cathodic reduction of oxygen from the surroundings takes place on the metal surfaces outside:

Crevice corrosion can take place in most metals. The risk of crevice corrosion should be especially heeded with passive metals, e.g. stainless steel.

Crevice corrosion not only takes place in the crevices between surfaces of the same metal, but also when the metal is touching a nonmetallic material. A combination of crevice corrosion and bimetallic corrosion can take place when two different metals form a crevice. The presence of Cl⁻, Br⁻ or I⁻ ions generally accelerates this type of corrosion. As in the case of pitting, crevice corrosion is initiated only above a certain electrode potential.

Deposit Corrosion

Corrosion which is associated with a deposit of corrosion products or other substances and which takes place under or immediately around the deposit is called *deposit corrosion*.

This type of corrosion is caused by moisture being held in and under the deposit. Because the movement of water is poor, corrosive conditions can be created under the deposit in a similar way to that described in crevice corrosion. The result is that a corrosion cell is formed with the anode under the deposit and the cathode at, or just outside, the edge.

Deposit corrosion is found, for example:

- under the road-mud in the wheel arch of a car,
- under leaves which have collected in guttering, and
- under fouling on ships' hulls and in sea-water-cooled condensers.

Selective Corrosion

Selective corrosion can be found in alloys and results from the fact that the components of the alloy corrode at different rates.

The most well-known example of selective corrosion is the *dezincification* of brass. During dezincification the zinc is dissolved selectively, while the copper is left as a porous mass having poor structural strength. Similar corrosion processes are the *dealuminization* of aluminium bronze and the *selective dissolution of tin* in phosphor bronze.

Graphitic corrosion in grey cast iron provides another example of selective corrosion where the metallic constituents of the iron are removed. The remaining graphite allows the object concerned to maintain its shape but its strength and weight are severely reduced.

Intergranular Corrosion

Intergranular corrosion means corrosion in or adjacent to the grain boundaries of the metal. Metals are usually built of crystal grains. When a metal solidifies or is heat treated, several processes take place which cause the grain-boundary region to take on other corrosion characteristics than the main mass of the grain.

Intergranular corrosion can occur in most metals under unfavorable conditions. Most well known is intergranular corrosion in stainless steel (Fig. 12.41) as a consequence of chromium carbide formation when the carbon concentration is too high and unfavorable heat treatment has occurred, e.g. in the heat-affected zone along a weld.

Intergranular corrosion can occur in certain types of stainless steel which have a high carbon content (0.05–0.15% C). This can take place if the stainless steel is heat treated so that chromium carbide precipitates in the grain boundaries and the material is subsequently

exposed to an acidic solution or sea water. The precipitation of chromium carbide takes place only under certain conditions, for austenitic steel this is in the temperature range 550–850 °C. The steel is then said to be *sensitized*. The carbide precipitation results in a narrow zone near the grain boundaries becoming so depleted in chromium that the steel loses its stainless character.

Sensitization is not restricted to manufacturing heat-treatment processes. It can also occur as a result of welding, since a region of the metal near the weld will pass through the above temperature range. On exposure to a corrosive environment the chromium-depleted zones, together with the remaining parts of the grains, form corrosion cells. In these the chromium-depleted metal acts as the anode and is attacked, resulting in intergranular corrosion.

Intergranular corrosion does not usually influence the shape of the object but the strength characteristics can be catastrophically reduced. In a chloride environment, e.g. sea water, the attack can be visible as pitting. Intergranular corrosion also results in the loss of metallic sound when the affected component is struck.

Countermeasures are designed so as to counteract the precipitation of chromium carbide, which is the cause of the sensitization. The following possibilities exist:

- the choice of stainless steel with a low carbon content ($< 0.05\%$ or preferably $< 0.03\%$),
- the choice of steel which has been *stabilized* by the addition of titanium or niobium, which bind the carbon as carbides so that the formation of chromium carbide is prevented,
- the shortest possible time at 550–850 °C and
- *solution heat treatment*; the material is heated to about 1050 °C to dissolve precipitates of chromium carbide that have formed, followed by subsequent rapid cooling so that new chromium carbide precipitates have no time to form.

The resistance of stainless steel to intergranular corrosion can be evaluated through:

Fig. 12.41 Intercrystalline corrosion

- *Strauss test* (ASTM A 262 practice E); the test piece is exposed to a boiling copper sulphate solution containing sulphuric acid and metallic copper; after exposure the test piece is deformed by bending, and the surface is then examined for cracks,
- *Streicher test* (ASTM A 262 practice B); the test piece is exposed to a boiling ferric sulphate–sulphuric acid solution for 120 h; after the exposure the weight loss of the test piece is determined, and
- *Huey test* (ASTM A 262 practice C); the test piece is exposed to a boiling 65% nitric acid solution; evaluation consists of determining weight loss; Huey testing is particularly significant for material that is to be used in strongly oxidizing media.

Layer Corrosion

With *layer corrosion* the attack is localized to internal layers in wrought metal. As a rule the layer is parallel to the direction of processing and usually to the surface. The attack can result in the unattacked layers becoming detached and looking like the pages in a book. But the result can also be the formation of blisters swelling the metal surface, because of the voluminous corrosion products. Layer corrosion is rather unusual. It is best known amongst certain aluminium alloys.

12.6 Corrosion with Mechanical Loading

When investigating corrosion systems it is advisable to distinguish between corrosion systems where no external mechanical load is applied or residual stresses are present and systems which include influences of me-

chanical stresses. The distinction is useful because the forms of corrosion involved are different from their appearance as well as their mechanistic background. The same considerations apply for the test methods. Testing

of corrosion systems where mechanical stress is part of the environmental conditions the metal is subjected to means to study the influence of additional parameters, e.g. mechanical stress or strain, which may be supplied to the material in a static or dynamic regime. In summary this requires the study of the interaction of all parameters involved and very often the mechanical parameters are of higher importance with respect to the corrosion behavior than the electrolytic conditions.

There is also completely different equipment and evaluation of test data. The introduction of mechanical stresses into the test system needs an apparatus to supply stresses or strains to the system in a static or dynamic manner and the type of specimen may be smooth, notched or precracked, depending on the specific parameter to be studied (crack initiation or propagation).

12.6.1 Stress Corrosion

General

Stress corrosion cracking means crack initiation and propagation in the presence of certain corrosive media under static tensile stresses. In some cases residual stresses within the material are sufficient to initiate this form of corrosion. Contrary to most other manifestations of corrosion, the failure, due to a sudden brittle fracture, often occurs without formation of detectable corrosion products and is not necessarily characterized by any previously occurring visible damage.

For assessing the corrosion, parameters of the medium as well as of the material are important. In practice, where complex corrosion conditions often exist, adequate knowledge of the corrosion process is therefore required in the evaluation of failures. Stress corrosion cracking can be subdivided into an initiation and a propagation process. In theory, such a differentiation is possible, but experimentally it is very difficult to detect as the two processes overlap during the stepwise progress of the cracking [12.68]. Furthermore, metal surfaces often have incipient cracks and crevices already present in the as-delivered state which could act as crack nuclei, which means that crack initiation in such cases is not necessary at all.

Considerable differences can be found when comparing experimentally determined crack-growth rates of various metal/environment systems. This immediately indicates that stress-corrosion cracking cannot be explained satisfactorily by only one theoretical model. The spectra of the proposed mechanisms range from models where crack growth is regarded as a very fast local metal dissolution at the crack tip to models that assume

that the adsorption of certain species of the medium at the metal surface weakens the binding forces between the metal atoms and favors brittle fracture along the cleavage planes. A comparison of both mechanisms shows that in the first case hydrogen-induced and in the second case brittle fracture is the predominant factor. Between both cases various transitions are possible which means that the degree of the corrosion effect is also different [12.68].

When discussing stress corrosion cracking a differentiation has to be made between an anodic and a cathodic mechanism. Stress corrosion cracking is usually described as anodic when the propagation rate is equivalent to the anodic metal dissolution rate at the crack tip. Cathodic stress corrosion cracking (HISCC) results from the embrittlement of the material due to hydrogen, which is generated by cathodic hydrogen evolution at the metal surface. Although the external appearance of the damage in both cases shows similarities, the mechanisms responsible for the failure are different.

Anodic Stress Corrosion Cracking

Anodic stress corrosion cracking requires several preconditions: (i) the electrolyte must have a specific effect on the material, (ii) the material itself has to be susceptible to stress corrosion cracking, and (iii) the tensile stresses have to be sufficiently high. The stress corrosion cracking susceptibility of a material is not a material property comparable to the tensile strength but a manifestation which the material shows under specific conditions. It is based on a three-component system consisting of the material (strength, microstructure, surface condition), mechanical stresses (external stresses, residual stresses) and a specific electrolyte. Furthermore the existence of protecting layers on the metal surface is a necessary but not sufficient prerequisite for initiation of stress corrosion cracking. Local damage of this surface layer – which could result from chemical as well as mechanical effects – provides starting points for crack formation. The mechanisms of crack propagation can be subdivided into two groups. The first group considers stress corrosion cracking as selective electrochemical metal dissolution at the crack tip while the other group supposes that the reduction of binding forces of the atoms at the crack tip in the presence of specific ions or molecules is responsible [12.69].

Test Methods for Stress Corrosion Cracking

Corrosion systems with simultaneous corrosion load and mechanical stresses are very complex as the con-

ditions change with time and the changes resulting from the parameter interactions are often difficult to interpret. It is therefore necessary to set up stress corrosion cracking tests in such a way that the main parameters are clearly defined and measured during the test. The existing literature provides standards [12.70, 71] and summaries [12.72] in which all relevant aspects are presented and discussed. In the next section the main parameters will be discussed on the basis of these references as these provide a basis for a practice-related test method for assessing the susceptibility of prestressing steels. Nearly all mechanical types of stress have been used for investigating prestressed steels.

Aim of Stress Corrosion Test

From the definition of stress corrosion it is clear that stress corrosion cracking is a special case of stress corrosion and that under certain circumstances corrosion will not lead to the formation of cracks.

Although there is an agreement that crack formation is the normal test result, other manifestations have also been found like intergranular corrosion or elongated fine cracks which are intensified in the presence of stresses.

There is a large variety of methods to assess the stress corrosion cracking properties of metals. Each of them has its specific advantages and disadvantages.

It is important to recall that the term test in connection with the resistance or susceptibility to stress corrosion cracking has a special meaning. Whether stress corrosion cracking occurs in a certain case or not depends on the environmental and mechanical conditions as well as the material properties of the material. The word susceptibility does not describe a material property or quality which can be related to an overall valid scale as the ranking of a series of alloys can be very different depending on the exposure conditions.

In an ideal case for a given application the likelihood of occurrence of stress corrosion cracking can only be determined by carrying out simulation tests under all possible exposure conditions. In practice this is difficult and sometimes even impossible. Therefore, on the basis of practical experience, a certain number of standard test methods have been developed which give useful guidance for the likely practical behavior in specific cases of application. These laboratory standard test methods are only suitable for such practical conditions if they are based on experience or where relevant relations exist, even if they are only empirical.

The fact that a given material may or may not pass a test which was previously useful for another material may not be significant and, similarly, a test which

correctly distinguishes between two materials for one application does not necessarily provide reliable evidence when exposure conditions are different. Therefore the use of a standard test for conditions outside the scope of the test requires validation.

Selection of the Test Method

Prior to starting a programme for stress corrosion cracking testing it is necessary to decide which kind of test is suitable. Such a decision mainly depends on the purpose of the test and the type of information to be obtained. While some test methods try to simulate practical conditions as far as possible, this being of great value to plant engineers, other tests are directed towards evaluating certain mechanistic effects of failure. In the first case limitations with respect to e.g. material, space, time etc. can lead to relatively simple test methods while under different conditions refined methods are necessary. For example, investigations on the crack growth rate can require the use of cracked specimens, but these are unsuitable for evaluating the effects of surface treatments. Although improved techniques are available the use of a simple test can be valuable for conditions where the more complicated techniques cannot be used.

In selecting a test method which only gives a failure/non-failure result it is important to ensure that it is not so severe that it leads to rejection of a material which has already proven its suitability in a special practical application. On the other hand it must not be so mild that it encourages the use of a material under conditions which could lead to rapid failure.

In general the aim of a stress corrosion cracking test is to obtain quicker information on the prediction of practical behavior than is possible from practical experience. There are various possibilities to achieve this, such as using higher stresses, continuous slow straining, cracked specimens, higher concentration of certain substances in the test environment and higher temperatures, i.e. compared to service conditions, and also electrochemical stimulation. However, it is very important that the methods used and parameters selected do not change the details of the failure mechanism.

Loading Systems

General. The methods for loading the specimens (smooth, notched or cracked) are usually classified as follows:

- constant strain
- constant load
- slow strain rate

In the case of cracked specimens the limiting conditions are defined by the critical threshold stress intensity factor K_{ISCC} .

Tests with Constant Strain

The various types of bending tests that are in use often belong to this category. These can simulate stresses from production which are often the cause for failures in service conditions.

The advantage of bending tests is the use of simple and hence often cheap specimens and clamping devices. Problems with this kind of tests usually result from the low reproducibility of the stress level – if indeed this can be measured at all. Tests to improve this situation have led to refined types of bending tests, e.g. four-point loading instead of three-point loading. But the limitations of the simple bending theory which is usually used to calculate the stress level can lead to errors, especially if straining beyond the elastic limit is necessary. The application of strain gauges to measure the stresses at the surface can be useful. The preparation of bend-shaped parts for U-formed bending specimens introduces significant plastic deformation which could affect crack initiation.

Tensile tests with constant strain are sometimes preferred to bending tests as the application and calculation of the stress is simplified. However, more massive stressing frames are required than for bending specimens of similar cross section.

Apart from affecting the value of the maximum initial load the stiffness of the frame can also affect the time to failure of the specimen. In most of the tests with constant strain, especially when testing ductile materials, the initial elastic elongation is partly converted into plastic deformation as the crack formation proceeds.

The magnitude of any loading relaxation can differ from specimen to specimen and can affect the time to failure of the specimen depending on the number of pits or cracks that are present. In the case of specimens with many cracks or pits considerable relaxation can be observed while in the presence of only a few cracks little relaxation can be observed. Thus if only one single crack occurs it does not necessarily have to grow to a considerable size for sudden failure (fracture) of the specimen to occur as the applied load will remain high. On the other hand the significant relaxation of the loading that takes place in the presence of many stress corrosion cracks means that these cracks have to proceed further to reach a size that will be sufficient to generate stress conditions for a sudden fracture to occur at relatively low loading.

Tests with Constant Load

These tests are more suitable for simulating failures due to stress corrosion cracking brought about by loads or stresses occurring in practice. As the effective cross section of a specimen is reduced by propagating crack formation tests with constant load include an intensified stress situation. Hence, it is more probable that such tests will lead to an earlier failure or fracture compared to tests with constant total elongation.

Tests with constant load lead to an increasing stress situation as the initiated cracks continue to grow and therefore it is more unlikely that cracks, once started, will be arrested in these tests than those in a constant strain test below the critical stress threshold. As a consequence, in any particular system the value for the critical stress threshold is probably lower when determined under constant load than under constant strain.

Tests with Slow Strain Rate

The application of dynamic slow straining, which originally was only employed as a quick selection test, has now become more important for simulating conditions in practice.

This method includes a relatively slow strain or deformation rate (e.g. 10^{-6} s^{-1}) of a specimen under defined environmental conditions, which is continued until fracture occurs.

For stress corrosion cracking, crack propagation rates are generally in the range of 10^{-3} to $10^{-6} \text{ mm s}^{-1}$ which means that in laboratory tests under constant total strain or constant loading failure of specimens with usual dimensions will take place within a few days. This has also been observed in practice in those systems where stress corrosion cracking can easily be initiated. On the other hand it is common experience that specimens do not fail even after very long testing times; for such situations the test will be stopped after an arbitrary time period.

The first applications of this test procedure were aimed at getting data to compare the effects of such variables as material composition and microstructure or the addition of inhibitors to stress corrosion cracking initiating environments. It was also used to initiate stress corrosion cracking for material /environment combinations which did not show crack formation under constant load or constant total strain in the laboratory. This means that this test is relatively severe as it often initiates failure of the specimen due to stress corrosion cracking where other types of loading of smooth specimens did not lead to crack formation. In view of that it must be classified

in the same category as tests with precracked specimens where the failure of the specimen is also inherent to the test.

Composition of Test Solution

Although it is unavoidable that the medium is a very important factor for SCC tests, some of the solutions are often used in combination with special alloys. Two examples are boiling MgCl solution for stainless steels and boiling nitrate solutions for carbon steels. Such solutions have been criticized for various reasons; most importantly because they do not represent practical service conditions. This can be very significant, because relative susceptibilities of a series of materials are not always the same in different media.

The effect of a change in the pH value is well known in the case of general corrosion in electrolytes, and as far as corresponding experiments exist, such effects are no less obvious with SCC. Changes of media pH value during a test can be as important as the initial pH value. Any change of pH value during a test will depend on solution volume, surface area of exposed specimen and time. Use of a relatively large solution volume combined with a small surface area of the metal or replenishment or exchange of solution during the test is likely to lead to a smaller pH change and therefore a different time to failure of the test specimen than would be the case with a small solution volume and large metal surface.

Small changes of O concentration can have significant influence where oxygen plays an important role in corrosion reactions causing crack initiation.

Electrochemical Aspects

Free corrosion experiments, i. e. at the free corrosion potential, can be used for reference and serial experiments. They are always problematic if the corrosion medium does not contain a defined redox system with enough redox capacity since electrochemical reactions can change with time. Controlled electrochemical experiments can be used to determine the dependence of SCC on potential and to obtain information on the effect of system parameters on the potential. These parameters include, for instance, the redox systems of aggressive environments and, under special circumstances, the alloying components of the metal. Controlled electrochemical experiments have been used to achieve a reduction in the time to failure of the specimen by setting the test electrochemical conditions to give maximum susceptibility to SCC. In such cases care has to be taken that the corrosion type and mechanism do not change. This can be examined by metallographic analysis.

Discussion and Evaluation of Results

In tests under constant load, the SCC sensitivity of different materials can only be assessed by determination of the following values:

- fracture: yes/no;
- cracks: yes/no;
- depth and amount of cracks.

An assessment of relative resistance to SCC of different materials based only on the time to failure is not possible, for the reasons given above. Tests with slow strain rate provide the following evaluation possibilities for determining SCC susceptibility. For experiments continued until fracture:

- (a) depth of secondary cracks;
- (b) elongation after fracture;
- (c) reduction of area;
- (d) breaking load.

For experiments finished before fracture:

- (e) experimental duration and measured crack depth.

Evaluation regarding (a) and (e) is usually more sensitive than (b–d). Information regarding the SCC behavior of a system can more easily be obtained if the mechanical values (b–d) are related to values measured in an inert environment (air, oil).

In general, a metallographic evaluation of the specimen following the experiment is necessary to determine reliably the resistance to SCC of metallic materials using the slow-strain-rate test method. For other types of tests metallography is also in many cases the only method for the reliable detection of SCC and for distinguishing different types of SCC. The average or maximum depth of secondary cracks and resulting crack growth rates can be used as the basis for comparison tests.

12.6.2 Corrosion Fatigue

Corrosion fatigue is a process which involves conjoint corrosion and alternating straining of the metal, often leading to cracking. It may occur when a metal is subjected to cyclic straining in a corrosive environment. Corrosive or otherwise chemically active environments can promote the initiation of fatigue cracks in metals and alloys and increase the rate of fatigue crack propagation. Corrosion fatigue processes are not limited to specific metal/environment systems and reliable estimates of fatigue life for all combinations of loading and environment cannot be made without data from laboratory tests.

Regarding the parameters involved in the process there are some similarities between stress corrosion cracking and fatigue but especially the mechanical loading is different. For testing a metal's resistance to corrosion fatigue in general two types of test have been developed: cycles to failure testing (ISO 11782-1) and crack propagation testing (ISO 11782-2).

Cycles to Failure Testing

In the presence of an aggressive environment the fatigue strength of a metal or alloy is reduced to an extent which depends on the nature of the environment and the test conditions. For example, the well-defined fatigue strength limit observed for steels in air may no longer be evident as illustrated in Fig. 12.42. Interpretation of results is then based on the assumption of an acceptable life of the component.

The test involves subjecting a series of specimens to the number of stress cycles required for a fatigue crack to initiate and grow large enough to cause failure during exposure to a corrosive or otherwise chemically active environment at progressively smaller alternating stresses in order to define either the fatigue strength at N cycles,

Fig. 12.42 Schematic comparison of S - N behavior during fatigue and corrosion fatigue for steel. Key: 1 fatigue in air, 2 fatigue limit in air, 3 corrosion fatigue (no fatigue limit)

S_N , from an S - N diagram or the fatigue strength limit as the fatigue life becomes very large.

The test is used to determine the effect of environment, material, geometry, surface condition, stress, etc., on the corrosion fatigue resistance of metals or alloys subjected to applied stress for relatively large numbers of cycles. The test may also be used as a guide to the selection of materials for service under conditions of repeated applied stress under known environmental conditions.

Specimens

The design and type of specimen used depends on the fatigue testing machine used, the objective of the fatigue study and the form of the material from which the specimen is to be made. Fatigue test specimens are designed according to the mode of loading, which can include axial stressing, plane bending, rotating beam, alternate torsion or combined stress.

Specimens may have circular, square, rectangular, annular or, in special cases, other cross sections.

The gripped ends may be of any shape to suit the holders of the test machine. Problems may arise unless the gripped portion of the specimen is isolated from the corrosive test environment.

The test section of the specimen shall be reduced in cross section to prevent failure in the grip ends and should be of such a size as to use the middle to upper ranges of the load rating of the fatigue machine to optimize the sensitivity and response of the system. The transition from the gauge section to the gripped ends of the specimen shall be designed to minimize any stress concentration. It is recommended that the radius of the blending fillet should be at least eight times the specimen test section diameter or width. The cross-sectional area of the gripped ends should, where possible, be at least four times that of the test section area. The test section length should be greater than three times the test section diameter or width.

For tests run in compression, the length of the test section shall be less than four times the test section diameter or width in order to minimize buckling. For the purposes of calculating the load to be applied to obtain the required stress, the dimensions from which the area is calculated shall be measured to within 0.02 mm. Specimens should be identified by an indelible marking method, such as stamping, on surface areas, preferably on the plain ends, without having an influence on the test results. Specimens should be stored after appropriate cleaning under desiccated conditions prior to testing in order to avoid corrosion which may influence the test results.

Cylindrical Specimens

Two types of specimens with circular cross section are frequently used for corrosion fatigue tests:

1. Specimens with tangentially blending fillets between the test section and the grip ends; these are suitable where axial loading is employed;
2. Specimens with a continuous radius between the grip ends with the minimum diameter at the center; these are suitable for rotating bend tests.

A minimum cross-sectional diameter of 5 mm is preferred.

Flat Sheet or Plate Specimens

Flat specimens for fatigue tests are reduced in width in the test section and may have thickness reductions.

If the specimen thickness is less than 2.5 mm, and the tests are performed in compression, provisions for lateral support should be made to prevent buckling without affecting the applied load by more than 5%.

The most commonly used types include:

1. Specimens with tangentially blending fillets between the test section and the grip ends;
2. Specimens with a continuous radius between the grip ends.

Notched Specimens

The effect of machined notches on corrosion fatigue strength can be determined by comparing the S – N curves of notched and unnotched specimens.

The data for notched specimens are usually plotted in terms of nominal stress based on the net cross section of the specimen.

The effectiveness of the notch in decreasing the fatigue limit is expressed by the fatigue notch factor K_f (the ratio of the fatigue limit of unnotched specimens to the fatigue limit of notched specimens).

The notch sensitivity of a material in fatigue is expressed by the notch sensitivity factor q

$$q = \frac{K_f - 1}{K_t - 1}, \quad (12.78)$$

where K_t is the stress concentration factor; $q = 0$ for a material that experiences no reduction in fatigue limit due to a notch; $q = 1$ for a material where the notch exerts its full theoretical effect.

If the standard size cannot be met other specimen configurations can be used with appropriate caution.

Specimen Size Effects, Surface Condition and Environmental Considerations

Size effects can be important in fatigue for several reasons, including residual stress distribution, variations in the stress gradient across the diameter (plain or notched specimens in bending or tension and notched specimens in axial tension–compression loading), variations in surface area, variations in hydrogen concentration gradient (in appropriate environmental conditions). There is a tendency for the fatigue strength to decrease as the specimen size increases but this may not always be the case. The size effect means that it can be difficult to predict the fatigue performance of large components directly from the results of laboratory tests on small specimens.

Corrosion fatigue properties can be very sensitive to surface condition since fatigue cracks usually initiate at the surface. In general, fatigue life increases as the magnitude of the surface roughness decreases. Therefore, attention must be paid to the surface preparation of corrosion fatigue test specimens. Unless it is required to investigate the behavior of an as-manufactured surface, it is recommended that a metallographically polished surface free of machining grooves and scratches should be used. The direction of polishing can be important and in axial loading the final surface preparation should involve grinding, or polishing in the longitudinal direction, i. e. in the same direction as the applied stress.

Other important parameters which must be considered in the test design and evaluation include surface and residual stress and microstructural surface effects. More detailed information on these topics is given in the relevant standards. For environmental factors all considerations presented in Sect. 12.5.1 on stress corrosion cracking apply.

Stressing Considerations

Cyclic Frequency. Cyclic frequency is of far greater importance when cycles to failure tests are conducted in aggressive environments rather than in air, where cyclic frequency usually has little, if any, effect. This sensitivity to frequency is due to time-dependent processes associated with the material–environment interaction. In a narrow context this may simply reflect the timescale of overall testing for significant pit development but more broadly the cycle period affects the extent of reaction or transport during a load cycle and consequently the extent of crack advance.

In the presence of an aggressive environment the fatigue strength of a metal or alloy generally decreases as the cyclic frequency is reduced. It is important, therefore,

that a cyclic frequency relevant to the service application be used during testing.

Waveform

In some cases, corrosion fatigue strength is strongly affected by the waveform of the loading cycle. This is particularly so where the cycle incorporates hold times during which time-dependent corrosion or stress corrosion processes may influence crack initiation and growth.

The rate of loading and unloading may also influence environmental effects if these involve, for example, diffusion or repassivation processes. It can be important, therefore, to employ a waveform representative of that encountered during service. Sinusoidal, triangular, sawtooth and square waveforms are often employed to simulate service loading conditions and, where appropriate, hold times can be imposed during the cycle.

Variable-Amplitude Loading Patterns

Some practical applications involve exposure to random loading cycles or to well-defined periodic changes in

Fig. 12.43 Corrosion fatigue crack propagation rate as a function of the range of the stress intensity factor

the cyclic loading conditions. While some insight into the influence of these fluctuations may be gained by the summation of the effects observed during a series of tests under different loading conditions, it is preferable to simulate the service conditions by computer control using block or random loading programs.

Test Report

The test report should include the following information:

1. Specimen design, dimension, machining processes and surface condition;
2. For notched specimens, details of the notch and its stress concentration factor;
3. Description of the test machine, including the method of verification of dynamic load monitoring;
4. Test material characterization in terms of, for example, chemical composition, melting and fabrication process, heat treatment, microstructure, grain size, nonmetallic inclusion content and mechanical properties; product size and form shall also be identified; the method of stress relief, if applicable;
5. Specimen orientation and its location with respect to the parent product from which it was removed;
6. Test loading variables, including stress amplitude and stress ratio, fatigue life or cycles to end of test, cyclic frequency and waveform for each specimen;
7. The initial solution composition, pH, degree of aeration (or concentration of other relevant gases), flow conditions, temperature and electrode potential; specification of flow rate should be in terms of approximate linear rate past the specimen if determined by the recirculation rate; the reference electrode used shall be indicated; the potential shall be reported and referred to an appropriate standard electrode (for example, the standard hydrogen electrode or saturated calomel electrode at 25 °C);

Fig. 12.44 Three-point single-edge notch bend specimen (SENB3)

Fig. 12.45 Four-point single-edge notch bend specimen (SENB4)

8. The starting procedure for the test, for example any change in initial electrode potential;
9. Transients in the environment or in the loading (including test interruptions) during testing, noting the nature and duration;
10. Description of the environmental chamber and all equipment used for environmental monitoring or control;
11. Failure criterion;
12. An $S-N$ diagram plotting the maximum stress, minimum stress, stress range or alternating stress against the number of cycles to failure; it is conventional to plot fatigue life, N , in cycles logarithmically on the abscissa while stress is plotted arithmetically or logarithmically on the ordinate; all data should be plotted in the $S-N$ diagram along with a best-fit regression analysis line; this procedure develops the $S-N$ diagram for 50% probability of survival when the logarithms of the lives are described by normal distribution

Crack Propagation Testing Using Precracked Specimens

This part describes the fracture mechanics method of determining the crack growth rates of preexisting cracks under cyclic loading in a controlled environment and the measurement of the threshold stress-intensity factor range for crack growth below which the rate of crack advance falls below some defined limit agreed between parties.

Principle of Corrosion Fatigue Crack Propagation Testing

A fatigue pre-crack is induced in a notched specimen by cyclic loading. As the crack grows the loading conditions are adjusted until the values of AK and R are appropriate for the subsequent determination of AK_{th} or crack growth rates and the crack is of sufficient length for the influence of the notch to be negligible.

Corrosion fatigue crack propagation tests are then conducted using cyclic loading under environmental

and stressing conditions relevant to the particular application. During the test, crack length is monitored as a function of elapsed cycles. These data are subjected to numerical analysis so that the rate of crack growth, da/dN , can be expressed as a function of the stress-intensity factor range AK .

Crack growth rates presented in terms of AK are generally independent of the geometry of the specimen used. The principle of similitude allows the comparison of data obtained from a variety of specimen types and allows da/dN versus AK data to be used in the design and evaluation of engineering structures provided that appropriate mechanical, chemical and electrochemical test conditions are employed. An important deviation from the principle of similitude can occur in relation to short cracks because of crack-tip chemistry differences, microstructurally sensitive growth and crack-tip shielding considerations.

The threshold stress-intensity factor range for corrosion fatigue, AK_{th} , may be higher or lower than the threshold in air depending on the particular metal/environment conditions. It may be determined by

Fig. 12.46 Compact tension (CT) specimen

Fig. 12.47 Center-cracked tension specimen (CCT)

a controlled reduction in load range until the rate of growth becomes insignificant for the specific application. Practically, from a measurement perspective it is necessary to assign a value to this.

Results of corrosion fatigue crack growth-rate tests for many metals have shown that the relationship between da/dN and AK can differ significantly from the three-stage relationship usually observed for tests in air, as shown in Fig. 12.43. The shape of the curve depends on the material/environment system and for some cases time-dependent (as distinct from cycle-dependent) cracking modes can ensue which can enhance crack growth producing frequency-dependent growth-rate plateaux as shown in Fig. 12.43.

Specimen Design

A wide range of standard specimen geometries of the type used in fracture toughness testing may be used (see ISO 11782-2). The particular type of specimen selected will be dependent upon the form of the material to be tested and the conditions of test. Pin-loaded specimens such as compact tension (CT) specimens are not suitable for tests with R values of zero or less than zero because of backlash effects. For such purposes four-point single-edge notch bend (SENB4) or center-cracked tension (CCT) specimens loaded by friction grips are suitable.

A basic requirement is that the dimensions of the specimens be sufficient to maintain predominantly triaxial (plane strain) conditions in which plastic deformation is limited in the vicinity of the crack tip. Experience with fracture toughness testing has shown that for a valid K_{Ic} measurement a , B and $(W - a)$ should not be less than

$$2.5 \left(\frac{K_{Ic}}{\sigma_y} \right)^2, \quad (12.79)$$

where σ_y is the yield strength.

It is recommended that a similar criterion be used to ensure adequate constraint during corrosion fatigue crack growth testing where K_{max} is substituted for K_{Ic} in the above expression.

Specimen geometries which are frequently used for corrosion fatigue crack growth rate testing include the following:

1. three-point single-edge notch bend (SENB3),
2. four-point single-edge notch bend (SENB4),
3. compact tension (CT),
4. center-cracked tension (CCT).

Details of standard specimen designs for each of these types of specimen are given in Figs. 12.44–12.47 and permitted notch geometries are given in Fig. 12.48.

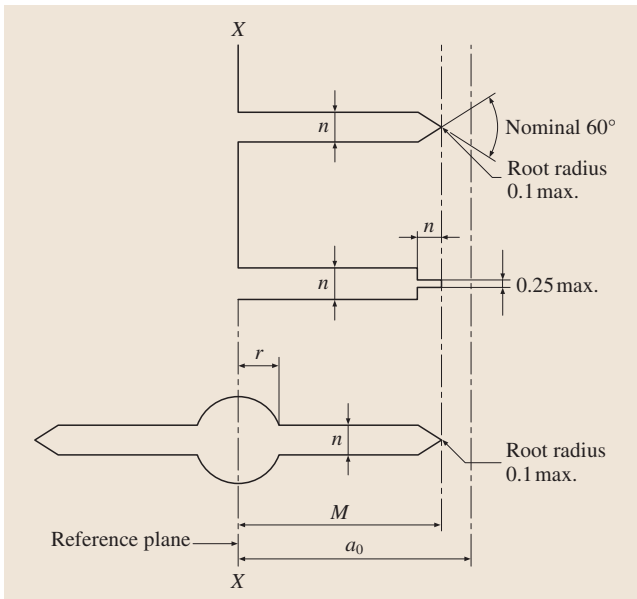

Fig. 12.48 Permitted notch geometry

ISO 11782-2 is recommended for specific and detailed information regarding test procedure, determination of corrosion fatigue crack propagation rates

and stress-intensity factor range where an overview on methods for measuring crack lengths is also available.

12.7 Hydrogen-Induced Stress Corrosion Cracking

Hydrogen-induced stress corrosion cracking or hydrogen embrittlement is a process where the uptake of hydrogen into a material leads to brittle cracking of the material under nominally uncritical loads. Its display has many similarities in comparison to stress corrosion cracking but there are also certain differences, namely that it most frequently in high-strength materials and the brittle fracture must be traced back to a different mechanism.

12.7.1 Electrochemical Processes

In the case of hydrogen-induced stress corrosion cracking or hydrogen embrittlement the adsorbed hydrogen at the steel surface is responsible for the crack growth. As hydrogen is mostly generated by the cathodic partial reaction of the corrosion process this kind of corrosion mechanism is also called cathodic stress corrosion cracking. A prerequisite for the absorption of hydrogen into the metal is that the hydrogen is present in a dissociated form. The practical importance of hydrogen-induced stress corrosion cracking lies in the fact that, even under otherwise harmless humidity conditions (condensation) on the steel surface, minor corrosion reactions could provide sufficient hydrogen to initiate crack growth. Experimentally determined crack growth of stressed high-strength steels in low-aggressive media such as humid air or distilled water have shown that even small amounts of hydrogen are sufficient to embrittle these steels [12.73].

For high-strength steels this type of corrosion does not require a specific medium. Only a sufficient amount of atomic hydrogen capable of adsorption is necessary and this can be formed by the Volmer reaction in acid and neutral media or by water dissociation in alkaline media. In both cases the hydrogen evolution is quantitatively coupled to the anodic partial reaction (iron dissolution) of the corrosion process even though a considerable metal loss does not necessarily take place. Often pitting corrosion due to chlorides and subsequent acidification of the electrolyte within the corrosion pits is the cause for hydrogen evolution (pitting-induced stress corrosion cracking). In this case there is an overlapping of local

acid corrosion with local cathodic hydrogen evolution and anodic metal dissolution. This has led to the idea of anodic hydrogen embrittlement. During anodic crack growth hydrogen evolution takes place in the electrolyte at the crack tip and atomic hydrogen could then enter the metal lattice leading to embrittling processes [12.74,75].

In fracture mechanics investigations too it has been observed that hydrogen-induced fracture mechanisms exist not only with cathodic polarization but also with anodic polarization [12.76]. Even with passive steels in aqueous alkaline solutions hydrogen evolution has been proved experimentally to be the result of the cathodic partial reaction of the dissolution of passive iron [12.77]. On the other hand, the free corrosion potential is strongly dependent on the aeration conditions. Measurements of the free corrosion potential of prestressing steel in saturated $\text{Ca}(\text{OH})_2$ solution gave values between -0.79 V normal hydrogen electrode (NHE) with nitrogen saturation and $-0.03\text{ V}(\text{NHE})$ with aeration. In oxygen-free solutions the range of free corrosion potentials and the range of cathodic hydrogen evolution potentials overlap and hydrogen can consequently also be generated at prestressing steels in alkaline solutions. Even small amounts of cathodically evolved hydrogen have resulted in strong changes of the fracture properties determined in constant-extension-rate tests (CERT) [12.78].

The hydrogen reduction reaction can be split into different steps. In the first step protons are discharged at the phase boundary

H atoms adsorbed at the metal surface recombine in a second step according to the Tafel equation

or the Heyrovsky reaction

H_2 molecules formed by this reaction can escape to the atmosphere. With kinetic inhibition of the recombination adsorbed hydrogen atoms build up near the surface and can lead to high H activities, resulting in the

penetration of hydrogen into the metal:

An equilibrium exists between the concentration of adsorbed hydrogen at the surface and dissolved H atoms in the metal matrix. With an increasing degree of coverage by adsorbed atomic hydrogen the probability of H absorption increases.

For hydrogen-induced corrosion the activity of the adsorbed hydrogen and not the evolution rate of hydrogen is the main determining factor. Hydrogen only leads to a chemical reaction with the material, or to a metal–physical hydrogen absorption if additional critical conditions exist with respect to the state and type of material, environment, electrochemical conditions and mechanical loading.

12.7.2 Theories of H-Induced Stress Corrosion Cracking

From the metal physics point of view there are four main theories of H-induced corrosion [12.79]. The basic principles of these different mechanisms will be briefly described below.

Pressure Theory

The first theory to explain the mechanisms of H-induced corrosion was the pressure theory [12.80]. It is based on the recombination of atomic hydrogen at internal surfaces of the metal especially at sharp-edged inclusions. This results in high pressure, which can initiate pore formation or microcracks. The pressure theory is able to explain the formation of blisters and H-induced internal cracks.

Adsorption Model

The basic idea of the adsorption model is that, as a result of the adsorption of certain species, e.g. atomic hydrogen, at the crack tip the surface energy is reduced [12.81]. The reduction of the surface energy lowers the critical stress which is necessary for crack propagation. An improvement of this model that is mainly based on thermodynamical considerations was achieved using an atomistic point of view. According to this, the binding energy of the atoms forming the crack tip is reduced by adsorption of certain species; brittle fracture is favored when the cohesive strength of the lattice drops below the critical shear stress at the crack tip. But the applicability of this model to explain chemH-induced material fracture is limited as H-induced crack nuclei are not formed at the surface of the crack tip itself but within the mater-

ial in the vicinity of the crack tip due to the concentration of stresses there.

Dislocation Theory

Today it is well accepted that atomic hydrogen is enriched in areas of high dislocation densities and can be transported together with the dislocations through the metal lattice when tensile loading of the metallic material is present [12.82]. A possible cause of H-induced material damage arising from the interaction of hydrogen and dislocations could be the diffusion of hydrogen into the dilatation zone of the dislocation and, by forming a Cottrell cloud, restraining the dislocation mobility, changing the gliding mechanisms and handicapping the deformation behavior, especially the deformation ability in front of the crack tip due to strengthening and thus favoring brittle fracture.

The interaction of dissolved hydrogen and dislocations is often taken either as the only cause or in combination with other mechanisms of H-induced corrosion to explain H-induced material fractures. The increased hydrogen mobility due to the transport via dislocations is especially important for face-centered-cubic metals due to the low diffusion rate of the interstitially dissolved hydrogen atoms in these lattice structures.

As a result of tests with high-strength martensitic steels which indicated an increased dislocation mobility after hydrogen uptake the slip softening model was developed. According to this model the preferential crack growth of high-strength steels is explained by the increased dislocation mobility resulting from hydrogen uptake, which facilitates the deformation ability.

Decohesion Theory

The decohesion theory proposed by *Troiano* [12.83] and further improved by *Oriani* [12.84] differs from the adsorption model in that it considers the formation of fracture nuclei in the vicinity of the crack tip within the bulk metal. The basic idea of this model is that the binding force of the metal atoms in the metal lattice can be reduced as a result of interactions with atomic hydrogen and then, in combination with high mechanical stresses, result in pure elastic rupture of the material. Hydrogen absorbed by the metallic material diffuses to areas of high stresses which are present at notches and therefore also in front of the crack tip because of the multiaxial state of stress. The area with the highest stresses is the boundary between the plastically deformed skin layer and the elastically deformed center. With sufficient hydrogen concentration the cohesion forces between the single atomic layers in the lattice are reduced so that

crack initiation and crack growth are possible. Crack initiation occurs near the surface but contrary to anodic stress corrosion cracking not at the surface in contact with the medium. Critical hydrogen contents are most likely to occur in areas of high lattice defect density, i. e. at dislocation pile-ups, and at phase or especially grain boundaries vertically oriented to the acting stress. The crack propagation develops stepwise. For each propagation step enough hydrogen must be accumulated through diffusion into the region of the highest triaxial state of stress that occurs at the transition from the plastically deformed zone at the crack tip to the elastically stressed center. This produces an additional crack which then grows and coalesces with the initial crack. The decohesion theory enables material ruptures to be explained even with low hydrogen absorption. Among the different hypotheses put forward to explain hydrogen-induced embrittlement, the decohesion theory seems to be the most reasonable for high-strength prestressing steels.

12.7.3 Environment and Material Parameters

Since hydrogen is adsorbed in the atomic and not the molecular form its uptake will be substantially increased by the presence of agents (promoters) which hinder the recombination of hydrogen atoms to hydrogen molecules by reaction [12.81]. Effective promoting agents are certain compounds of the fifth and sixth main groups of the periodic system, e.g. As, S, Se and Te compounds. Sulfides and thiocyanates have been identified as technically relevant substances in connection with prestressing steels. Even small amounts of contaminants or other active substances in building materials can substantially accelerate stress corrosion cracking of susceptible steels [12.85].

Because of its low atomic diameter hydrogen forms an interstitial solid solution with iron, the hydrogen atom releasing its electron to the electron gas of the metal and so remaining present as a proton. The low diameter and the interstitial position of the hydrogen atoms as well as the high mobility of protons lead to a high diffusibility of hydrogen within the iron lattice. The dissolved hydrogen can interact with itself, with dislocations and with other lattice defects and thus influence the mobility of the dislocations in the metal which, in turn, can change the deformability of the material. For the damage mechanism of hydrogen-induced stress corrosion cracking the actual source of the hydrogen is of minor importance. The damage probably proceeds via a two-step process. In the first step hydrogen can be picked up from the ma-

terial in the absence of mechanical loading, and then, in a second step, failure occurs after stress is applied. The extent of the corrosion damage is determined by the hydrogen activity.

Hydrogen solubility depends on lattice structure, amount of internal surfaces and temperature. Internal surfaces are interfaces of cracks, pores and other voids as well as phase boundaries [12.86]. More hydrogen can be dissolved in face-centered-cubic lattices (by a factor of about three) than in body-centered-cubic lattices. This results in a lower hydrogen susceptibility for austenitic steels. The diffusion coefficient is also dependent on the lattice structure. At a certain temperature in a body-centered-cubic lattice it is from 3–6 orders of magnitude higher than in a face-centered-cubic lattice. Therefore under critical conditions there is a higher risk of hydrogen-induced stress corrosion cracking for ferritic and martensitic steels. Those structural anomalies of a perfect iron lattice with which hydrogen can react are often called traps. These are disturbances of the lattice which can trap hydrogen and hold it for a certain period of time.

As well as the parameters mentioned above hydrogen-induced stress corrosion cracking and propagation also depend on hydrogen concentration and tensile stresses. With high tensile stresses susceptible steels require only very low hydrogen activity ($a_H 0.1$), to initiate crack growth [12.87].

Hydrogen-induced stress corrosion cracking of high-strength steels of the quenched and tempered type is characterized by cracks with intergranular corrosion along the former austenite grain boundaries.

12.7.4 Fractographic and Mechanical Effects of HISC

The process of hydrogen-induced brittle fracture can be described as follows. Initially, the change of tensile stress immediately in the crack initiation zone is so slow that hydrogen can diffuse to the crack tip and act decohesively. The consequence is to produce a stable intergranular fracture along the grain boundaries which act as weak spots of the microstructure. Ductile regions and micropits can be observed at the grain surfaces. With increasing crack propagation rate hydrogen cannot diffuse sufficiently to the crack tip and an area with a dimple fracture appearance is formed. As the fracture develops unstable crack propagation takes place with the formation of a radial structure (quasi-cleavage fracture area) and finally, when the monoaxial state of stress is reached, the formation of a shear stress lip, which is

characterized by the appearance of a fracture with fine dimples.

The effect of hydrogen is mainly to reduce the binding energy of the metallic atoms thus favoring crack initiation and propagation. When the crack growth has reached a level where the diffusion of hydrogen to the crack tip is no longer possible the further crack progress is similar to a non-embrittled sample. In some cases in the area of the radial structure hydrogen can also influence the structure of the fracture surface, i. e. sometimes the cleavage fracture will show clear signs of intergranular components.

When assessing hydrogen embrittlement of pre-stressing steels the type of mechanical loading has to be considered in addition to the hydrogen content. A tensile test cannot always prove the embrittling effects of hydrogen caused by diffusion processes. With high strain rates hydrogen-charged samples show nearly the same reduction of area as samples free of hydrogen. It is only at very low straining rates that hydrogen results in brittle behavior. The reason for this phenomenon is that with high deformation rates not enough hydrogen can be provided to cause a brittle fracture. Ductile behavior can be observed, i. e. a minimum time period is necessary for crack initiation and crack propagation of a critical

length [12.75, 87]. Fractography can provide proof of hydrogen embrittlement even in those cases where there are only slight changes in mechanical properties. Undeniable indications can be found in the surface area of the crack breakthrough. Hydrogen-embrittled quenched and tempered steels always have an intergranular crack zone. This is clearly different from the behavior of notch-based brittle fractures or ductile spontaneous fractures. Apart from the crack area the other parts of the fracture surface could look like notch-based brittle fractures.

12.7.5 Test Methods

For testing the susceptibility of a material against hydrogen-induced stress corrosion cracking or determining the effect of specific environmental conditions on a metal with regard to hydrogen embrittlement all test methods previously described in Sects. 12.5 and 12.6 are applicable. In addition to these tests also the uptake of hydrogen in an electrochemical cell which has been proposed by Devanathan can be investigated and the data evolved may be used for determining the diffusion coefficient of hydrogen in a metal or, if the diffusion coefficient is known, provide data on hydrogen activity at the surface of the metal.

12.8 High-Temperature Corrosion

In industrial high-temperature applications corrosion is a major life-limiting factor for in-service components. Such applications are e.g. fossil-fuel power stations, petrochemical and chemical plants, exhaust ducts, land based gas turbines and jet engines, etc. There exist a number of tests aiming at evaluating the effect of the high-temperature environment on material performance for the different applications that in most cases are laboratory tests, although some field testing may also be performed. In the laboratory tests it is usually intended to simulate conditions which are close to the industrial situation with regard to environment, temperature and mechanical stresses. As the situation in high-temperature applications in most cases is very complex it is, however, not easy to simulate the actual conditions on a one-to-one basis. Therefore most of the high-temperature corrosion tests in the laboratory are based on a simplification of the practical conditions or on conditions leading to an acceleration of the test. In the latter case it should, however, be kept in mind that accelerated testing may lead to a change in the corro-

sion mechanism and, thus, possibly to misinterpretation of the data for the material performance under practical conditions. Furthermore extreme care should be taken if the results of such accelerated laboratory tests are taken for life time extrapolation.

12.8.1 Main Parameters in High-Temperature Corrosion

Corrosion Testing

The basic principles for high-temperature corrosion testing are relatively easy. Actually there are *two types* of parameters which are usually measured. The first is parameters related to mass change that results from the reaction of the material with its environment by which either a mass gain or a mass loss can take place. A mass gain will occur if the reaction leads to the formation of a solid corrosion product on the surface and/or in the metal subsurface zone. Mass losses will occur when either the solid corrosion product spalls from the surface (e.g. oxide bits flake off the sample) or if

volatile corrosion products are formed which evaporate. Since the mass change is proportional to the amount of species from the environment taken up by the material in the oxidation reaction or to the amount of material evaporated by formation of volatile corrosion products the high-temperature corrosion kinetics can easily be determined by continuous or discontinuous measurements of the specimen weight or mass in tests. Such mass measurements can of course also be performed with specimens from field exposure so that it becomes possible to determine corrosion kinetics also in field testing.

In combination with mass measurements it is beneficial and even necessary to characterize additional damage parameters resulting from the corrosion process. These parameters are determined by post-experimental sectioning of the specimens in the metallography and measurement of geometrical data on surface scale thickness and on internal corrosion depth. Again this method can also be applied to specimens from field testing. In the present chapter it is intended to focus on laboratory testing. Actually many of the aspects dealing with laboratory testing (especially those on the evaluation of the corrosion data) can also be applied to field testing. With regard to the specific aspects of field testing, please refer to [12.88].

12.8.2 Test Standards or Guidelines

Although high-temperature corrosion testing has been performed in industry and scientific laboratories now for almost a century there are very few guidelines or standards describing the test procedures. In the following the more important of these standards or guidelines are listed:

- **ASTM G 54** *Practice for simple static oxidation testing* [12.89]:
This standard covers the determination of the relative growth, scale, and microstructural characteristics of an oxide on the surface of a pure metal or alloy under isothermal condition in still air. This standard was later withdrawn but is still regarded as useful.
- **ASTM B 76** *Method for accelerated life test of nickel-chromium and nickel-chromium-iron alloys for electrical heating* [12.90]:
This standard covers the determination of the resistance to oxidation of nickel-based electrical heating alloys at elevated temperatures under intermittent heating using a constant-temperature cycle test. This test method is used for comparative purposes only.
- **ASTM B 78** *Method for accelerated life test of iron-chromium-aluminium alloys for electrical heating* [12.91]:
This standard covers the determination of the resistance to oxidation of iron-chromium-aluminium alloys for electrical heating at elevated temperatures under intermittent heating similar to **ASTM G 76**. This test is again used for comparative purposes only.
- **ASTM G 79** *Practice for evaluation of metals exposed to carburization environments* [12.92]:
This standard covers procedures for the identification and measurement of the extent of carburization in a metal sample and for the interpretation and evaluation of the effects of carburization. It applies mainly to iron- and nickel-based alloys for high-temperature applications.
- Draft code of practice: *TESTCORR – Discontinuous corrosion testing in high-temperature gaseous environment* (ERA report 2000-0546) [12.93]:
This draft code of practice, which is the result of a research programme supported by the CEC standards, measurements and testing programme describes in detail the procedures for the determination of specimen wastage using mass and dimensional change. A major consideration is the traceability of the measurements and the validity of the statistical treatment of the data generated. These procedures have been developed in conjunction with specimen preparation guidelines and recommendations for a statistical analysis of the data.
- **JIS** (Japanese Institute of Standards) **Z 2281-1993** *Test method for continuous oxidation test at elevated temperatures for metallic materials* [12.94]:
This Japanese standard covers one of the most often-used tests in high-temperature corrosion. A tentative translation from the Japanese manuscript into English is available from **JIS**.
- **JIS Z 2282-1996** *Method of cyclic oxidation testing at elevated temperatures for metallic materials* [12.95]:
This standard covers another most often used high-temperature corrosion test in industry and is also available as a tentative translation from Japanese into English.
- EFC publication no. 14 *Guidelines for methods of testing and research in high temperature corrosion* [12.96]:
This publication contains the papers of a workshop on this topic organized by the working party on corrosion by hot gases and combustion products of the

European Federation of Corrosion where all major aspects of high-temperature corrosion testing were addressed.

- EFC publication no. 27 *cyclic oxidation of high temperature materials – mechanisms, testing methods, characterization and life time estimation* [12.97]: This publication is based on the papers presented at a workshop of the same title again organized by the aforementioned working party of the European Federation of Corrosion. The workshop was solely devoted to thermal cycling oxidation testing.

Especially at the last mentioned workshop with strong international participation from around the world it was stated that the situation with regard to standardization of high-temperature corrosion testing is rather unsatisfactory at present. As a consequence two initiatives were started. One was in the form a European research project named COTEST [12.98] which aims at the development of a code of practice for a test method for thermal cycling oxidation testing. The second initiative was started by Japanese industrial researchers aiming at the development of an ISO standard based on the existing Japanese standards mentioned above. A workgroup was formed in the ISO technical committee 156 (corrosion of metals and alloys) which has the designation WG 13, high-temperature corrosion. The aim of this work group is to develop ISO standards in the following fields:

- Thermogravimetric testing:
ISO work group definition: in situ mass measurements at elevated temperatures on a single specimen without intermediate cooling.
- Continuous isothermal exposure testing:
ISO work group definition: single post-exposure mass measurement on a series of specimens without intermediate cooling.
- Discontinuous isothermal exposure testing:
ISO work group definition: series of mass measurements on a single specimen with intermediate cooling at predetermined times not necessarily regular.
- Thermal cycling oxidation testing:
ISO work group definition: series of mass measurements on a single specimen with repeated, regular and controlled temperature cycles.
- General guidelines for a post-exposure examination:
No definition by the ISO work group.

In the development of these work items the knowledge existing in the form of the national standards and European guidelines mentioned above is being used. This

particularly concerns the results from the TESTCORR document and the COTEST document as well as the Japanese standards. These ISO standards are expected to be the first documents with international acceptance in the field of high-temperature corrosion testing. As these documents are still under development, in the present chapter the most recent situation with regard to the working drafts of these standards will be taken into account. This chapter on high-temperature corrosion testing, therefore, cannot yet rely on generally accepted existing standards but the content will be presented in a way which is supposed to be compatible with the future ISO standards.

12.8.3 Mass Change Measurements

Principles

The basic idea behind the mass change measurements is to have an easy method providing information about the oxidation or corrosion kinetics. This kinetics allow an assessment of materials performance from the viewpoint of oxidation or corrosion resistance according to the schematic representation in Fig. 12.49. The ideal situation with regard to high-temperature corrosion resistance is the formation of a very thin and dense protective ox-

Fig. 12.49 Schematic of the most common types of oxidation/corrosion kinetics at high temperature

ide scale on the surface of the material. This behavior is usually characterized by parabolic kinetics with small-scale growth rates, i. e. the mass increase or the increase of the oxide scale thickness follow a parabolic time law

$$(\Delta m/A)^2 = k_p t, \quad (12.84)$$

where Δm is the mass increase, A is the specimen surface area, k_p is the parabolic oxidation rate constant and t is oxidation time. A slow oxidation rate means that k_p has a very low value. Equation (12.84) can also be written in terms of the increase of the oxide scale thickness according to

$$x^2 = k'_p t, \quad (12.85)$$

where x is the oxide scale thickness. As in many cases oxidation does not strictly follow a parabolic rate law, (12.84) and (12.85) can also be written in the more general form including the temperature dependence [12.99]:

$$\Delta m/A = [k(T)]^{1/n} \left(\frac{t}{t_o} \right)^{1/n}, \quad (12.86)$$

$$k(T) = k^o e \left(\frac{-E_A}{RT} \right) \quad (12.87)$$

with $k(T)$ as a temperature-dependent oxidation rate constant [for the parabolic case $k(T) = k_p$], t_o as the time basis (e.g. 1 sec if seconds are used for t), k^o as the general oxidation rate constant, E_A as the activation energy, T as temperature and R as the general gas constant. The exponent n characterizes the type of rate law, e.g. $n = 2$ for the parabolic case. If oxidation or high-temperature corrosion occur only via the formation of a surface layer the mass change results can be converted into scale thickness data by

$$\Delta m/A = x f_z \quad (12.88)$$

$$\text{with } f_z = \rho_{MeX} \frac{z M_X}{M_{MeX}} \quad (12.89)$$

with ρ_{MeX} being the density of the compound MeX and M_{MeX} being the molar mass of the same compound. M_X and z are the molar mass and a stoichiometric, respectively, of the reacting species of the environment. For several oxides the values of f_z are given in tables [12.100]. This estimation, however, requires that the surface scales are single phase and practically fully dense and do not show any significant degree of porosity. Furthermore internal corrosion is neglected by this conversion.

In the following, Fig. 12.49 shall be discussed in some more detail as this schematic shows all the potential results which may come out of the mass change

measurements. The following situations can be encountered.

Nonprotective oxidation behavior. In this case oxidation/corrosion occurs at a very high rate, i. e. rapid conversion of metal into the corrosion product layer on top of the specimen is observed. This surface layer does not have any protective character, which can be due to cracks or pores in the scale or due to high diffusion rates in the scale lattice. In most cases the corrosion kinetics are linear ($n = 1$) but can also be of the parabolic type ($n = 2$) with a high k_p value if the growth of the corrosion product layer is diffusion controlled. This case is undesired in material service.

Temporary protective oxidation behavior: In many practical applications at the beginning of oxidation or life time of the component a protective situation is observed following slow parabolic kinetics or sometimes even cubic kinetics ($n = 3$) which also points towards a protective behavior of the oxide scale formed. However, after a certain period of time it may happen that, due to scale cracking and/or depletion processes in the oxide/subsurface-metal system, so-called break-away oxidation starts, i. e. the formerly protective oxide scale is converted into a nonprotective type that ends up in a significant increase of the oxidation rate (acceleration of oxidation). The characteristic values of this type of curve are k_p for the protective region, t_B for the moment at which accelerated oxidation starts (break-away time) and k_{pb} for the oxidation rate constant in the nonprotective post-breakaway time range. It should be pointed out here that many laboratory tests for technical materials ended before t_B had been reached so that protective behavior of the material was assumed. However, under industrial application oxidation times are usually much longer than laboratory tests so that t_B may easily be exceeded. Therefore laboratory results may sometimes be questionable, which also illustrates the problems which may arise from short-time accelerated testing.

Protective oxidation behavior. This is the ideal situation which guarantees resistance of the material against high-temperature corrosion and which is usually observed when a thin and dense protective slowly growing oxide scale is formed. In this case oxidation kinetics can often be described by (12.88) and (12.89) with k_p having very low values. The value k_p is therefore the key value that characterizes the oxidation resistance and is therefore determined in the oxidation tests.

Fig. 12.50 Oxidation rate constants k_p for the alloy groups “ Al_2O_3 -scale formers” and “ Cr_2O_3 -scale formers” (after [12.101])

Protective oxidation behavior but spalling of the protective scale. In particular when temperature changes occur during oxidation, the protective oxide scale may crack and spall due to different values of the coefficients of thermal expansion (CTE) of the oxide scale and the substrate. As a consequence, starting from a certain point of time, a sudden decrease in mass occurs, followed by an increase of mass due to ongoing oxidation. During the next spalling period mass decreases again and increases by oxidation until a further spalling period starts, leading to a repeated sequence of spalling and scale growth. Unless healing of the spalled oxide occurs, and thus a restoration of the protective effect becomes possible, spalling usually leads to a nonprotective situation.

Oxide scale growth with superimposed evaporation at corrosion products. If a solid corrosion product scale is formed during high-temperature corrosion, accompanied by the formation of a volatile corrosion species, then after an initial mass increase a continuous mass decrease will occur. As an example such situations can be encountered in oxidizing/chloridizing environments where the oxide scale is reduced or destroyed by the formation of volatile metal chlorides [12.102]. A similar situation may also occur with other metal halogen compounds. Kinetics in this case can be described by

$$\Delta m/A = [k(T)]^{1/n} \left(\frac{t}{t_0} \right)^{1/n} - k_{-l} \left(\frac{t}{t_0} \right) \quad (12.90)$$

where k_{-l} in the negative linear rate constant.

Corrosion only by evaporation of volatile corrosion products. If neither solid nor liquid corrosion products are formed but only gaseous species result from the corrosion reaction then a continuous linear decrease in mass will be observed. This linear decrease is characterized by $n = 1$ and a linear negative rate constant of k_{-l} .

Summarizing Fig. 12.49, it is actually only the protective case that can be accepted for industrial use of the materials. For most technical materials the exponent n in this case usually ranges between 2 and 3 and $k(T)$ takes low values. The temporary protective case can be accepted if t_B is not much shorter than the expected exposure time in service and the spallation case can be accepted if the amount of spalling is relatively small. The same is valid for scale growth with superimposed

Fig. 12.51 Schematic of a thermobalance for continuous in situ mass measurements

evaporation but all other cases lead to severe problems in practical use.

The test methods described in the following serve for the quantitative determination of the parameters of Fig. 12.49 and also for the qualitative characterization of oxidation/high-temperature corrosion behavior according to these systematic cases. For further illustration in Fig. 12.50 examples of values of the parabolic rate constant are given for protective oxides scales and a temperature range 800–1400 °C [12.101]. This figure shows that alumina surface scales are superior to chromia surface scales with regard to the protective effect. Figure 12.50 furthermore can serve for orientation whether the measured values determined in the experiments characterize protective or nonprotective behavior of the materials.

Thermogravimetric testing. Mostly in scientific laboratories the thermogravimetric method is a widely used type of test used to investigate the oxidation kinetics and other types of high-temperature corrosion continuously in situ. The principles of the equipment are given in Fig. 12.51. The weight of the specimen is continuously recorded by a laboratory balance, which usually sits on top of a laboratory furnace. To hang the specimen platinum wires or silica strings, which are supposed to be inert in most environments, are normally used. (It should however be mentioned here that under certain conditions even platinum and silica may evaporate and, thus, lead to a decrease in weight of the string which is also measured by the balance.) The specimen and the weighing system are usually encapsulated in a retort to allow the use of defined gas compositions. The interior of the laboratory balance should be shielded against penetration of the reactive gas in the furnace by counterflow of inert gas (e.g. Ar). The gas entrance should be opposite to the gas exit. In most cases the retort is manufactured from quartz. Especially at very high temperatures, alumina retorts are also used. For accelerated testing the measurements are sometimes performed under thermal cycling conditions (see later). The same equipment can be used with a moveable furnace, the movement of which is controlled by an electronic device that allows defined temperature cycles. The temperature at the specimen is monitored by a thermocouple, which is placed close to the specimen, although no friction between the thermocouple and the specimen should occur. Furthermore any friction between the quartz string or the platinum wire leading to the balance and the retort or tube walls should be avoided. Further recommendations for the thermogravimetric tests are given below in

the section on continuous and discontinuous isothermal exposure testing. (For the latter test a detailed draft work item from ISO group TC 156/13 already existed when the present chapter was prepared, which was not the case for the thermogravimetric test.)

As indicated in Fig. 12.51 it is also possible to combine this type of measurement, especially in the case of thermal cycling testing, with acoustic emission measurements. In this case the platinum wire that is connected to the specimen can be used simultaneously as an acoustic waveguide. Acoustic emission signals can reveal the extent to which cracking or spalling of the oxide scale occurs either during isothermal or during cycling oxidation. The results of the thermogravimetric measurements are the curves shown schematically in Fig. 12.49. However, a major disadvantage of this method is that only one sample can be tested at a time so that generating a large number of comparative data for different materials is a lengthy process. This is the main reason why industrial laboratories prefer to test multiple samples simultaneously. This issue will be addressed in the next section.

Continuous and Discontinuous Isothermal Exposure Testing

To accommodate a larger number of specimens in one furnace a special arrangement of equipment is necessary, as shown schematically in Fig. 12.52. This equipment is again composed of a temperature-regulating device for heating the test piece(s) uniformly at a constant temperature and, ideally, a testing portion capable of separating the test piece(s) from the outside air (i.e., a closed system). Since for many materials humidity in the test environment may have a significant effect on oxidation behavior, a humidifying regulator should be used to continuously supply a gas kept at a constant humidity, which should be monitored with a hygrometer. As for all closed systems, including those for thermogravimetric testing, the gas supply should be controlled by a gas-flow meter. It is important that the test-piece chamber is not composed of a material that reacts with the test environment during the test to a degree that changes the composition of the atmosphere. If closed systems with a test-piece chamber cannot be used, then tests may also be performed in an open system with laboratory air. In this case it is recommended that the humidity of the air should be recorded and that the laboratory should be kept free from temperature changes and the influence of weather conditions as far as possible.

The furnace has to be characterized prior to testing to determine the length of the isothermal zone

Fig. 12.52 Basic design of a horizontal exposure furnace for discontinuous oxidation/corrosion testing

inside the furnace and the set point of the apparatus. A common method is by the use of an independent movable thermocouple. The draft of the present ISO work item recommends that the temperature-regulating device should be capable of guaranteeing that the temperature of the test piece is kept within a permissible range, given in Table 12.4. The material of the thermocouples has to withstand this test temperature. The temperature has to be measured by a suitable device according to ASTM E 633-00 [12.103]. Thermocouples of type S (Pt-10% Rh/Pt), type R (Pt-Pt/13%Rh) up to 1000 °C or type B (Pt/30% Rh-Pt/6% Rh) up to 1700 °C are preferred. A thermocouple should be positioned close to the test-piece surface and must be calibrated in accordance with standards ASTM E 220-02, ASTM E 230-02 and ASTM E 1350-97 [12.104–106]. If, however, the environment does not allow the use of such thermocouples in this way the test-piece temperature has to be deduced from the furnace calibration using dummy test pieces and appropriate thermometry in an inert environment. The thermocouple should be capable of confirming that the test temperature is within the range given in Ta-

ble 12.1. It should be located at a defined, fixed position as close to the test pieces as possible.

When a humidifying regulator is used it should be capable of adjusting to the desired humidity and the space between the humidifying regulator and the test-piece chamber should be kept above the dew point to avoid condensation. The water-vapor content should be measured, which can be achieved by, e.g., the use of a hygrometer before the test-piece chamber or measuring the amount of water after condensation of the exhaust gases. The gas flow has to be high enough to ensure that no depletion of the reacting species will occur. At the same time the gas flow must be slow enough to allow the gas mixture to preheat and in some applications to reach reaction equilibrium. The TESTCORR document recommends 1–10 mm/s.

It is recommended that the test pieces have a minimum surface area of 500 mm² [12.93]. Their shape can be a rectangular plate, a disc or a cylinder. Final surface finishing of the test pieces should be 1200 grit according to the Federation of European Producers of Abrasives (FEPA) standard 43-1984 R 1993 [12.107] and

Table 12.4 Permissible tolerance of temperature of test piece [12.98]

≤ 573 K	573 K < T ≤ 873 K	873 K < T ≤ 1073 K	1073 K < T ≤ 1273 K	> 1273 K
±2 K	±3 K	±4 K	±5 K	±7 K

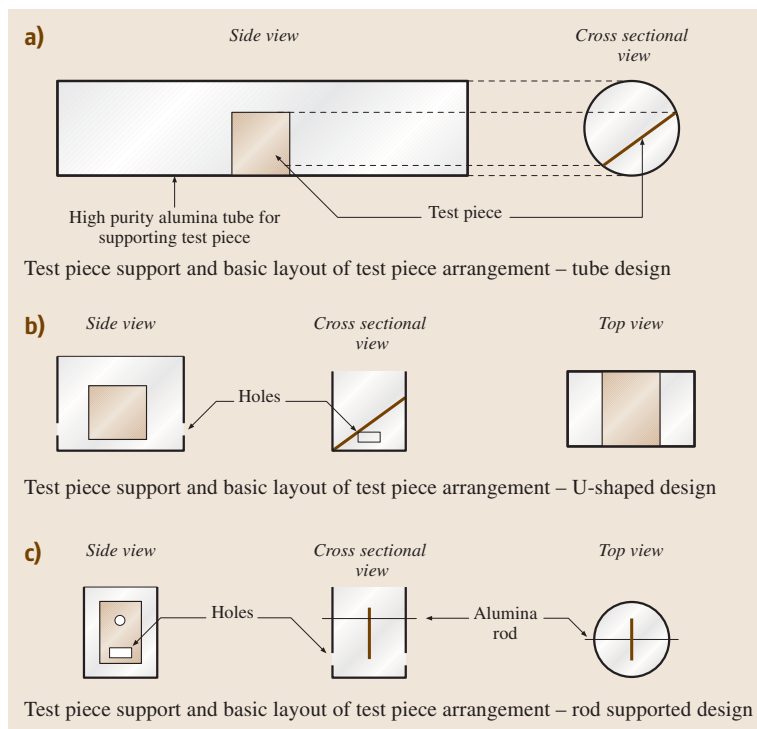

Fig. 12.53 (a) Test-piece support and basic layout of test-piece arrangement – tube design; (b) Test-piece support and basic layout of test-piece arrangement – U-shaped design; (c) Test-piece support and basic layout of test-piece arrangement – rod-supported design

ISO 6344 [12.108]. Deformation by marking, stamping or notching of the surface should be avoided. Identification of the test pieces should be solely on the basis of recording their relative position within the test chamber. In particular for hanging specimens, e.g. for the thermogravimetric test, holes for the test-piece support are permissible. The test pieces must be dried after degreasing in an ultrasonic bath using isopropanol or ethanol. Before exposure the mass of the test pieces $m_T(t_0)$ has to be determined by three independent measurements with the difference between the measurements not exceeding 0.05 mg.

Several test pieces exposed for different times are necessary to define the oxidation kinetics of the material. Therefore it is recommended that duplicate test pieces are used with (at least four) exposure times increasing progressively (e.g., 10 h, 30 h, 100 h, 300 h, ...). The material used for the test-piece supports should not react at the test temperature neither with the environment nor with the specimen. Examples of recommended test-piece supports are shown in Fig. 12.53. Where the possibility of depletion of active species in the test atmosphere is a concern, the exchange of the test atmosphere can be improved by the use of holes or slots in the bottom part of the side walls of the

test-piece support. To remove volatile compounds it is furthermore recommended that new test-piece supports should be baked for at least 4 h at 1000 °C in air. In addition to the mass of the test pieces, that of the test-piece supports $m_s(t_0)$ should be determined prior to exposure.

Thermal cycling oxidation testing

In the majority of industrial applications temperatures are never constant. Therefore temperature cycling oxidation/corrosion tests are most often used in industry. The test equipment is rather similar to that for isothermal testing, with the major difference that either the specimen or the furnace can be moved so that temperature cycles are possible in the test. In Figs. 12.51 and 12.52 the test equipment shown for isothermal testing already allowed for the possibility of moving the furnace, so that in the same equipment cyclic oxidation testing would also be possible. The advantage of the equipment shown in Figs. 12.51 and 12.52 is that these tests can be performed in a defined environment. In some of the more traditional thermal cycling oxidation test rigs the specimens are moved by some device out of and into the furnace, which usually requires that these tests are performed in an open system. As mentioned above, closed

Fig. 12.54 Equipment for thermal cyclic testing of heat-exchanger tubes (after [12.109])

systems with defined environments are preferred over open systems with laboratory air.

For completeness it should be mentioned that, as well as tests with small laboratory specimens, component tests, e.g. with complete heat-exchanger tubes, can even be performed under thermal cycling conditions, as shown by the schematic in Fig. 12.54. In this case the

furnace consists of two half shells that can be moved apart on a rail system so that the test-piece chamber is at ambient temperature when the furnace is open. The test piece, which in this example is a heat-exchanger tube, is placed inside a quartz tube and sealed at the ends with flanges. This design allows the possibility of having defined environments on the outer surface of the tube as well as on the inner surface. These two environments can even be different from each other, e.g. combustion gas on the outside and steam on the inside of the tube. Component tests as in this example are always desirable when geometrical effects of these components on the oxidation behavior are to be investigated. Figure 12.54 again includes the possibility of using the acoustic emission technique for the detection of failure of the protective oxide scales due to thermal cycling and spalling.

Generally all the recommendations given in the continuous and discontinuous isothermal exposure testing section are also applicable to thermal cycling testing. The difference compared to discontinuous isothermal testing is that in thermal cycling testing the temperature cycles always have the same shapes. Based on a detailed scientific model calculation the parameters characterizing such a thermal cycle have been determined as follows [12.110, 111]. The heating period of the cycle starts when the test piece enters the furnace and ends with the beginning of the hot dwell. The

Fig. 12.55 Schematic of a temperature cycle in thermal cycling oxidation testing

latter is defined as the time when the actual temperature exceeds 97% of the desired hot dwell temperature measured in Kelvin. The hot dwell time ends and the cooling time starts when the heating of the test piece is stopped, e.g. by the removal of the test piece from the furnace. The end of the cooling time is defined as when the actual test-piece temperature falls below 50 °C. The cold dwell time starts after the test pieces have cooled below 50 °C and ends when the test pieces are heated again. The characteristic parameters of a thermal cycle are summarized in Fig. 12.55.

Depending on the type of industrial application, *three* general types of thermal cycles are regarded as typical. The *first* type is long-dwell-time testing, which aims to simulate conditions in large-scale industrial facilities encountered in applications such as power-generation plants, waste-incineration plants or chemical industry. In these applications the metallic components are designed for extremely long-term operation, e.g. typically for up to 100 000 h. Thermal cycling of the materials occurs due to plant shutdowns, e.g. for regular maintenance, or due to unplanned shutdowns as a result of offset conditions. Therefore, the time intervals between various thermal cycles are relatively long and the number of cycles is (related to the long operation time of the components) relatively small, e.g. typically around 50 cycles. A recommended test cycle for this application consists of an overall time of 24 h with a 20-h hot dwell time and 4-h period, which includes the cooling time, the cold dwell time and the heating time.

The *second* type is thermal cycling with short dwell times, which is typically experienced in applications such as jet engines, automotive parts, and heat-treatment facilities. The intervals between start and shutdown of the facilities are generally much shorter than in applications with long dwell times. Also the life times and/or the times until complete overhaul/repair (typically 3000–30 000 h) are shorter and, depending on the specific practical application, the number of cycles is much higher than in the cases above. The recommended testing cycle in this case consists of one hour hot dwell time and 15 min cold dwell time.

The *third* type of testing has ultrashort dwell times and mainly addresses applications of high-temperature alloys as heating elements in the form of wires or foils. Another typical application in which such ultrashort cycles prevail is catalyst foil carriers, e.g. in cars. In such applications the number of cycles is related to the overall design life (typically several hundred to a few thousand hours) and can be extremely high, and the time intervals between heating and cooling can be as low as minutes or

Fig. 12.56 Schematic of a test rig for thermal cycling oxidation testing using ultrashort temperature cycles

even seconds. Such conditions are commonly also encountered in a number of other industrial applications such as burners and hot gas filters, as well as in a large variety of domestic applications where metallic heating elements are used e.g. in cooking plates, toasters, boilers, dryers, and fryers. The recommended test cycle for ultrashort-dwell-time testing consists of 5-min hot dwell and 2-min cold dwell. For this specific type of test a special test rig is needed, as described in detail in [12.112]. A schematic of this rig is shown in Fig. 12.56.

Generally the test duration in thermal cycling testing should be at least 300 h of accumulated hot dwell time to allow significant oxidation or corrosion of the test pieces. For more reliable results it is however recommended to extend the accumulated hot dwell time to at least 1000 h.

Evaluation of the mass change

After the tests, or during the tests at intervals when the specimens are cold, the mass has to be determined to quantify the corrosion kinetics. For this weighing procedure the specimens have to be taken out of the equipment but they should never be touched with hands, to eliminate any contamination (grease, salts). Generally the use of tweezers is recommended. After removing from the furnace the test-piece supporters containing the test pieces should be settled in the weigh-

Fig. 12.57 Example of a plot of net mass change versus time as a direct plot

ing room for 15 min to allow them to acclimatize. The test pieces should not be descaled unless specified. For each mass-change determination the sum m_{ST} of the mass of the test-piece support (m_S) containing one test piece (m_T) and the spalled scales (m_{sp}), i.e. $m_{ST} = m_S + m_T + m_{sp}$, the mass $m_s + m_{sp}$ of the test-piece support including the spalled scales, and the mass m_T of the test piece including the adherent scales should be measured. The following values have to be determined:

1. Gross mass change Δm_{gross} , i.e. mass change of test piece after cooling including collected spall

$$\Delta m_{\text{gross}} = m_{ST} - [m_S(t_0) + m_T(t_0)] ; \quad (12.91)$$

2. Mass of spalled oxide Δm_{sp} , i.e. scale flaked from the test piece

$$\Delta m_{\text{sp}} = m_S - m_S(t_0) ; \quad (12.92)$$

3. Net mass change Δm_{net} , i.e. mass change of test piece after cooling without spall

$$\Delta m_{\text{net}} = m_T - m_T(t_0) . \quad (12.93)$$

The net mass-change results of the test pieces from these measurements are plotted against time, as shown in Fig. 12.57. To determine the quantitative key parameters characterizing the corrosion behavior of the material a double logarithmic plot (log net mass change vs. log time) as shown in Fig. 12.58 is used. From the y-axis intercept the oxidation rate constant $k(T)$ can be calculated as

$$a = \log k(T)^{1/n} \rightarrow a = 1/n \log k(T) \rightarrow k(T) = 10^{an} . \quad (12.94)$$

If spalling or breakaway oxidation occur, the time at the beginning of these mechanisms can also be of significant interest. In [12.109] a detailed procedure is described that allows the quantitative determination of these parameters.

12.8.4 Special High-Temperature Corrosion Tests

Burner Rig Tests

In addition to the standard tests described so far several special tests have also been developed that try to take the specific loading situation under practical conditions into account. Especially in the gas-turbine manufacturing industries the so-called burner rig test has become of some importance. In this test the test environment is produced by combustion of fuel with air, see Figs. 12.59 and 12.60. In Fig. 12.59 a schematic of the so-called *high-velocity burner rig* is shown, where the gas stream on the specimen surface can reach velocities of up to mach 0.3. In the case of a *low-velocity burner rig*, combustion in a zone in the vicinity of the specimen supporter produces the test gas, which flows at a relatively low rate through a large tube to the specimens, Fig. 12.60. Especially in the case of a low-

Fig. 12.58 Double logarithmic plot of the data of Fig. 12.57 for the evaluation of the parameters $k(T)$ and n

Fig. 12.59 Schematic of a high-velocity burner rig (after [12.88])

Fig. 12.60 Schematic of a low-velocity burner rig (after [12.88])

velocity burner rig, impurities are often added to the combustion environment, first of all in the form of salt water [12.88].

Typical test specimens have the shape of a rod with a rotating specimen carousel in the test rig carrying a larger number of these rods. Using this carousel,

Fig. 12.61 Schematic of a closed system for crack growth measurements in high-temperature corrosion environments (after [12.113])

corrosion of rotating parts in engines is simulated. Furthermore all specimens are subjected to the same test conditions. In most cases with the burner rig test a thermal cycling test is performed, where the carousel with the specimens is automatically moved out of the hot zone once every 30 or 60 minutes and then cooled before reinsertion.

Corrosion with Mechanical Loading

A parameter which is neglected in standard high-temperature corrosion tests is the role of mechanical

stresses, which are omnipresent in practical operation. Their role has been investigated extensively over the past two decades and it turned out that significant effects on the life time of high-temperature components can be possible [12.109, 114–116]. For this reason different types of tests have also been developed that combine mechanical stresses with attack by high-temperature corrosion. In most cases the equipment for such kinds of tests is basically the same as for the determination of the mechanical properties of materials at high temperatures. In other words, standard creep test [12.117] or constant-strain-rate test [12.118] as well as low cycle fatigue (LCF) and high cycle fatigue test (HCF) [12.119] rigs have been used. In some cases even creep fracture mechanics approaches have been combined with high-temperature corrosion investigations [12.113, 120]. For these mechanical high-temperature corrosion tests the standard mechanical test rigs were equipped with an environmental chamber that can hold different types of test gases. Examples of the design of such environmental chambers are shown in Figs. 12.61 and 12.62, where Fig. 12.62 shows the environmental equipment to be inserted into a constant-load creep testing machine with two separate specimens, where the strain can be monitored by either mechanical or electronic strain gages. Figure 12.61 shows the schematic of a creep fracture mechanics environmental equipment for CT specimens where ceramic pull rods had been used. The information received from these experiments is the mechanical properties under the influence of corrosive attack, i. e. strain versus time, strain rate versus time, or stress versus strain curves. In the LCF and HCF test rigs it is usually the number of cycles to failure and the cyclic deformation curve that are measured. There are also examples in the literature where crack growth rates at high temperatures have been measured under corrosive conditions [12.113, 120, 121].

An important aspect of these tests is post-test evaluation by metallographic sectioning and microanalysis of the corrosion products. The results from such investigations can reveal whether internal formation of corrosion products at grain boundaries or at crack tips can significantly reduce the life time of components by corrosion-assisted crack initiation and crack growth. A number of examples have been studied in the literature [12.114].

12.8.5 Post-Test Evaluation of Test Pieces

Macroscopic Evaluation

The macroscopic appearance of the surface of the test piece should be photographed if necessary using

a low magnification. Color photographs are preferred over black and white photographs since coloring may already give some information about the type of oxidation/corrosion of the surface.

Metallographic Cross Section

For scale thickness measurements by metallographic cross sections it is recommended that the recommendations in [12.89] be followed. Care has to be taken in mounting the specimen orthogonally to the primary axis of the test piece. The cross section of the test pieces is analyzed using conventional light microscopy. The measurements consist of

- deposit thickness,
- scale thickness,
- depth of internal penetration inside the grains and at grain boundaries,
- depth of any depleted zone,
- remaining cross section of unaffected material.

A minimum of eight measurements per test piece should be taken. In addition the position of maximum attack is measured.

Reporting

The report of each test should contain the following information:

- Test material: manufacturer, name of the material [manufacturer designation, ASTM designation, Deutsches Institut für Normung (DIN) designation, etc.], grade or symbol, heat number/batch number, chemical composition, processing conditions, heat-treatment conditions.
- Test piece: designation of test piece, dimensions and surface area of test piece, surface finish condition of test piece, degreasing method of test piece, method of test-piece support, initial mass.
- Temperature and testing environments: test temperature (and maximum and minimum temperatures during the test), test duration, hot dwell time, cold dwell time, heating time, cooling time, dew point temperature of humidified test gas or humidity of laboratory air, flow rate of the test gas, type of system (open or closed).
- Test results: plot of net mass change per area $\Delta m_{\text{net}}/A$ in mg/cm^{-2} versus time t , results of any metallographic investigations, amount of spalled scale Δm_{sp} in mg, photograph of appearance after testing, photograph of the metallographic section of

Fig. 12.62 Two examples of closed systems for constant load creep testing in high-temperature corrosion environments (after [12.122])

the test piece including the surface layer after testing, oxidation rate constant $k(T)$, exponent of growth law n , the number of cycles N_B and the accumulated hot dwell time t_B that correspond to the onset of spallation or breakaway oxidation. If existing the report should also contain analytical results from scanning electron microscopy/EDS (Energy Dispersive Spectrometer), electron probe microanalysis/WDS (Wavelength Dispersive Spectrometer) or X-ray diffraction.

12.8.6 Concluding Remarks

The aim of this section has been to provide a concise and informative overview of the measurement methods used today in high-temperature corrosion testing. Two of the more commonly used test methods were described in some detail while the others were only discussed very briefly. For more detailed information it is recommended to read the literature given in the list of references. It should, however, be pointed out that there is still significant development work going on in these

test methods. A certain settlement of this situation will be reached after finalization of the present work items of work group 13 in ISO technical committee 156. In

the meantime it is recommended to follow the work of this work group closely when planning the set up of new high-temperature corrosion testing facilities.

12.9 Inhibitor Testing and Monitoring of Efficiency

The addition of small amounts of chemicals capable of reducing corrosion of the exposed metal is a preventative measure known as corrosion inhibition. According to the ISO 8044 definition corrosion inhibitors are chemical substances that decrease the corrosion rate when present in the corrosion system in sufficient concentration, without significantly changing the concentration of any corrosive agent.

Inhibitors may act on both cathodic and anodic partial reactions and are termed accordingly either cathodic or anodic inhibitors. A cathodic inhibitor shifts the corrosion potential in a negative direction, while the anodic inhibitor causes a positive change; in both cases the corrosion rate decreases.

Investigating corrosion inhibitor efficiency aims to gather information on the profile of the functional additive, including its inhibition mechanism. Corrosion experiments as well as electrochemical and surface analytical methods are the major tools in such investigations. In this context it is of utmost importance to note that electrochemical measurements are not corrosion experiments and cannot replace real corrosion experiments. On the other hand, testing tries to find out if and how well a functional substance performs under specific experimental conditions. Performance in a test may not correlate with performance under service conditions. There are numerous examples where functional compounds have been developed and designed to pass specific tests but have failed in service application. *Monitoring* in this context intends to create online information on the time-related status of the corrosion intensity of an inhibited corrosion system. Appropriate correlation between monitoring data and the real corrosion status of a system needs a detailed knowledge of the corrosion system itself.

12.9.1 Investigation and Testing of Inhibitors

As corrosion inhibitors are active at the electrified interface their performance can be investigated by electrochemical means.

Various electrochemical measuring methods have been developed and applied for investigations of inhib-

ited systems. The questions arise: which method gives which information and what are the application limits of the methods? Before applying any of the methods one has to consider the actual task of the investigation. Is it aimed mainly at scientific research or is information needed on the performance of inhibitors under service conditions.

In scientific research it is important, which of the two partial reactions (Fig. 12.63), the *anodic metal dissolution*,

or the cathodic reduction of an oxidizing agent,

is influenced by the inhibitor. Is it an anodic, cathodic or anodic–cathodic inhibitor (Fig. 12.64a–c)? Is the corrosion rate controlled by charge transfer or by mass transport (Fig. 12.65a–c)? Is the inhibition effect due to the formation of films, adsorption on metal surfaces (e.g. in corrosion product pores) or incorporation in corrosion product layers? (Fig. 12.65c)?

For practical applications information is needed on the effect of inhibitors on, e.g.,

- the reduction of metal loss in corrosive environments,
- the influence of hydrogen uptake of the metal (in systems with hydrogen formation in the cathodic partial reaction),
- the likelihood of localized corrosion.

Before starting any investigation the corrosion system must be carefully studied in terms of the appearance of

Fig. 12.63 Schematic representation of electrochemical corrosion

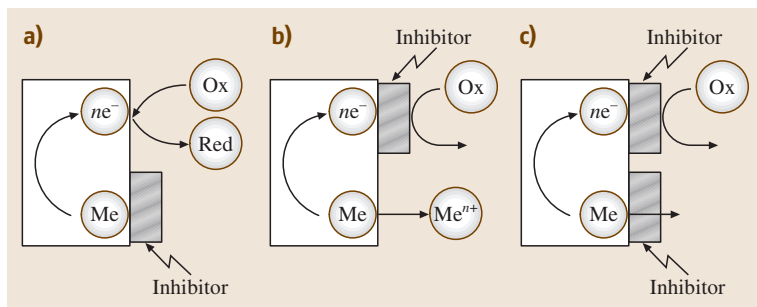

Fig. 12.64a–c Schematic representation of inhibitor action on bare metal surface: (a) anodic inhibition, (b) cathodic inhibition, (c) anodic–cathodic inhibition

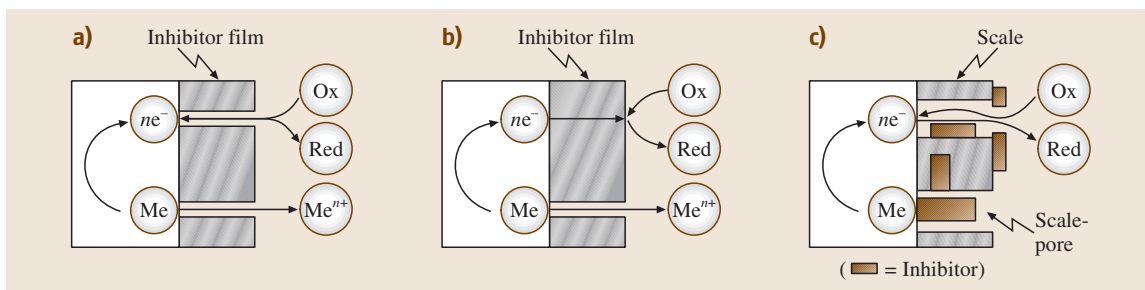

Fig. 12.65a–c Schematic representation of inhibitor action: (a) mass transport control at films (b) charge-transfer control at films (c) inhibitor action on scaled surfaces

corrosion (uniform, local, ability to passivation, character of layers developed by corrosion, scaling etc.) and the rate-determining step of the corrosion process. Particularly in exposure testing the analysis of the electrolyte over the period of testing can play an important role.

The methods of investigation were generally outlined in Sects. 12.1 and 12.2. All conclusions regarding the applicability and interpretation of such tests also apply for testing of inhibitors. Special care has to be taken if results from laboratory testing are transferred into practice. In any case it is advisable to carry out performance monitoring during service. The aim of this section primarily focuses on performance of systems affected by corrosion. Therefore monitoring of efficiency will be the main focus of this publication.

12.9.2 Monitoring of Inhibitor Efficiency

General Remarks

It is important to monitor the effectiveness of a corrosion-inhibitor treatment. It is even more important to ensure that the conditions under which the monitoring is carried out are representative and relevant to the operational conditions. Monitoring should ideally be carried out under the worst conditions that are likely to be en-

countered (e.g. stagnant areas or very high flow rates etc.), otherwise failures may occur while the monitoring process indicates that inhibition is effective.

Variables that need to be considered when monitoring include:

- environment – both normal and extraordinary conditions fluid flow conditions, including multiphase flow patterns,
- temperature,
- fluid velocity chemical analysis – to cover seasonal variations,
- type of system – closed, open evaporative cooling, once-through.

Application of Monitoring Data

The broad objective of carrying out monitoring is to manage the corrosion problem, in this case to control the corrosion-inhibitor treatment so that it works properly. The management process thus requires objectives to be set, and measurements to be made that can be compared with these objectives, so that adjustments to the treatment can be made as necessary to achieve the required performance. The objectives may include one or more of the following, depending upon the corrosion management philosophy:

- to achieve a specified degree of corrosion protection (corrosion rates), to correlate with previous experience or tests (corrosion rates, inhibitor concentrations),
- to achieve a required inhibitor efficiency E_i :

$$E_i = 100(w_o - w_{inh}/w_o) ;$$

- where w_o = weight loss or corrosion rate without inhibitor, w_{inh} = weight loss or corrosion rate with inhibitor.

It is important that the type of measurement made provides the data required. Thus, if the objective is to maintain a specified inhibitor concentration, corrosion rate measurements will be of little value.

Measurement of Inhibition Parameters to be Measured

A number of parameters relevant to corrosion inhibition may be measured:

- actual inhibitor concentration,
- inhibitor efficiency by corrosion monitoring,
- operational parameters in the plant that may affect inhibitor performance,
- chemical composition of the fluid containing the inhibitor.

Frequency of Measurement

The frequency of measurement may depend upon corrosion monitoring practice. In general it is important to monitor immediately after the first addition of the inhibitor, and then at least daily until the level has stabilized, since some of the inhibitor will be removed from the fluid by adsorption on surfaces within the system.

Open systems are more likely to suffer unplanned upsets than closed ones, and therefore should be monitored more frequently. For critical systems online measurements are useful. Online measurement systems have other advantages:

- they allow more rapid detection of changes or trends in corrosion, and data can be continually analyzed to reveal longer-term trends,
- they eliminate variations associated with sampling processes.

Chemical Analysis of Inhibitor Concentration Sampling techniques. It is essential to take as representative a sample of the fluid as possible. The location of sampling points is important:

- avoid dead legs,
- if possible, use isokinetic sampling techniques,
- avoid long sampling lines with high surface:volume ratios.

When taking a sample:

- always run a volume of the fluid to be sampled to waste before taking a sample,
- wash out the container with fluid before filling with the sample,
- observe sample preservation requirements (e.g. air exclusion, cool in ice).

Measurement of Inhibitor Concentration

The efficiency of an inhibitor is usually closely dependent upon its concentration in solution, since it is assumed that there is an equilibrium of the form: dissolved inhibitor + surface \rightarrow inhibited surface.

Measurement of the concentration of the inhibitor does not give direct information about its efficiency. A minimum concentration is usually specified for the inhibitor to provide the required performance, and this depends upon the conditions. Changes in operating conditions may therefore require adjustments to be made in inhibitor concentration to maintain the same performance.

Allowing the concentration to fall below the specified level can be very dangerous with anodic inhibitors, since partial failure of anodic inhibition can lead to a high-cathode-area low-anode-area situation, and induce rapid localized corrosion.

Characteristics of Commercial Inhibitors

Measuring the concentrations of commercial inhibitors may not be straightforward as:

- commercial inhibitors are rarely pure analytical-grade chemicals,
- they may be formulated with other chemicals to improve their performance (solvents, surfactants),
- their specification may allow a range of compositions.

The variability in concentration and composition may make it desirable to analyze the product before use, unless a quality-assurance scheme is in operation. The supplier's recommendations for the concentrations to be used should be adhered to; this avoids complications if problems or failure occurs.

Table 12.5 Field methods of analysis

Species	Semiquantitative method	Quantitative
CrO_4^{2-}	Diphenylcarbazone complex	Photometry of diphenylcarbazone complex
NO_2^-	Magenta azo dye	(a) Photometry of magenta azo dye; (b) Acidimetric titration with sulfamic acid
PO_4^{3-}	Phosphomolybdenum blue	Photometry of molybdenum–vanadate – phosphoric acid
$\text{SiO}_2/\text{silicate}$	Silicomolybdenum blue	Photometry of silicomolybdenum blue
Zn	Zn-thiocyanate-brilliant green	Atomic absorption spectroscopy

Laboratory Methods of Analysis

These have a number of advantages:

- they are very versatile,
- they can be very sensitive,
- high selectivity is possible.

A wide range of techniques is available. Separation and detection techniques are combined to increase sensitivity. Particularly useful are:

- **ICPS** – inductively coupled plasma spectrometry;
- **MS** – mass spectrometry;
- **HPLC** – high-performance liquid chromatography;
- **IC** – ion chromatography.+.5

The disadvantages are:

- they require special, usually expensive, equipment,
- good performance requires well-trained operators,
- samples have to be returned to the laboratory, resulting in a time delay.

Field Methods of Analysis

These have a number of common features:

- they give almost instant results,
- they employ preprepared and prepacked reagents (the sell-by date should not be exceeded),
- they usually involve color formation reactions,
- they compare color to intensity scale or use a battery-operated photometer.

Some common methods are specified in Table 12.5

Some disadvantages are:

- individual kits cover limited concentration ranges; choose the one you need,
- look out for possible interferences (other colored species present),
- color intensity may vary with time, may bleach in sunlight,
- the number of species that can be detected is limited (pH, nitrite, chromate).

Interpretation: Inhibitor Loss Processes

Lower than expected concentrations of inhibitor may be the result of a number of processes:

- precipitation, which may depend on temperature, solution composition,
- chemical reaction with other species, e.g. oxygen,
- adsorption on surfaces (metals, solids in suspension, corrosion products, precipitates),
- degradation by microorganisms,
- thermal degradation.

To assist in finding the reason for the loss of inhibitor, measurements of other fluid chemistry parameters may be useful, as suggested below.

Additional Measurements

- Water chemistry: including pH, dissolved species – chloride, iron etc.,
- Mass balance: gross check of concentration – chemicals used, make-up water volume,
- System features:
 - concentration of atmospheric impurities in open systems,
 - process-side leaks,
 - inefficient blow-down microbiological activity,
 - fouling of surfaces, including heat transfer surfaces.
- Operational parameters:
 - fluid temperature surface temperature, including hot-spots,
 - flow velocities – periods of shut-down.

12.9.3 Monitoring Inhibition from Corrosion Rates

General

The main objective of using inhibitors is to control corrosion, therefore a measurement of the corrosion rate can be the most direct way of assessing the effectiveness of a corrosion control programme. However, a number of points need to be borne in mind:

- the technique must replicate the type of corrosion (general, localized etc.),
- the results must be presented simply and be easy to interpret,
- some techniques are real-time online measurements, others are not,
- most rates are measured with samples in the form of a probe or coupon; the results will depend on the geometry (flush, cylindrical, crevice etc.).

Electrical Techniques

Polarization resistance.

- These are based on the rates of cathodic and anodic electrochemical corrosion reactions.
- They may be difficult to interpret if protective layers are formed.
- Other redox reactions may occur at the same time as the corrosion reaction.
- Bimetallic and selective corrosion processes cannot be detected.

Electrical resistance.

- This depends upon the change in resistance of a wire or thin plate due to corrosion and/or erosion,
- It can be very sensitive: 1–1000 mpy,
- The metallurgical state of probe may be very unrepresentative of the real material; geometry may be important (e.g., flush, intrusive).

FSM – electrical fingerprint.

- This is similar to electrical resistance in principle.
- It uses the actual vessel, pipe.
- It provides non-intrusive, real-time, on-line wall thickness data.
- It allows multiple (96) measurements at different locations e.g. in multiphase flow.
- Changes in thickness are measured from voltage changes when current passed.
- Computer display is provided.
- It is relatively expensive.

Corrosion coupons. These are the most widely used means of monitoring corrosion. Their advantages are:

- cheap to buy,
- available with standard finish, weighed, degreased,

- can give information about localized corrosion,
- bimetallic and welded coupons can be prepared,
- effects of stress can be reproduced in C-rings or four-point load probes can be inserted and retrieved during operation through access fittings.

The measurements that can be made with coupons include:

- weight determination after drying (look out for spalling of deposits, corrosion product),
- weight loss after pickling,
- percent area of localized corrosion,
- pit depth by sectioning, grinding,
- analysis of corrosion products,
- optical, SEM metallography of corroded surface.

They have a number of limitations:

- They must be electrically insulated from plant components they only provide integrated measurements of corrosion;
- They must be of reasonable area (1500–2000 mm²) to avoid cut-edge effects;
- The extent of localized corrosion may depend on area;
- The surface finish and material should be the same as for components to be tested;
- There is no standard pre-corroded surface;
- The location of the coupon is important (fluid flow, temperature effects).

A special type of corrosion coupon is required for measurements under heat-transfer conditions. Such specimens usually have tubular geometries. A number of features have to be considered in choosing and setting up such specimens:

- choice of electrical or sensible fluid heating,
- electrical control is most convenient, and easiest,
- most industrial heat transfer involves fluids,
- conditions at the surface depend on the heat-transfer coefficient,
- the heat-transfer coefficient depends on the fluid and the flow conditions, surface temperature or heat flux control.

Table 12.6 provides information on techniques used in the field and their most important features.

Table 12.6 Summary of techniques

Technique type	Information	Time for measurement	Response to change	Corrosion type	Application interpretation
Optical	Distribution of attack	Fast, if, accessible	Slow	Localized	Simple
Analytical methods	Corrosion state, total	Fairly fast	Fairly fast	General	Relatively easy, needs knowledge of corrosion in system, inhibitor present
Corrosion coupons	Average rate of corrosion and form	Long exposure	Poor	General or localized	Easy, simple
Polarisation resistance	Corrosion rate	Immediate	Fast	General, localized	Simple to complex
Electrical resistance	Integrated corrosion	Immediate	Moderate	General	Relatively simple
Corrosion potential	Corrosion state	Immediate	Fast	General or localized	Easy to apply, needs knowledge and experience to interpret
ZRA = zero-resistance ammetry	Corrosion state	Immediate	Fast	Bimetallic galvanic corrosion	Fairly easy, needs corrosion knowledge
Ultrasonics	Thickness of metal left cracks, pits	Fast	Fairly poor	General or localized	Easy to apply, care with sensitivity
Eddy currents	Cracks, pits	Immediate	Fairly poor	Localized	Easy
Acoustic emission	Propagation of cracks, leak detection, cavitation	Immediate	Fast	Cracking, leaks	Expensive, needs specialist
Hydrogen probe	Total corrosion	Fast	Poor	General	Easy, only in acid
Sentinel holes	Go/no go for slow remaining thickness		Poor	General	Easy, relatively simple
Thin-layer activation (TLA)	Integrated material removal	Slow	Variable	General, localized	Simple, special equipment

Friction and Wear

Almost all mechanical systems, artificial or natural, involve the relative motion of solid components. Wherever two surfaces slide or roll against each other, there will be frictional resistance, and wear will occur. The response of materials to this kind of interaction, often termed *tribological*, depends not only on the precise nature of the materials, but also on the detailed conditions of the contact between them and of the motion. Friction and wear are system responses, rather than material properties. The measurement of tribological behavior therefore poses particular challenges, and a keen awareness of the factors that influence friction and wear is essential.

This chapter provides definitions of the key concepts in Sect. 13.1, and provides a rationale for the design and selection of test methods in Sect. 13.2. Various standard and other tribological test methods are comprehensively reviewed in Sect. 13.3, which is followed by descriptions of methods used for the quantitative assessment of both friction (Sect. 13.4) and wear (Sect. 13.5). Methods used for characterizing worn surfaces and wear debris are addressed in Sect. 13.6.

13.1 Definitions and Units

Tribology is the science and technology of interacting surfaces in relative motion, which includes the study of friction, wear and lubrication. Friction and wear represent two key aspects of the tribological behavior of materials. Like other measurements of material perfor-

mance, such as corrosion or biodegradation, both friction and wear result from exposure of the material to a particular set of conditions. They do not therefore represent intrinsic material properties, but must be measured and defined under well-characterized test conditions.

13.1.1 Definitions

Wear can be defined as damage to a solid surface, generally involving progressive loss of material, due to relative motion between that surface and a contacting substance or substances [13.1]. Materials in contact are subjected to relative motion in many different applications. In some cases this motion is intentional: for example in rotating plain bearings, pistons sliding in cylinders, automotive brake disks interacting with brake pads, or in the processing of material by machining, forging or extrusion. It may also be unintentional, as in the small cyclic displacements known as fretting which can cause wear in certain structural joints under oscillating loading. If hard particles are present, for example as contamination in a lubricant, or intentionally as in abrasive machining, then these particles will have a profound influence on the resulting wear process.

The friction force is defined as the force acting tangentially to the interface resisting motion, when, under the action of an external force, one body moves or tends to move relative to another. The friction force F may be associated with sliding motion or with pure rolling motion of the bodies; in some practical engineering applications such as the contact between ball and track in a ball-bearing or between a pair of mating gear teeth, there may be more complex motion involving both sliding and rolling.

The coefficient of friction μ is a dimensionless number, defined as the ratio F/N between the friction force F and the normal force N acting to press the two bodies together. The kinetic coefficient of friction μ_k is the coefficient of friction under conditions of macroscopic relative motion between the two bodies, while the static coefficient of friction μ_s is the coefficient of friction corresponding to the maximum friction force that must be overcome to initiate macroscopic motion between the two bodies. The coefficient of friction is a convenient method for reporting friction force, since in many cases F is approximately linearly proportional to N over quite large ranges of N . The equation

$$F = \mu N \quad (13.1)$$

is sometimes called “Amontons Law”.

The value of μ can be expected to depend significantly on the precise composition, topography and history of the surfaces in contact, the environment to which they are exposed, and the precise details of the loading conditions. Although tables of coefficients of friction have been published, they should not be regarded as anything more than general indications of relative val-

ues under the specific conditions of measurement. The coefficient of friction usually lies in the range from 0 to 1, although there is no fundamental reason why it need do so. Negative values of μ may be thought of as being rather artificial, since they result from adhesive forces between the bodies involved which result in a tangential force while the bodies are subjected to a tensile normal force, and “friction” is perhaps not a helpful term to describe this phenomenon; but values of μ greater than 1 are physically quite reasonable, and can be encountered, for example, in the interaction between a car tire and a dry road surface, or in the sliding of certain ductile metals in the absence of oxygen.

A large number of specialist terms used in tribology have been formally defined, most recently by ASTM [13.1]. An earlier compilation including many other terms, as well as their translations into French, German, Italian, Spanish, Japanese, Arabic and Portuguese, was published by an international group [13.2]. A particularly useful term is “triboelement”, defined as one of the two or more solid bodies involved in a tribological contact.

13.1.2 Types of Wear

It is important, especially when describing wear, to distinguish clearly between the nature of the relative motion responsible for the wear and the physical mechanisms by which the material is removed or displaced in wear. Wear tests are designed to produce specific types of relative motion, which can often lead to different mechanisms of wear in different materials, or at different loads or speeds. Methods that can be used to distinguish between wear mechanisms are discussed in Sect. 13.6.

Figure 13.1 illustrates some common types of relative motion that can result in wear. These represent idealized examples and can be further subdivided. For example, sliding and rolling motions may be either continuous or interrupted, and may occur along the same track on a rotating counterbody or on a continuously fresh track. They may involve constant relative velocity (continuous sliding), or varying velocity (such as reciprocating motion with perhaps sinusoidal or linear velocity variation).

When analyzing the motion in a tribological contact, the nature of the contact must also be examined. It is helpful to consider how the contact region moves with respect to the surfaces of the bodies in contact. For example, in the simple example of a small block sliding on a larger counterbody shown in Fig. 13.1, the contact region is fixed relative to the block, which is in continuous

contact, whereas it moves along the larger triboelement, so areas of this experience contact only for a certain period. In the case of simple rolling shown in Fig. 13.1, the contact region moves relative to the surfaces of both triboelements, and areas on both of these surfaces are therefore in intermittent contact.

In many practical situations there is a lubricant film present, but in some others, as well as in many laboratory studies, the sliding or rolling occurs unlubricated in air.

Relative motion normal to the surface of a triboelement may result in impact. Repeated impact by a large counterbody on an essentially single-contact region can lead to wear, as can impact by a large number of small particles or even liquid droplets, in which case the impact sites are usually distributed over an area of the surface. Wear can also result from the collapse close to a solid surface of vapor or gas bubbles produced by local pressure fluctuations in a cavitating liquid.

The presence of small particles in the contact region, usually harder and thus less deformable than one of the moving bodies, leads to a significantly different wear process to that for plain sliding. The most common types of wear associated with hard particles in a sliding contact are illustrated in Fig. 13.2. If the particles are attached to one of the sliding bodies, either forming part of it (for example, as hard discrete phases in a softer matrix, or as particles fixed to the surface, as in abrasive paper) or embedded in the surface, then they will be

Fig. 13.1 Examples of tribological contacts involving relative motion of triboelements, as well as erosion by particle impact, liquid impact or cavitation in a liquid

Fig. 13.2 Examples of abrasive wear due to the presence of hard particles in a sliding contact, and scratch damage

dragged over the counterbody in a process described as sliding abrasion. This type of abrasion is often termed “two-body” abrasion, since the particles effectively form part of one of the two triboelements. If the particles are free, and roll between the sliding bodies, then their interaction with them is different and can be described as rolling abrasion; this is also known as “three-body” abrasion, since the particles form a distinct “third body” which moves with respect to the two sliding bodies. The terms “two-body” and “three-body” can lead to confusion, since the motion of free particles in a sliding contact will depend on the relative hardnesses of the surfaces and on the applied pressure, and can vary between sliding and rolling even in different regions of the contact. The conditions of abrasive wear are sometimes described as either “low-stress”, in which the abrasive particles themselves are relatively undamaged in the wear process, or “high-stress”, where the particles experience extensive fracture.

If surface damage results from the action of a single hard asperity, or a small number of relatively large asperities, then it is often termed “scratching”, and scratch testing can be used to characterize the response of a material to this type of deformation (see Sect. 13.3.5). Scratching is also shown schematically in Fig. 13.2.

13.1.3 Units for Wear

Since wear is often associated with the removal of material from a surface, it is usually quantified in terms of the volume of material removed, the mass removed, or the change in some linear dimension after wear. All three can be used as primary measurements. For example, the volume of material worn from the end of a spherically-ended pin to form a flat area on the pin may be calculated from a measurement of the diameter of the flat area; volume changes in more complex geometries may be derived computationally from the difference between profile traces recorded before and after wear.

Measurement of mass loss is in principle comparatively straightforward, although great care must be taken in the experimental technique to reduce errors. Linear changes in dimensions (for example, the reduction in length of a pin specimen, or the change in clearance in a bearing) are also in principle straightforward to measure, but are prone to error and so careful experimental procedures are needed. Measurements of mass change can be affected by material transfer and oxidation; dimensional changes can also be influenced by thermal expansion. These and other aspects of experimental techniques are discussed in Sect. 13.5.

In some cases material may be lost from both triboelements, or significant transfer of material may occur between the triboelements, and particular care is then needed in both measuring and describing the magnitude of wear. If wear is associated with the movement of material within the surface of a single triboelement, it will lead to changes in the topography of the surface which can be detected by profilometry, as discussed in Sect. 13.6.2.

The amount of wear that occurs when two surfaces slide over each other tends to increase with sliding distance, and hence with time. The wear rate can then be defined as the rate of material removal or dimensional change per unit time, or per unit sliding distance. Because of the possibility of confusion, the meaning of the term “wear rate” must always be defined, and its units stated. In the case of erosion the wear rate is usually quoted as the mass or volume loss per unit time; for erosion by solid particle impact, it may also be expressed

as the volume or mass loss per unit mass of impinging particles.

Many quantitative models for sliding wear have been developed, but one of the simplest, due to Archard, is useful for comparing wear rates and material behavior under different conditions. The Archard model leads to the equation:

$$Q = KW/H, \quad (13.2)$$

where Q is the volume of material removed from the surface by wear per unit sliding distance, W is the normal load applied between the surfaces, and H is the indentation hardness of the softer surface. Many sliding systems do show a dependence of wear on sliding distance which is close to linear, and under some conditions also show wear rates which are roughly proportional to normal load. The constant K , usually termed the Archard wear coefficient, is dimensionless and always less than unity. The value of K provides a means of comparing the severities of different wear processes. Equation (13.2) can be applied to abrasive wear as well as to sliding wear; an analogous equation can also be developed for erosion by solid particle impact, from which a value of K can be derived.

Figure 13.3 shows, very approximately, the range of values of K seen in various types of wear. Under unlubricated sliding conditions (so-called dry sliding), K can be as high as 10^{-2} , although it can also be as low as 10^{-6} . Often two distinct regimes of sliding wear are distinguished, termed “severe” and “mild”. Not only do these correspond to quite different wear rates (with K often above and below 10^{-4} respectively), but they also involve significantly different mechanisms of material loss. In metals, “severe” sliding wear is associated with relatively large particles of metallic debris, while in “mild” wear the debris is finer and formed of oxide particles. In the case of ceramics, the “severe” wear regime is associated with brittle fracture, whereas “mild” wear results from the removal of reacted (often hydrated) surface material.

When hard particles are present and the wear process involves abrasion (by sliding or rolling particles) or erosion (by the impact of particles), then the highest values of K occur; the relatively high efficiency of the removal of material by abrasive or erosive wear explains why these processes can also be usefully employed in manufacturing.

The values of K that occur for unlubricated sliding, or for wear by hard particles, are generally intolerably high for practical engineering applications, and in most tribological designs lubrication is used to reduce

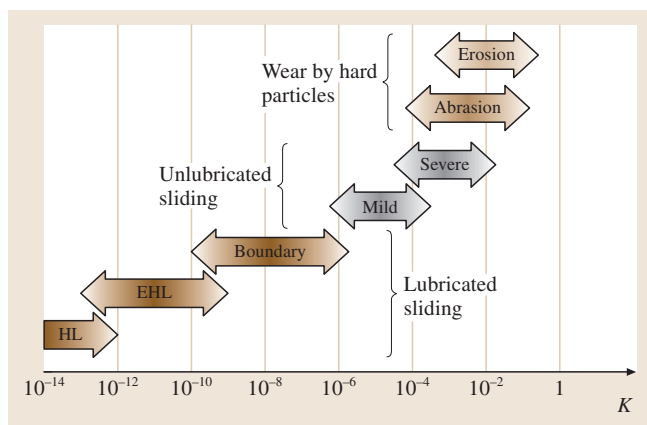

Fig. 13.3 Typical ranges of wear coefficient K exhibited under various tribological conditions: hydrodynamically lubricated (HL); elastohydrodynamically lubricated (EHL); lubricated by a boundary film; unlubricated sliding; abrasive wear; and erosive wear

the wear rate; the effect of lubrication in reducing wear is far more potent than its effect on friction, and the increase in life which results from the reduction of wear is generally much more important than the increase in efficiency from the lower frictional losses. As Fig. 13.3 shows, even the least effective lubrication can reduce the wear rate by several orders of magnitude, and as the thickness of the lubricant film is increased in the progression from boundary, to elastohydrodynamic (EHL) and then to hydrodynamic lubrication (HL), the value of K falls rapidly. In the hydrodynamically lubricated components of a modern automotive engine, values of K as low as 10^{-19} are achieved.

The quantity $Q/W (= K/H)$, given the symbol k , and sometimes termed “specific wear rate” (UK) or “wear factor” (USA), is also useful. The units in which k is expressed are usually mm^3/Nm , representing the

volume lost (mm^3) per unit sliding distance (m) per unit normal load on the contact (N). These units are commonly used when quoting experimentally measured rates of wear. It is useful to note that for a material with a Vickers hardness H of 1 GPa ($\approx 100 \text{ HV}$), then the numerical value of K (dimensionless) is the same as that of k (in units of mm^3/Nm).

Although k (or K) is effectively constant over quite large ranges of load or sliding speed in many cases of sliding wear, in some instances sharp transitions can occur, and k may change by a factor of 100 or even 1000 for a relatively small change in the conditions. This behavior is associated with a change in the predominant mechanism of material removal; for this reason it is always dangerous to extrapolate wear data to predict the likely rate of wear in a system from data obtained under different conditions.

13.2 Selection of Friction and Wear Tests

Friction and wear testing is often carried out to ensure that good tribological performance is achieved from materials. This information is required at different times in the life cycles of products. Designers require data that will enable them to design products that will not wear out or have unacceptably low efficiency, or even fail to function, due to frictional losses; process engineers need equipment to make the products that will function cost-effectively without premature failure from wear; and those marketing the products need to know that they will have good tribological performance. Other tests are performed for more fundamental reasons to investigate wear mechanisms or material performance, perhaps as part of a program of material development.

Friction and wear are important in most industrial sectors, but there is now also increasing attention paid to the application of tribological testing to societal needs. Traditionally, the evaluation of friction and wear has been of major concern in areas such as mining and drilling, transport power plant, power generation and machine tools. Now there is increasing attention to areas such as the tribological performance of biomedical implants and the degradation of decorative finishes. In recent years there has also been much attention given to the design and development of microelectromechanical systems (MEMS) where friction and wear are strongly influenced by the scale of these small components, hampering the development of new devices.

13.2.1 Approach to Tribological Testing

There are many different approaches to friction and wear testing, illustrated schematically in Fig. 13.4, that differ in the scale and complexity of the element that is being tested. Ultimately field testing of the final product will always be required for final proof of effectiveness, but it can often be prohibitively expensive to evaluate several different alternative materials or design variations by this method. It also suffers from a lack of control of the parameters that define the wear processes that are occurring, so that an understanding of the dependence of wear mechanisms on important factors such as load and speed cannot be developed.

As Fig. 13.4 demonstrates, it is possible to break down the complete product into its functional elements. The final stage of this process of abstraction is to use laboratory tests that simulate a particular tribological element of the complete product. Moving away from field trials towards laboratory testing, in general, reduces the costs of testing and increases the ability to control the important factors that affect the magnitude of friction and wear. This enables programs of testing to be designed that allow for the cost-effective development of materials and tribological systems through better understanding of the tribological processes.

There are two main situations for which laboratory tests are required. The first is to provide information on

Fig. 13.4
Schematic illustration of types of tribological test [13.3]

the tribological performance of materials when they are being developed or selected for a general field of application, but when the specific conditions that will be applied are not well-defined. In this case there is little information to guide the specification of the test parameters to be used in any test program, and indeed the specific test that should be used is not always clear. However, it is important to consider carefully how the materials will be used in order to eliminate inappropriate tests that will only lead to misleading results. Thus, for materials that are being developed for applications where abrasion is extremely likely to occur, sliding wear tests cannot be expected to give relevant data. Nevertheless, so long as the likely mode of wear can be predicted, useful information can be obtained on the likely performance of the materials in practice.

The second situation is where there is a requirement to simulate a specific application. Here the conditions that are operating in the tribological contact should be better defined, so that the design of a program of laboratory wear tests reduces to choosing the appropriate test and test parameters to achieve the correct simulation of the practical application. Although in some cases the best approach is to design and manufacture a specific rig that is intended to reproduce the conditions in the application precisely, in most cases a well-established test can be used, perhaps with some adjustment of the test parameters, to provide a reasonable match with the application. The selection of these parameters is the key to generating a valid test.

As it is often difficult to achieve an exact simulation in the laboratory, it is always important to check that the same mechanisms of wear occur in the laboratory test as in the real application. When this is achieved, the laboratory test is likely to give results that will reliably predict performance in the application. Figure 13.5 shows an example of such a comparison, from tests performed to simulate the abrasion of cemented carbide extrusion tools used to form ceramic roof tiles. The features of the worn surfaces of the cermets were very similar in both laboratory tests and the samples recovered from the practical application, and subsequent field trials showed an excellent match between the results of the laboratory tests and the lifetimes of the components in service.

13.2.2 Test Parameters

Many parameters control and define the conditions in a tribological contact, and hence influence the resulting wear and friction. Important examples are listed in Table 13.1. Some of these parameters are only applicable to specific types of wear; for example the shapes of abrasive or erodent particles are relevant only to the processes of abrasion or erosion.

A full description of the effects of these test parameters is well beyond the scope of this chapter. The reader should refer to other sources for a fuller description [13.4, 5], but some aspects are discussed briefly here.

Table 13.1 List of some important parameters that influence tribological processes

Parameter	Units or type of information
Normal load	N
Sliding speed	m/s
Materials of triboelements	All aspects of composition and microstructure, at surface as well as sub-surface
Test environment (including any lubricant present)	Composition, chemical and physical properties of gas and/or liquid surrounding tribological contact
Temperature	°C
Type of relative motion between surfaces	Trajectory: sliding, rolling, impact etc.
Contact geometry (form)	Shapes of surfaces
Contact geometry (local)	Roughnesses of surfaces
Abrasive/ erosive particles	Material, shape (and distribution), size (and distribution)
Contact dynamics	Stiffness, damping, inertial mass

In laboratory testing it is normal to positively control only a few test parameters such as the applied normal load, relative speed and contact geometry. Other parameters that can have a major effect on the resulting wear and friction are the presence of lubrication, the environment and atmosphere of the test (including the air

humidity), the bulk temperature of the samples, and the mechanical dynamics of the test system. These parameters are normally held constant from one test to another, either by the application of a specific control methodology, or simply by using the same test system for the whole sequence of tests in the program.

The contact geometry is a crucial parameter in the design of a wear test where two bulk surfaces are in moving contact, as in sliding. The ideal situation, in which the nominal contact area, and hence nominal contact pressure, would not vary during the test, would be to achieve self-aligning conformal contact between the test samples. This can be achieved in some cases by careful design of the samples and their holders, but often it cannot be achieved, and then high initial contact stresses occur at the edges of the misaligned contacts. To avoid this uncontrolled nonconformal geometry, it is common to use a controlled nonconformal geometry with one triboelement in the form of a ball or spherically-ended pin loaded against a flat sample. A ball diameter of about 10 mm is typically used. The disadvantage of this approach is that although the initial contact geometry is well controlled, the initial contact stresses are high. The ball or pin then wears rapidly until a larger contact area is produced, resulting in a substantially lower contact pressure. This change may lead to a change in wear mechanism from the initial high-stress regime to a subsequent low-stress, larger contact area regime. An approach that reduces this effect is to use one triboele-

Fig. 13.5a,b Example of comparison of worn surfaces from a laboratory simulation and a practical application. The SEM images show WC/Co tools used to manufacture concrete tiles: (a) worn surface from production tool; (b) worn surface of sample after laboratory wear testing

ment with a large contact radius so that although the initial contact geometry is still well defined, the initial contact pressure is lower, and changes in mechanism are less likely.

The temperatures of the contacting triboelements can affect the tribological behavior through changes in their mechanical and chemical properties. As well as these bulk effects, the areas of the samples in contact become hotter through frictional heating; the power dissipated in the contact is given by μNv where μ is the friction coefficient, N is the normal load, and v is the relative sliding velocity. The local temperatures at the contact areas can therefore become much higher than the bulk temperatures [13.6]. This factor needs to be taken into account when designing wear tests or interpreting test results.

As outlined in Sect. 13.1.3, lubrication of the contacts will also affect the wear, often in terms of mechanism as well as amount. Under certain conditions of sliding speed, load and lubricant viscosity, the two surfaces become separated by a continuous, hydrodynamically-generated lubricant film, and the wear rate can fall to a very low level, as indicated in Fig. 13.3. Hydrodynamic lubrication (a thick lubricant film) is favored by low normal pressure, high lubricant viscosity, and high sliding speed. For conditions where the lubricant film thickness becomes comparable with the roughness of the triboelements, elastic deformation of these bodies becomes important and the pressure in the lubricant is high enough to cause a significant local increase in viscosity; this is the regime of elastohydrodynamic lubrication (EHL). For even thinner films (at low speeds or high contact pressure), the system enters the regime of boundary lubrication, where appreciable interaction occurs between asperities on the two surfaces. Here the chemical composition of the lubricant has a major effect on the nature and properties of the chemically formed surface films and on the wear that occurs.

13.2.3 Interaction with Other Degradation Mechanisms

Other degradation mechanisms such as chemical reaction and fatigue can also make a major contribution to the overall loss of material from moving contacting surfaces. Interactions often occur with the test environment through chemical reactions of the test materials. In wear corrosion, the triboelements are exposed to an aqueous medium, and corrosion of the materials acts in conjunction with mechanical processes to alter the amount of

material lost. There is positive synergy in most cases, so that the mass loss is greater than the sum of the contributions expected from pure corrosion or pure wear alone. Exceptionally, in negative synergy, corrosion can form a mechanically stronger layer on the surface which acts to protect the surface and thus reduce the total wear rate. Tribochemical reactions of materials may also occur; ceramics, for example, can react with water vapor to form hydroxides that reduce friction and protect the wearing surface.

When metals are heated, either through a bulk increase in temperature or by frictional heating, considerable oxidation can occur. At first this may reduce wear, as seen in the mild wear of steels, but as the temperature increases further, the production of weak oxide may increase to such an extent that the wear rate increases once more [13.4].

In many tribological systems, the surfaces of the contacting materials are subjected to alternating stresses. These stresses may be high enough to initiate and grow fatigue cracks in the material that may contribute to the material loss caused by other wear processes. Rolling contact fatigue is an important degradation mechanism in certain applications of materials, but lies outside the scope of this chapter.

13.2.4 Experimental Planning and Presentation of Results

When planning a program of tribological tests, the choice of test conditions must be determined, either by the relevant engineering application, or in order to achieve the appropriate mechanism of wear in more fundamental studies. In the development of materials, a range of conditions can be chosen to represent those likely to occur during actual use of the material.

There are many test factors that need to be controlled during a test. These can be grouped into those concerned with the mechanical test conditions (such as contact load or pressure, speed, motion type and test environment), and sample parameters (such as material composition, microstructure and the initial surface finish of the samples). A full program of testing under all combinations of these factors would be time-consuming and costly, and may not be required. Often a single factor can be identified as “key” to the material response, and in this case a good approach is to set all the other factors at constant values and vary the chosen factor in a controlled way in a series of tests. This approach is termed a parametric study. More complex statistical, experimental design procedures can be used, but care

needs to be taken in the design of experiments to account for the variability that is normally observed in the results of wear tests.

Mapping techniques can be used where two (or more) factors are changed in a controlled way (normally more coarsely than in parametric studies), with the friction and wear results plotted either as individual points or as contours. Regions on the map are then delineated on a mechanistic basis, with the region boundaries either defined by identifying the wear mechanism by microstructural techniques, or by identifying transi-

tions in friction and wear behavior as sudden changes in wear rate or friction coefficient. The mapping procedure is a very efficient way of determining the overall behavior of a material because it provides useful information about the position of transitions in wear behavior in a systematic and controlled way. This comes at the expense of a reduction in the detailed knowledge of the variation of friction and wear with any one factor, but once the regime of interest is better defined through the use of mapping studies, then a more detailed parametric study can be conducted.

13.3 Tribological Test Methods

This section gives some information on the tribological tests that are in common usage, and which have in many cases been standardized, particularly through the American Society for Testing and Materials (ASTM). Due to constraints on space, only a brief description can be given. Further information can be obtained from other sources [13.5, 7–12]. The main test parameters, the measurements that can be made, and the standards associated with each type of test are listed.

13.3.1 Sliding Motion

Wear tests for materials in sliding contact are characterized by continuous contact between the two samples in tribological contact. There are two distinctly different types of test.

In many tests, the extent of relative movement is sufficiently large (typically greater than 300 μm) so that all contact points on at least one of the bodies are out of contact for some of the test period. This is in contrast to the case of fretting, where at least part of the contact area on both samples is always in contact. In fretting tests, the debris is trapped at the interface between the two samples, leading to different behavior from that in tests involving larger extents of movement, in which the debris is more readily lost from the contact region.

Common tribological test geometries involving sliding motion are shown in Fig. 13.6. Pin-on-disc and reciprocating geometries are used most often, but pin-on-disc testing with continuous rotary motion is often not appropriate since many applications involve reciprocating motion. This difference is important, as it affects the retention of debris at the wear interface and the stress history on the surfaces. Fretting tests are always carried out with a reciprocating geometry; particular care is needed in apparatus design as the elastic deformation

Fig. 13.6 Examples of test geometries used for tribological tests involving sliding motion

of the test system can be similar in magnitude to the required sample motion, leading to difficulties controlling and measuring sample displacement.

Often balls are used instead of pins, and in some cases blocks (with large contact areas) are also used. The choice of a conformal or nonconformal contact geometry and the frictional generation of heat are factors that need to be carefully considered.

13.3.2 Rolling Motion

Tribological contacts often involve rolling motion. Suitable test geometries are shown in Fig. 13.7. If the application is concerned with bearing races, then this is one situation where laboratory tests can be carried out relatively easily on the components themselves. This is clearly appropriate for roller bearing applications, but the complexity of the test geometry means that it is of-

Fig. 13.7 Examples of test geometries used for tribological tests involving rolling motion

ten difficult to develop a fundamental understanding of the wear and friction processes that occur.

The four-ball test has been popularly used for many years to test, in particular, the maximum load and speed for failure at the contact points in this test geometry, from mechanisms such as scuffing and seizure. However, results from this test, which can involve very high contact pressures and frictional power dissipation, are not readily extended to practical applications, and the method also suffers from a lack of control of the detailed motion of the balls during the test.

In two-roller testing, on the other hand, there is independent control of the motion of the rollers, and it is possible to adjust the amount of relative sliding between them as well as the rolling speed. The cylindrical edge of the rollers sometimes has a flat cross-section, but is also commonly crowned.

13.3.3 Abrasion

Abrasion testing can be carried out with a range of tests, as shown in Fig. 13.8. The simplest type of testing is carried out by loading a sample pin against abrasive-coated paper supported on a solid backing. As well as using a rotating abrasive-covered disc, tests can also be carried out with abrasive paper held on to a drum, or with a belt of abrasive paper. An important issue with these tests is that, as abrasion of the test sample takes place, the abrasive paper degrades by clogging with wear debris and due to damage to the contacting regions of the abrasive particles, so that the wear of the test sample will typically decrease as the test progresses; in extreme cases the wear mechanism may change as sliding then occurs predominantly against debris rather than against the abrasive particles. The use of a spiral track on the abrasive paper can achieve a steady process of wear by ensuring abrasion against fresh particles.

In another common type of abrasion test, a sample is pressed against a rotating wheel in the presence of a continuous supply of free abrasive particles. An important parameter in these tests is the stiffness of the wheel or other counterbody. Tests can also be carried out dry or in fluids of different types, allowing tests to be made in the presence of corrosive media. Some tests with rotating wheels involve the recirculation of abrasive during a single test (ASTM B 611 [13.8]), while in others a continuous stream of abrasive passes through the wear interface and is not reused (such as the dry sand rubber wheel abrasion test, ASTM G 65 [13.8]).

Fig. 13.8 Examples of test geometries involving abrasion

A test that has received some prominence recently is the microscale abrasion test, in which a ball is rotated against a flat sample in the presence of abrasive. This test is particularly suited to determining the abrasion rate of a coating.

13.3.4 Erosion by Solid Particles

There are two main groups of particulate erosion tests, in which the particles either strike the sample in a gas (usually air), or are transported in a liquid, which is usually termed slurry erosion. Examples are shown in Fig. 13.9.

In the centrifugal accelerator, the erodent particles are accelerated along radial tubes in a rotor so that a stream of erodent particles emerges at some angle to the rotor periphery (which depends on the detailed design) to strike one or more samples located in a ring around the rotor. This test has the advantage that several different samples can be tested simultaneously, but there is usually some uncertainty in the angle with which the particles strike the samples, and only a fraction of the particles fed into the apparatus actually strike the samples. Some designs of centrifugal accelerator impart significant rotation to the particles, which may influence the resulting erosion rate. In the gas-blast test a compressed gas stream (usually air) accelerates the erodent particles along a nozzle towards the sample, which is held at a controlled angle to the stream. In this case only one sample can be tested at a time.

In slurry erosion testing a pump can be used to generate liquid flow through a nozzle. Erodent particles are incorporated into the jet, being either picked up through a venturi system or suspended in the erodent slurry. The resulting jet of slurry is directed against the test sample held at a controlled angle.

In all erosion tests the particle impact speed and the angle of impingement of the erodent stream against the sample are the most important variables.

13.3.5 Scratch Testing

Scratch testing was originally developed to evaluate the adhesion of coatings. In the scratch test an indenter of well-defined geometry is pressed onto and moves relative to a sample under a fixed or increasing normal load. The tangential force resisting the motion (usually described as the friction force) and acoustic emission from the sample are often both measured continually. The acoustic emission signal typically increases sharply when a brittle coating is

Fig. 13.9a–c Examples of tests involving erosion by solid particles: **(a)** gas-blast test; **(b)** centrifugal accelerator; **(c)** fluid jet rig

cracked, or the coating delaminates from the substrate.

When the test was developed, the adhesion of typical engineering coatings was quite poor and the scratch test provided reasonable results, representative of the adhesion of the coating. More recent coatings are much more adherent, and although the scratch test remains an extremely valuable test for coatings, the results are more difficult to interpret, giving information on the complex response of the coating–substrate composite system to the movement of the indenter.

In the context of wear testing, scratch testing can be used as a model abrasion test; the response of a material to the scratching of the indenter is treated as an analog of its response to a hard asperity or abrasive particle.

Parameters such as the frictional force generated and the scratch width can be measured. Multiple scratches

can be made both in the same position or intersecting one another to extend the model range.

13.4 Friction Measurement

As discussed in Sect. 13.1.1, the measurement of friction involves the measurement of the friction force. For a rotating component it may be useful to define the friction torque, the measurement of which also involves a force measurement combined with a length measurement.

13.4.1 Friction Force Measurement

A friction force measurement system is made up of one or more force transducers mounted between one of the triboelements and the base frame of the tribometer, and their associated instrumentation. A practical force transducer usually consists of a chain of several transducers. For example, the force may act upon and bend a metal beam, and the bending then alters the electrical resistance of a strain gauge bonded to the surface of the beam by an amount proportional to the force. For many types of force measurement system, the term “load cell” is commonly used in place of “force transducer”.

Most force transducers employ some type of elastic load-bearing element or combination of elements. Application of force to the elastic element causes it to deflect, and this deflection is then sensed by a secondary transducer which converts it to an output. The output may be in the form of an electrical signal (as from a strain gauge or **LVDT**, a linear variable differential transformer), or a mechanical indication (as in proving rings and spring balances). However, the most common method is for longitudinal and lateral strains to be sensed, and when this is done by electrical resistance strain gauges the transducer is known as a “strain gauge load cell”.

13.4.2 Strain Gauge Load Cells and Instrumentation

A strain gauge load cell is based on an elastic element to which a number of electrical resistance gauges are bonded. The geometric shape and elastic modulus of the element determines the magnitude and distribution of the strain field produced by the force to be measured. Each strain gauge responds to the local strain at its location, and the measurement of force

is determined from the combination of these individual measurements of strain. Each elastic element is designed to measure the force acting in a particular direction, and not to be affected by other components such as side loads. The material used for the elastic elements is usually tool steel, stainless steel, aluminium or beryllium-copper. The material should exhibit a linear relationship between the stress (proportional to the force applied) and the strain (output), with low hysteresis and creep in the working range. A further requirement is a high repeatability between force cycles, with no fatigue effects.

The most common materials used for strain gauges are copper-nickel, nickel-chromium, nickel-chromium-molybdenum and platinum-tungsten alloys. The foil strain gauge is the most widely-used type because it has significant advantages over the other types and is employed in the majority of precision load cells. A foil strain gauge consists of a metal foil pattern supported on an electrically insulating backing of epoxy, polyimide and glass-reinforced epoxy phenolic resin. It is constructed by bonding a sheet of thin rolled metal foil, 2–5 μm thick, on a backing sheet 10–30 μm thick. The measuring grid pattern including the terminal tabs is produced by photoetching, in a process similar to that used in the production of printed circuit boards.

Semiconductor strain gauges are manufactured from n-type or p-type silicon. The output from a semiconductor gauge is about 40 to 50 times greater than that from a metal foil gauge. While the output is not linear with strain, they do exhibit essentially no creep or hysteresis and have an extremely long fatigue life. Because of their high temperature sensitivity, careful matching of the gauges and a high level of temperature compensation is required.

Thin film strain gauges are produced by sputtering or evaporation of thin films of metals onto an elastic element. Wire strain gauges are used mainly for high-temperature transducers. The wire is typically 20 to 30 μm in diameter and is bonded to the elastic element with ceramic material.

The rated capacities of strain gauge load cells range from 0.1 N to 50 MN, at a typical total uncertainty of

Fig. 13.10
Example of strain gauges connected into a full-bridge circuit

0.02% to 1% of full scale. The range of capacity depends on the type of gauges, with thin film gauges having the highest sensitivity (typically 0.1 N to 100 N), followed by semiconductor gauges (1 N to 10 kN), and foil gauges (5 N to 50 MN).

The response of a load cell can be maximized using one or more strain gauges aligned to respond to a longitudinal strain and another set aligned either to a longitudinal strain of the opposite sign or to the transverse strain. When connected electrically in a Wheatstone bridge configuration, this has the additional advantage of minimizing temperature effects that act equally on all gauges. The resistance change is detected by measuring the differential voltage across the bridge (see for example Fig. 13.10). The load cell forms part of the measurement chain and requires an a.c or d.c. excitation voltage to be supplied, and amplification and conditioning of the output signal, before it can be used. The whole chain must be incorporated into the calibration procedure.

13.4.3 Piezoelectric Load Sensors

Another commonly used type of force measurement transducer is based on the piezoelectric phenomenon exhibited by certain crystalline materials, in which an electric field is generated within a crystal which is proportional to the applied stress. To make use of the device, a charge amplifier is required to provide an output voltage signal that is proportional to the applied force and large enough to measure. Piezoelectric crystal sensors are different from most other sensing techniques in that they are active sensing elements. No power supply is needed for the sensor (although it will be for the amplifier) and the mechanical deformation needed to generate the signal is very small, which gives

a stiff sensor and the advantage of a high-frequency response in the measuring system without introducing geometric changes to the force measuring path. To enable measurement of both tension and compression, piezoelectric force sensors are usually pretensioned by a bolt.

A typical piezoelectric transducer deflects by only 0.001 mm under a force of 10 kN. The high frequency response, typically up to 100 kHz due to the high stiffness, makes piezoelectric crystal sensors very suitable for dynamic measurements. The typical range of rated capacities for piezoelectric crystal force transducers is from a few N to 100 MN, with a typical total uncertainty of 0.3% to 1% of full scale. While piezoelectric transducers are ideally suited to dynamic measurements, they cannot perform truly static measurements because there is a small leakage of charge inherent in the charge amplifier, which causes a drift of the output voltage even with a constant applied force.

Piezoelectric sensors are suitable for measurements in laboratories as well as in industrial settings because of their small dimensions, the very wide measuring range, rugged packaging, and their insensitivity to overload (typically by > 100% of full scale). They can operate over a wide temperature range (up to 350 °C), and can be packed to form multicomponent transducers (dynamometers) to measure forces in two or three orthogonal directions.

13.4.4 Other Force Transducers

Interesting but less commonly-used examples of force measurement transducers are the “vibrating-wire transducer” and the “gyroscopic load cell”. The first uses a taut ferromagnetic wire which is excited to resonate in transverse vibration. The resonant frequency is a mea-

Fig. 13.11 Friction force signal from a load cell recorded with high time resolution, showing vibration at its resonant frequency superimposed on the more slowly varying friction force

sure of the wire's tension and hence the applied force at that instant. The advantage is its direct frequency output, which can be handled by digital circuitry, eliminating the need for analog-to-digital conversion.

Gyroscopic load cells exploit the force-sensitive property of a gyroscope mounted in a gimbal or frame system. The force to be measured is applied to the lower swivel and a couple is produced on the inner frame, causing the gimbals to precess. The time taken for the outer gimbal to complete one revolution is then a measure of the applied force. The gyroscopic load cell is essentially a rapidly responding digital transducer and is inherently free of hysteresis and drift.

Fig. 13.12 Friction force signal for one sliding cycle of a silicon nitride couple in reciprocating sliding, showing asymmetric behavior due to differences in the stiffness of the system in the two sliding directions [13.13] (r.h. = relative humidity)

13.4.5 Sampling and Digitization Errors

In the case of a strain gauge load cell, the output signal from the whole force measurement chain depends on the mechanical properties of the elastic element to which the strain gauges are bonded and on the electronic circuitry used to convert the resistance changes in the strain gauges (caused by the bending force applied to the elastic element) into a recordable electrical signal proportional to the force. Similar considerations apply to other types of load cell. The design of the elastic element defines the resonance frequency of the load cell. If the dynamic properties of the force to be measured excite this natural frequency, then the output signal will no longer be proportional to the applied force.

Figure 13.11 shows the output signal from a strain gauge load cell, recorded with a high sampling rate; the friction force was generated between a pair of titania specimens sliding at 1 m/s at a temperature of 400 °C. The dominant component of the alternating signal occurs at the natural resonant frequency of the load cell, due to vibration induced by the friction between the triboelements. Derivation of a friction force from such a signal will clearly lead to error. Such effects will still occur but not be obvious if the sampling rate is too low or if the electronic circuitry used has a long time constant, integrating over the rapid signal variations. Recording the output from a load cell with an analog chart recorder usually filters out such fast signal changes and integrates them.

Another example of a dynamic friction signal is presented in Fig. 13.12. The friction signal, measured with a piezoelectric sensor, for one sliding cycle of a silicon nitride couple exhibits different extents of variation for the two half-cycles, indicating that the sliding couple under these test conditions tends to stick/slip motion. The difference in behavior is caused by the difference in the stiffness of the construction elements in the two directions. For such a system it is not possible to define a quantitative friction level because the measured signals are dominated by the vibrations of the elastic sensor element and are thus not proportional to the friction forces. Results of this type only allow the tendency to stick/slip motion to be deduced.

13.4.6 Calibration

Even with good transducers and a good overall system design, measurements of forces cannot be relied upon without calibration. Instruments capable of performing force calibrations are known as “force standard

Table 13.2 Types of force standard machine

Type	Principle	Uncertainty attainable	Category
Deadweight machines	A known mass is suspended in the Earth's gravitational field and generates a force on the support	< 0.001%	Primary or secondary
Hydraulic amplification machines	A small deadweight machine applies a force to a piston-cylinder assembly and the pressure thus generated is applied to a larger piston-cylinder assembly	< 0.02%	Secondary
Lever amplification machines	A small deadweight machine with a set of levers which amplify the force	< 0.02%	Secondary
Strain-gauged hydraulic machines	The force applied to an instrument is reacted against strain-gauged columns in the machine's framework	< 0.05%	Secondary
Reference force transducer machines	A force transfer standard is placed in series with the instrument to be calibrated	< 0.05%	Secondary

machines". Primary standards in force measurement are machines whose uncertainty can be verified directly through physical principles to the fundamental base units of mass, length and time. Secondary standards can be compared with primary standards through the use of a force transfer standard, which is a calibrated force transducer, frequently a strain gauge load cell. Standards document ISO 376 describes the calibration and classification of transfer standards.

Table 13.2 lists types of force standard machines that have been developed for the calibration of static forces acting along a single well-defined axis. The principles used for the calibration of multicomponent force sensors remain the same, but cross-talk between the different axes must also be considered. For the measurement of dynamic forces it is assumed that the statically-derived force transducer sensitivities are applicable, but attention must also be paid to the natural frequencies of the load cell.

The calibration of a force transducer can be performed with the transducer in its permanently installed position by using a transfer standard, or prior to its installation and by removal as required for further calibration.

More information on force measurement and calibration can be found elsewhere [13.14, 15].

For very small forces, as measured with an atomic force microscope (AFM), special calibration procedures are needed. An AFM can be used to measure friction forces in the nN range. The calibration methods used for this force-measuring machine also use known masses under gravity, but the lowest attainable uncertainty is much greater than that described above for macroscopic forces. The AFM scans a probe tip over the surface under examination. It operates like a stylus profilometer with constant contact force, which is maintained by steering the bending of the cantilever beam carrying the probe tip using a piezoelectric el-

ement (Fig. 13.13). The bending of the cantilever is sensed by a segmented photodiode which measures the intensity of laser light reflected from the back of the cantilever. The piezoelectric driving voltage is adjusted during the scan over the surface to hold the resulting difference in photocurrent between segments (1 + 2) and segments (3 + 4) constant. A constant photocurrent implies constant beam deflection, which is equivalent to a constant force. The piezoelectric voltage needed to hold the photocurrent constant is thus a measure of the topographical height at the instantaneous position of the tip. The height resolution of an AFM is in the range of atomic dimensions.

If the direction of scanning is perpendicular to the axis of the cantilever, the torsion of the cantilever provides a measure of the friction force between the tip and the sample. The torsion is measured by the difference between the photocurrents from segments (1 + 3) and segments (2 + 4). The calibration of the relevant spring constants of the cantilever (in bending and torsion) is not a trivial procedure [13.16–18].

this technique, complementary images of the friction force can be obtained by simultaneously recording spatially-resolved electrical contact resistance and friction measurements. The technique provides information about the history of friction and wear processes [13.19]. When measuring the electrical contact resistance, care must be taken that the electrical sensing current remains low, because otherwise the wear process may be influenced.

13.4.7 Presentation of Results

In most cases the specification of a single coefficient of friction is not adequate. This can be seen from the examples in Fig. 13.12 and Fig. 13.14, depicting the evolution of friction during individual experimental runs. At the very least, all relevant test and system parameters should be specified. The list in Table 13.1 provides a general guide, and is supplemented by the more specific lists of parameters in Table 13.3 and Table 13.4.

13.5 Quantitative Assessment of Wear

13.5.1 Direct and Indirect Quantities

The amount of wear can be specified in terms of direct or indirect quantities.

Indirect quantities are often used in technical assessments of the lives of machinery and in practical engineering. Examples include:

- wear-limited service life (used for cutting tools for example: h , d , number of parts)
- wear-limited throughput (used for the flow of abrasive materials or objects through pipelines for instance: number of parts, m^3 , kg)

Direct wear quantities specify the change in mass, geometrical dimensions or volume of the wearing body. Examples include:

- wear amount:
 - mass loss (kg)
 - linear dimensional change (m)
 - volume loss (m^3)
- wear resistance = $1/(\text{wear amount})$ (m^{-1} , m^{-3} , kg^{-1})
- wear rate = $(\text{wear amount})/(\text{sliding distance or time})$ (m/m , m^3/m , kg/m , m/s , m^3/s , kg/s)
- wear coefficient, or specific (or normalized) wear rate (also sometimes called wear factor) = $(\text{wear rate})/(\text{normal force})$ ($m^3 N^{-1} m^{-1}$).

The primary measurement from which these quantities are derived is usually mass loss, dimensional change or volume loss, although other methods can also be used (see Sect. 13.5.5).

13.5.2 Mass Loss

The loss of substance from the surface of a triboelement can be determined by weighing it before and after wear. Continuous sensing of the wear process in terms of mass loss is usually not possible. Mass loss measurement at defined intervals, to obtain information about the development of wear (and hence to investigate running-in, stability of wear rate, and so on), require the test to be halted and the triboelement(s) removed for weighing. In this process the danger exists that the microcontact geometry will be changed on reassembly. Such a change in microgeometry can influence the wear rate. Debris present in the contact region is also likely to be disturbed, and often removed. The most important period in the development of the wear rate may be missed, and

the act of interrupting the test in order to weigh the specimen may alter the progress and even the predominant mechanism of wear.

The sensitivity of this method of wear quantification is relatively low. The method is applicable only for wear rates high enough that a significant mass loss (typically of the order of at least 1 mg) is reached after a reasonable time for a test sample not heavier than about 0.5 kg . For materials which experience significant mass changes from other causes, such as the absorption or loss of water by certain polymers, or the oxidation of metals at high temperatures, special care must be taken to ensure that the mass changes measured are genuinely associated with tribological processes and are not due to other phenomena. Suitable control specimens, not subjected to wear but otherwise exposed to the same conditions as the triboelements, may be helpful for eliminating such effects and also for correcting for any long-term drift in the calibration of the balance.

The accuracy of weighing may be limited by the accuracy or sensitivity of the balance (especially in the case of heavy triboelements), by changes in humidity between the two weighings, or by particle or debris attachment or detachment. Material transfer and oxidation during the wear process often complicate the interpretation of the measured mass values and can sometimes lead to erroneous interpretation of the wear behavior.

Wear is sometimes expressed in units of volume, and in order to convert mass loss to volume loss, the density of the worn material must be known. For a homogeneous bulk material this will usually pose no problems, but if wear is occurring from a coating or treated surface layer then the relevant density may not be accurately known.

13.5.3 Dimensional Change

Changes in linear dimensions due to wear are frequently measured on-line (continuously) during friction tests. This has advantages over making measurements by interrupting the test, because one can then get information about the continuous evolution of wear during the test and, by detecting transitions in the measured linear wear rate, about changes in the dominant wear mechanism.

In most cases a change in the distance between the mounting fixtures of the two triboelements is measured. This implies that only the sum of the linear wear contributions from both elements can be obtained. Material transfer from one triboelement to the other may lead to misinterpretation. For example, in the frequently used

test arrangement with a ball or pin sliding continuously on a disc surface, transfer of material from the disc to the ball will change the distance between them. Depending on the amount of wear of the disc or the ratio of wear to transfer, the measured distance can be reduced, eliminated or increased. This last case may occur if much of the material worn from the larger wear scar on the disc is transferred to the smaller wear area on the ball or pin. Figure 13.14 shows an example of such behavior for an alumina ball sliding on an alumina disc. For up to about 3500 s of sliding, the displacement of the sample increases steadily, with the system apparently showing “negative” wear. The reason for this is that wear debris is accumulating in the contact region. The agglomerated particles of worn material then suddenly detach, leading to a negative total displacement, which is then followed by further accumulation of debris. The friction force also changes, which is associated with a change in the nature of the surface interaction.

In some cases wear of one or both triboelements leads to a significant change in the local geometry of the contact. An example of this behavior is shown in Fig. 13.15. As wear occurs on the steel ball the contact area progressively increases, and the wear rate detected in terms of a change in the distance between the two triboelements falls rapidly with time, although the associated volume wear rate varies much less. In this experiment there was also a substantial change in friction force.

Fig. 13.15 Example of online measurement of linear wear (total displacement of ball relative to disc W_1) and friction force (f) for reciprocating steel ball on a diamond-coated disc (courtesy of D. Klaffke)

For on-line measurements of the changes in linear dimensions or displacements, inductive or capacitive sensors are frequently used. Inductive sensors can attain a resolution down to 1 μm , and capacitive sensors can reach a resolution in the nanometer range. Both types of sensors and their associated electronic circuits exhibit some temperature drift and a limited bandwidth (frequency range over which the defined specification of repeatability, resolution and accuracy is achieved). However, in most cases, the dimensional changes due to temperature variations in the test samples, their fixtures, and the mechanical construction of the apparatus induce greater measurement errors than those of the sensor system itself. Capacitive displacement sensors require a relatively clean environment: dirt, dust, water, oil or other dielectric media in the measuring gap will influence the measurement signal. Inductive sensor systems are generally less expensive and also less sensitive to environmental influences.

13.5.4 Volume Loss

The volume loss from a specimen in a tribological test can be derived from the mass loss if the density of the material is known. As indicated in Sect. 13.5.2, there may however be uncertainty in the density, especially in the case of a coated or surface-treated sample. In principle, the volume loss can also be derived from measured dimensional changes. In many cases this method will be more accurate than weighing a sample before and after testing.

For tests such as the ball-on-disc, pin-on-disc or block-on-ring geometries, this is particularly true for the two limiting cases when the wear occurs on only one of the triboelements. For example, for reciprocating sliding tests with the ball-on-plate configuration, relatively simple equations for the wear volume can be deduced.

If wear occurs only on the ball, then the wear volume of the ball $W_{v,b}$ is given by

$$W_{v,b} \approx (\pi d_a^2 d_p^2 / 64R) . \quad (13.3)$$

The total linear wear is given by

$$W_1 \approx d_a^2 / (8R) \quad (13.4)$$

and therefore

$$W_{v,b} = W_{v,tot} \approx \pi R W_1^2 , \quad (13.5)$$

where the symbols are defined below.

If wear occurs only on the plate (so the ball wear volume is zero), then the wear volume for the plate $W_{v,d}$

Fig. 13.16 Example of determination of wear volume for a flat specimen after a sliding test with ball-on-flat geometry, by measurement of the cross-section of the wear scar on the flat. The *upper image* shows the end of a linear wear scar produced by reciprocating sliding, and the *lower graph* shows a profilometer trace across it at a representative position

is given by:

$$W_{v,d} \approx (\pi d_a^2 d_p^2 / 64 R) + \Delta x W_q \quad (13.6)$$

The planimetric wear is

$$W_q \approx d_a^3 / 12 R \quad (13.7)$$

and therefore

$$W_{v,d} = W_{v,tot} \approx (\Delta x d_a^3 / 12 R) + (\pi d_a^2 d_p^2 / 64 R) \quad (13.8)$$

$$\approx \Delta x d_a^3 / 12 R \quad (13.8a)$$

since the second term in (13.8) is small compared with the first one in the case of reciprocating sliding, where Δx is large compared with d_a and

$W_{v,d}$ wear volume of the plate,

$W_{v,b}$ wear volume of the ball,

$W_{v,tot} = W_{v,d} + W_{v,b}$ total wear volume,

- d_p diameter of the wear scar on the ball, parallel to the sliding direction,
- d_a diameter of the wear scar on the ball, perpendicular to the sliding direction,
- W_q planimetric wear (plate),
- W_l total linear wear,
- Δx stroke of motion,
- R radius of the ball.

Combining (13.4), (13.5), and (13.8a) leads to:

$$W_{v,d} = W_{v,tot} \approx (4/3) \Delta x (2R)^{1/2} W_l^{3/2} \quad (13.9)$$

This equation allows the evolution of the volumetric wear to be related to the evolution of the continuously measured linear wear.

Usually, however, wear occurs on both bodies. In this case a “rule of mixtures” can be used

$$W_{v,tot} = \alpha \pi R W_l^2 + \beta (4/3) \Delta x (2R)^{1/2} W_l^{3/2}, \quad (13.10)$$

where α and β describe the contribution of ball and plate to the wear, respectively.

However, the values of α and β are not known beforehand, and can change during the test. Therefore, the determination of the wear volume offline from the dimensions of the wear scars is usually more accurate than online determination from the measurement of the change in linear dimensions during the test.

Measurements of volumetric wear from topographic changes determined with a stylus profilometer, laser profilometer or white light interferometer in most cases deliver more accurate results than online measurement of dimensional changes. With these methods, the three-dimensional profiles before and after the test are determined and the wear volume derived by subtracting one from the other. A precondition for this method is the ability to align the two profiles correctly. With wear scars which are extended in one direction (such as scars formed in linearly reciprocating or rotating triboelements), line scans can be performed across the wear scars and the wear volume calculated from the resulting two-dimensional cross-section profile and the length of the wear scar (Fig. 13.16). This method may, however, lead to large errors if the depth of the wear scar is not much greater than the roughness of the surface.

If the cross-sectional area W_q of a wear scar is measured by profilometry after a ball-on-flat test with reciprocating sliding, the wear volume of the ball can be calculated from:

$$W_{v,b} = (\pi d_a^2 d_p^2 / 64) \cdot [(1/R) - (1/R^*)], \quad (13.11)$$

Fig. 13.17 Example of wear scar produced by a ball cratering test on a coated sample (optical micrograph); the boundary between the titanium nitride coating and the steel substrate is clearly seen. Typical wear scar diameter is 1–2 mm

where R^* is the radius of the wear area of the ball. This value can be calculated from the profile of the wear scar on the flat

$$R^* = d_a^3 / (12W_q) . \quad (13.12)$$

The wear volume of the flat is given by

$$W_{v,d} \approx (\pi d_a^2 d_p^2 / 64)(1/R^*) + \Delta x W_q . \quad (13.13)$$

In the case of well-defined wear scars of known geometry, for example those produced in ball-cratering abrasion tests (Fig. 13.17), the volume of wear can also

be calculated from the diameter of the wear scar and the radius of the ball, the change in which during the test can usually be assumed to be negligible. The diameter of the wear scar may be measured with a stylus profilometer or an optical microscope.

13.5.5 Other Methods

Very small amounts of wear can be determined in real time, for example during the operation of internal combustion engines, by radionuclide (or radioactive tracer) techniques [13.20, 21]. Before starting the wear test, a very thin layer at the surface of one or both triboelements (such as the piston ring and cylinder liner in an internal combustion engine) is activated by irradiation with heavy ions from a particle accelerator. Since only a thin layer is activated, only rudimentary radiation precautions are required. The wear debris from the activated triboelements during the operation of the engine are radioactive and are transported within the oil circuit to a filter. A γ -ray detector close to the filter measures the radiation activity, as shown in Fig. 13.18. The increase in this activity with test duration is proportional to the amount of wear. If the two triboelements (such as the piston ring and cylinder liner) contain different alloying elements, the activation will lead to radioactive isotopes of these elements which emit γ -rays with different characteristic energies. In this case, the wear of each triboelement, and not only the sum of both, can be separately measured online.

Measurement of the electrical contact resistance during a friction test between metallic triboelements, with one contact partner insulated, can provide information about the formation and removal of reaction layers, such as oxides. Special arrangements involving insulation and embedded conductive wires or sensors in a test sample can be used to detect a wear limit [13.22–24].

13.5.6 Errors and Reproducibility in Wear Testing

As mentioned above in Sect. 13.4, the filtering effect of the electronic circuits used for signal recording, as well as the sampling rate in digital signal recording, may introduce errors into measurements of dynamic friction force signals. Vibrations excited at the resonant frequency of the sensor system may be superimposed on the friction force signal, leading to variations in the measured friction force which would not be present in the absence of the sensor system. These vibrations can also influence the wear rate of the system. In the case of

Fig. 13.18 Principle of wear determination in an internal combustion engine by the radionuclide measurement method (courtesy of Southwest Research Institute, USA)

occur in continuous sliding on a rotating disc or ring. For these types of test, the time for which the wear scar surface is exposed to the atmosphere, out of contact with the other triboelement, depends on the detailed geometry of the triboelements and the kinematics of their relative motion.

The interpretation of the specific wear rate k derived from a tribological test also needs care. This quantity is defined as the wear volume divided by the sliding distance and the normal force (Sect. 13.1.3). Specific wear rates at higher normal forces can therefore be lower than those at low normal forces, despite the total wear being the same or higher. This may happen if a system can sustain loads up to a certain limit without any change in damage or wear rate.

Accelerated tribological tests, achieved by increasing the load (or pressure) or velocity, for example in order to estimate component life-time, run the danger of encountering a transition in the wear mechanism,

which may be from a relatively low-wear to a high-wear regime. Predicting system wear behavior based on such an accelerated test can lead to errors of one or even two orders of magnitude. Much more reliable information can be provided by “wear mapping”, as described in Sect. 13.2.4.

One reason for variability in friction and wear results is inhomogeneity of the test samples. Material properties can vary between positions on a test sample, and a test which involves a large area of the triboelement will generally be more reproducible than one which samples only a small area. Fretting tests, for example, typically show lower reproducibility than tests involving continuous sliding, since a fretting test with a ball on a flat, with a very small amplitude of motion, may be located close to a flaw in the material, or on an essentially flaw-free region. In a continuous sliding test, however, the response of the material will tend to be averaged over a much larger region.

13.6 Characterization of Surfaces and Debris

Worn surfaces, and the debris resulting from wear, may be examined for several reasons:

- to study the evolution of wear during an experiment, or during the life of a component in a practical application,
- to compare features produced in a laboratory test with those observed in a practical application,
- to identify mechanisms of wear,
- (by studying debris) to identify the source of debris in a real-life application.

13.6.1 Sample Preparation

Samples for surface examination may vary greatly in cleanliness. At one extreme are those which have been prepared and tested under very clean laboratory conditions, perhaps even in ultrahigh vacuum, and at the other extreme, those which have been salvaged from field trials on heavy machinery operating under dirty conditions.

After tribological testing under vacuum conditions, or in a controlled atmosphere, the specimen may be moved directly through a transfer port into a vacuum chamber for instrumental examination (for example by SEM or the various surface analytical techniques described in Sect. 13.6.2 below) without being exposed to air. In some experiments, the tribological tests may be

performed within a vacuum system so that imaging and surface analysis can be carried out during or immediately after the experiment.

However, most tribological tests (and most tribological applications of materials) occur in air, and the presence of atmospheric oxygen and sometimes humidity often plays an important role in the wear process. Further exposure of the specimen to dry air will probably have little effect on the surface film, although any significant corrosion that might occur in steel samples should be avoided by keeping them dry (for example in a desiccator).

Test samples are often contaminated with lubricant. Wear debris may be present, as may corrosion products and, in the case of samples retrieved from field trials or components exposed to wear in service, even extraneous dirt introduced while dismantling the machine and extracting the sample to be studied. These features pose particular challenges, since on the one hand they may obscure or confuse the examination of the worn surface, but on the other hand, as in the case of wear debris, they may be valuable in providing extra information about the wear process. Although each case may present individual problems, it is possible to provide some general guidelines. The sample should be removed as soon as possible after the test apparatus or machine has stopped, to avoid possible additional

corrosion, which might for example be enhanced by the condensation of water in a system which cools below the dew point after running at a higher temperature. Organic lubricants can be removed with organic solvents, and visual and low-magnification optical inspection should reveal the presence of any gross solid contaminants. Corrosion products may not be readily distinguishable from wear debris, and indeed in many cases the wear debris will result from chemical reaction of the substrate material with the environment; but any debris which is localized in and around the worn region is more likely to result from the wear process than material which is more widely distributed on the sample and thus probably a product of general corrosion. When preparing the surface, a balance must be struck regarding the amount of debris to remove to allow the material surface to be studied. Solvent cleaning in a gentle ultrasonic bath, for example with ethanol, isopropanol or propanone, followed by hot-air drying, should produce a surface which is clean enough for microscopic examination, but such a process may remove debris, which can provide valuable information about the wear mechanism. It is sometimes possible to retrieve such debris by careful filtration of the solvent, and to examine the debris on the filter, or to further classify it, for example by ferrography.

Replication involves the preservation of the sample's surface topography by casting or molding a replicating medium against the surface, and then removing it. Careful experimental technique and the use of an appropriate replicating medium can lead to excellent results, and the reproduction of surface features on a submicrometer scale. Replication allows techniques such as SEM and profilometry to be applied to regions of large tribological contacts in the field from which conventional samples cannot be cut, or to which access is very difficult. It also allows a sequence of records to be made from a single specimen at intervals during a wear test, showing the evolution of surface features, since it is a nondestructive technique. The ability to build up a "library" of replicas of the same region of the specimen during a test allows the investigator to subsequently study in detail the evolution of features which only become known to be of particular interest at the end of the test sequence.

Control experiments can be valuable in providing assurance that the observations on the specimen are not associated with artefacts introduced by the method of specimen preparation.

In some cases, examination of the surface of a sample does not provide sufficient information about the

processes involved in wear, and the subsurface material, very close to the worn surface, must be studied. It may also be valuable to measure mechanical properties by micro- or nanoindentation in this region. Cross-sections of samples can be prepared for microscopy by conventional metallographic or ceramographic techniques, but since the regions of interest in the tribological context will be at or very close to the surface, special attention must be paid to retaining features in this region, and to avoiding the introduction of damage during preparation. The surface can be protected by applying metallic coatings (such as electroplated nickel) to metal specimens, or by using a hard embedding resin, preferably containing a hard filler (such as carbon or glass fibers, or ceramic particles), before the sample is cut perpendicularly to the worn surface and then ground and polished. Similar grinding and polishing rates should be aimed for in the protective material and in the worn sample itself, to achieve a perfectly plane cross-sectional surface for examination. Ceramics are particularly difficult to protect in this way, but edge protection may be achieved by clamping two samples of the same ceramic together, with the worn surface at the interface, before embedding and sectioning the composite sample.

Taper sectioning may also be used to study near-surface microstructure and reduce the effect of polishing artefacts close to the surface. This technique involves the examination of a section cut and polished at a shallow angle to the surface. For example, on a section cut at an angle of 5.7° to the surface, a distance of $10\text{ }\mu\text{m}$ normal to the edge of the sample corresponds to a depth beneath the surface of only $1\text{ }\mu\text{m}$ (since $\tan(5.7^\circ) \approx 0.1$).

Focused ion beam (FIB) milling provides a powerful technique to make cuts perpendicular to a worn surface, either for subsequent examination of the near-surface regions by SEM, or as a first step in the production of a sample for TEM. Since it is carried out on a fine scale and in regions which can be examined in detail by SEM before the milling takes place, it is possible to study the subsurface features associated with specific surface areas of interest.

13.6.2 Microscopy, Profilometry and Microanalysis

Worn surfaces are often imaged in order to characterize their surface topography and provide information about the wear mechanism. In many cases, accurate diagnosis of wear mechanism may not be possible from imaging alone, since information on the local chemical composi-

tion and microstructure of the near-surface material, as well as subsurface defects such as cracks or pores, may be required. Thus a wide range of techniques may be employed to study tribological surfaces and subsurface regions. These vary in the information they provide, the accuracy of that information, and the dimensional scale (in both lateral extent and depth into the surface) over which they provide information.

Table 13.5 summarizes commonly used techniques and their attributes. These include imaging techniques and methods of microstructural and compositional analysis. Resolution and sensitivity figures are approximate guides to relative performance, and there is often a trade-off between resolution and sensitivity. Further information on methods of surface chemical analysis can be found in Sect. 6.1 of this volume, and information on surface topography analysis in Sect. 6.2.

Scanning electron microscopy is very widely used to examine worn surfaces and, through the use of different imaging modes, can provide both topographic

(for example, from secondary electron detection) and compositional (such as the mean atomic number from back-scattered electrons) information. Stereo imaging, which involves the capture of two images of the same area of the surface tilted relative to each other by a small angle, can be used to provide qualitative information on topography, and the images can also be processed by suitable software to yield quantitative topographic maps. This method supplements the more traditional methods of profilometry, which use a stylus or optical means to map the surface heights (Sect. 13.6.2). Atomic force microscopy can be used to explore topography at the very finest level.

Low-vacuum and environmental SEMs can be especially valuable for studying some of the contaminated and poorly conducting (such as polymer and ceramic) samples encountered in tribological investigations. Ion channeling contrast can be used in a focused ion beam (FIB) microscope to reveal phase distributions and deformed microstructures, and as mentioned

Table 13.5 Surface examination techniques

Technique	Spatial resolution	Depth resolution	Analytical sensitivity (Z is average atomic number)	Applicability (Z is atomic number of element)
OM	0.2 μm	—	—	—
SEI (SEM)	1.5 nm	—	—	—
NCOP	1 μm	3 nm	—	Topography
CP	0.5 μm	1 nm	—	Topography, but may damage soft samples
XRD	10 mm	10 μm	5%	Crystal phase, lattice strain, particle/grain size
XRF	10 mm	10 μm	1–10 ppm	$Z > 4$
XPS	5 μm	3 monolayers	0.3%	$Z > 2$
LIMA	2 μm	1–2 μm	10–100 ppm	All Z
EDS (SEM)	1 μm	1 μm	0.1%	$Z > 4$
WDS (SEM)	1 μm	1 μm	100 ppm	$Z > 4$
BEI (SEM)	50 nm	50 nm	0.1 Z	
SSIMS	1 μm	2 monolayers	0.01%	All Z
DSIMS	20 nm	10 monolayers	<1 ppm	All Z
SAM	5 nm	3 monolayers	0.3%	$Z > 2$
EDS (STEM)	10 nm	20 nm	0.1%	Thin foil, $Z > 4$ peak overlap
EELS (STEM)	10 nm	20 nm	1%	Thin foil, $Z > 3$
APFIM	1 nm	1 monolayer	0.1–1%	All Z
EBSP	100 nm	50 nm	—	Crystal phase, orientation

Key: OM = optical microscopy; SEI = secondary electron imaging; BEI = back-scattered electron imaging; XRD, XRF, XPS = X-ray diffractometry, fluorescence and photoelectron spectroscopy; LIMA = laser-induced mass spectroscopy; EDS = energy-dispersive X-ray analysis; WDS = wavelength-dispersive spectroscopy; SEM = scanning electron microscopy; SSIMS, DSIMS = static and dynamic secondary ion mass spectrometry; SAM = scanning Auger spectroscopy; STEM = scanning transmission electron microscopy; APFIM = atom probe field ion microscope; EBSP = electron back-scattered diffraction pattern; EELS = electron energy loss spectrometry; NCOP = noncontact optical profilometer; CP = contact profilometer

in Sect. 13.6.1 the FIB can also be used to cut sections beneath the specimen surface for microscopy.

13.6.3 Wear Debris Analysis

Debris poses special problems in examination; the first challenge is to obtain a representative sample. In a lubricated system the technique of ferrography can be used to separate and grade magnetic debris. In ferrography, a suspension of wear debris flows through a magnetic field gradient and the particles become separated and

distributed according to size. Filtration can be used to separate nonmagnetic particles. The particles can then be examined (for example by optical or scanning electron microscopy), chemically analyzed, and their sizes and shapes characterized. Optical methods (such as laser light scattering) are commonly used to determine particle size distributions. Automated systems exist to evaluate and describe particle shapes in wear debris, and link them to wear mechanisms [13.25]. The methods of microscopy and microanalysis outlined in Sect. 13.6.2 can be used for debris as well as for worn surfaces.

Biogenic Imp.

14. Biogenic Impact on Materials

Materials as constituents of products or components of technical systems rarely exist in isolation and many must cope with exposure in the natural world. This chapter describes methods that simulate how a material is influenced through contact with living systems such as microorganisms and arthropods. Both unwanted and desirable interactions are considered. This biogenic impact on materials is intimately associated with the environment to which the material is exposed (Materials–Environment Interaction, Chap. 15). Factors such as moisture, temperature and availability of food sources all have a significant influence on biological systems. Corrosion (Chap. 12) and wear (Chap. 13) can also be induced or enhanced in the presence of microorganisms. Section 14.1 introduces the categories between desired (biodegradation) and undesired (biodegradation) biological effects on materials. It also introduces the role of biocides for the protection of materials. Section 14.2 describes the testing of wood as a building material especially against microorganisms and insects. Section 14.3 characterizes the test methodologies for two other groups of organic materials, namely polymers (Sect. 14.3.1) and paper and textiles (Sect. 14.3.2). Section 14.4 deals with the susceptibility of inorganic materials such as metals (Sect. 14.4.1), concrete (Sect. 14.4.2) and ceramics (Sect. 14.4.3) to biogenic impact. Section 14.5 treats the testing methodology concerned with the performance of coatings and coating materials. In many of these tests specific strains of organisms are employed. It is vital that these strains retain their ability to utilize/attack the substrate from which they were isolated, even when kept for many years in the laboratory. Section 14.6 therefore considers the importance of maintaining robust and representative test

organisms that are as capable of utilizing a substrate as their counterparts in nature such that realistic predictions of performance can be made.

14.1 Modes of Materials – Organisms Interactions

A number of interactions result from the contact between living systems and materials some of which result in either biodeterioration or biodegradation. The word ‘deteriorate’ comes directly from Latin and means ‘to make worse’. The term biodeterioration was adopted in the late 1950s to early 1960s for the study of the deterioration of materials of economic importance by organisms. However, this definition should probably be expanded to include not only the deterioration of materials, but also of constructions (e.g. structural timber as part of a building) or processes (e.g. a paper mill) of economic importance.

Of course, the interaction between biological systems and materials is not always undesirable. In contrast to the above, the word ‘degrade’ also comes directly from Latin and means ‘to step down’. Thus, biodegradation could mean activities of organisms which result in the breakdown of materials either to man’s detriment or benefit. Many essential geochemical cycles (e.g. the nitrogen and carbon cycles) are almost wholly dependent on biological (indeed microbiological) processes and of course in current times the term ‘biodegradable’ is considered an essential property of many manufactured materials to ensure that they can be recycled effectively at the end of their service life. So, although biodegradation may be seen by man as a direct opposite to biodeterioration, it is actually biologically exactly the same process and it is impossible to make a scientific distinction between them. Indeed, they are usually the same processes, changed in meaning and significance solely by human need.

A subdivision of the manifold effects of a ‘biogenic impact’ on materials may either be made according to materials or to organisms. Changes of materials or their service properties may be caused by microorganisms, higher plants as well as by insects and other animals. Among the microorganisms bacteria, yeasts and algae play an important role as do many molds and higher fungi and basidiomycetes. The dominating animal species that impact on materials are among the insects with termites and members of the orders coleoptera and lepidoptera having an especially great destructive potential. But higher animals such as rats, mice and birds also have a significant impact on the service life of many materials. In the marine environment molluscs and crustaceans are usually considered the main deteriorating organisms. Although studies on the interaction between material and biological systems need to be holistic in their approach whether this be to determine the degree

of protection required by a material in service or to examine the impact of a material on an ecosystem, they are usually sub-divided into specific areas to afford a more manageable route to their execution.

Materials primarily of natural origin, such as timber, pulp, paper, leather and textiles are particularly susceptible to deterioration by biological systems. However, many modern materials such as paints, adhesives, plastics, plasters, lubricating materials and fuels, technical liquids, waxes etc. can support microbial growth. Even the properties of inorganic products, such as concrete, glass, minerals and metals may suffer from biological attack. There are also many examples which demonstrate that not all breakdown of materials is undesirable as particular microorganisms are used for beneficial purposes, e.g., in extracting and processing raw materials such as alcoholic fermentation, antibiotics, flax retting, leaching etc. and even in extracting certain minerals in mining operations (e.g., bioextraction of uranium from mining residues).

14.1.1 Biodeterioration/Biocorrosion

A natural phenomenon of organisms, especially of microorganisms, is adhesion to surfaces of materials. For example, in the course of their proliferation a slimy matrix is produced by microbial communities at the interface with a material called a biofilm. In technical systems ‘biofouling’ occurs. Drinking or process waters become contaminated, often by biofilms, and further propagation of biomass results in blockages of filter systems, pipings and heat exchangers. Economic damage results from the decrease in performance of technical processes (such as loss of efficiency in a heat exchanger) and can even result in equipment or facilities coming to a complete standstill. Losses amounting to billions of Euros every year are attributable to the effects of unwanted biofilms.

Another prominent example of the impact of biological systems on materials can be seen in the interaction between the organisms employed in a process with the materials used to contain it in the microbial deterioration of concrete in sewage systems caused by acidic fungal excretions. The same mechanism is also responsible for the deterioration of historic frescos and monuments. Even seemingly inert materials, such as the glass in optical devices, for instance binoculars and microscopes, are susceptible to etching which impairs and ultimately destroys their optical properties.

Biological processes may also produce discoloration and bad odors of liquids such as paints, glues, lubricating and technical liquids without actually affecting the performance of the material. Of course, they may also induce changes in consistency and impair the serviceability of such products or result in complete failure of the material. With plastics, biodeterioration can result in loss of mass and changes of technical characteristics, such as elasticity and tensile strength.

Effects of biodeterioration produced by organisms can range from damage caused by inorganic or organic acids, complexation, organic solvents, salt stress, influence of H_2S , NO_3 , and NO_2 as well as enzymatic alterations or degradation. Biocorrosion of metals and metal alloys is also known to occur under a wide variety of conditions. The first reports on the corrosive properties of sulfate-reducing bacteria date back to the middle of the past century. Corrosion failures in oil refineries, pipelines and harbor facilities induced intensive research and investigations of the damage mechanisms. Spectacular accidents, such as the crash of a jet airplane due to corrosion of its aluminum fuel tanks illustrated the dangers of ‘microbially induced corrosion’ (MIC). In most cases both bacteria and fungi were found to be responsible for such damage. The corrosion processes were induced either by their metabolites, such as acids, ammonia and hydrogen sulfide or by electrochemical circuits associated with the terminal electron acceptors of anaerobic metabolism. The capability of these microorganisms to form adhesive films on the surface of metals exacerbated the problem as below such films, anaerobic conditions prevail where corrosion-inducing oxygen concentration cells are produced. Similarly, hydrogen embrittlement may be also attributed to the production of hydrogen by microorganisms and its uptake by the metal surface.

14.1.2 Biodegradation

The manifold metabolic processes of organisms have been utilized by man in the course of his evolution. Long before the term biotechnology was coined, people knew how to produce foods by exploiting microbial processes. Agricultural applications included flax retting and waste straw upgrading. Important medical applications such as the production of antibiotics emerged. For a number of microbiological metabolic processes the following synonyms for biodegradation became established; biotransformation/bioconversion, implying the biological transformation of materials as an alternative to chemical processes. Bioleaching: metal

extraction (especially of copper and uranium) from poor ores and mining spoil, the extraction of which would not be profitable by metallurgical processes. Biotreatment, for example, kaolin for producing porcelain but stained by iron oxides may be successfully bleached by reducing or complex-forming metabolites of microorganisms. Bioremediation, for example, TNT and a number of other explosives may be reduced to harmless substances and microbial processes are being used increasingly to decontaminate toxic substances in the environment.

14.1.3 Summary

As discussed above, biodeterioration can be defined as a decrease in the economic value of materials caused by biological organisms. From a physical point of view, biodeterioration can be defined as the transition of a material from a higher to a lower energy level or (chemically) from a more to a less complex state. From a biological point of view it is important to be able to relate biodeterioration and biodegradation events to the cycle of changes of materials which characterize the natural world. Thus, a material may be required to be stable towards biological attack while in service but needs to degrade in the environment to substances that are harmless to and totally integrated with the environment once the service cycle has ended. Many materials, constructions and processes must therefore be looked at in a true ‘cradle to grave’ context to ensure that the economic benefits at one point do not lead to adverse environmental (and economic) impact at a later stage in the cycle of that material’s ‘lifespan’.

14.1.4 Role of Biocides

Many methods exist worldwide for examining the relationship between organisms and both man-made and natural materials. Much of the emphasis of these methods is related to the spoilage, deterioration or defacement of materials whether these are foodstuffs, structural woodwork or water-based coatings [14.1]. Most of the testing technology is focussed on determining both the susceptibility of materials to attack and to the efficacy of agents intended to either prevent or limit this attack. In many cases, these tests are used to form the basis of claims about how well a certain material, additive or technology may be expected to perform when exposed to biological challenges. Often this information is used to make commercial comparisons between either different final products or additives as well as to attempt to

predict whether a material will comply with a certain specification (e.g. service life).

Biocides

Much of the technology mentioned above depends on the use of biocidal agents to prevent growth in association with the material to be protected. In other disciplines, such agents are employed to either limit the growth of or kill organisms within a process, possibly to prevent them from impacting on materials they may come in contact with. A good example of such agents is the additives employed in the water treatment industry. These agents are used in applications such as cooling and humidification systems and paper mills [14.1]. They are introduced to both eliminate health risks associated with the uncontrolled growth of microorganisms (e.g., prevention of the growth of *Legionella spp.* in calorifiers) and limit the impact that they may have on structural components within the process (e.g. corrosion, loss of heat transfer efficiency) and the products of the process (e.g. foul odor in air handling systems, defects in paper resulting from bacterial slimes).

Biocides are also employed to remove populations from either within the matrix of a material or on the surfaces of a material. These agents are often applied as washes or rinses and are used to either sterilize/disinfect or at least reduce either part or all of any population that may be present [14.2]. Such disinfection processes can also take the form of an addition of a biocidal agent to a matrix which contains a population (e.g., the reduction of microbial contamination in metal working lubricoolants, the treatment of timber infected with eggs/larvae of wood-boring beetles). Often this will be combined with the introduction of protection against further growth [14.3].

Biocidal agents may also be incorporated into a material to protect it in service. For example, preservatives are used in coating systems to protect the material from spoilage while in its wet state (so-called in-can protection) as well as to exhibit a biocidal effect in the finished film, preventing mold and/or algal growth on the surface of the coating once applied. Similarly, plasticized polyvinyl chloride (PVC) may be formulated with the addition of a fungicide to protect it from attack by microfungi and so protect the plasticizer and prevent loss of elasticity in service [14.4]. Wood may be impregnated with fungicides and insecticides prior to sale for structural applications.

In most of the situations described above, the treatment of a material is intended to either prevent deterioration of it, maximize the protection of the ma-

terial or remove a population from a system prior to its use. The biocides employed for such purposes and the approaches taken to achieve effective disinfection and preservation have been reviewed extensively elsewhere [14.1, 5]. However, in recent years a new form of interaction between a formulated material and biological populations has emerged. In part, this can be viewed as either an extension of the degree of protection provided to a material by the inclusion of a biocidal agent into it or as the transfer of the properties of external treatments of a material into the material itself. The inclusion of the biocidal agent is not simply to protect the material from deterioration but to exert a biological effect either to the immediate surroundings of that material or to items that come into contact with it. These effects may range from the prevention of growth of undesirable microbial populations on a material to which they pose no physical, chemical or biological threat, the immediate destruction of individual microbial cells as they come into close association with a surface (possibly without even coming into direct physical contact) or to the inclusion of insecticidal agents into netting intended as a barrier to mosquitos [14.6]. In all cases the effect is external to the material from which the article is constructed and is not merely present to protect either the material or the item itself. However, it is possible that the effect may take place within an item constructed from a modified/treated material. For example, one can imagine an air filter constructed of paper into which antimicrobial properties have been introduced which is intended to kill bacteria pathogenic to man which impact on it [14.7]. Similarly, a polyethylene foam sponge may be impregnated with an antimicrobial agent which is intended to prevent the growth of bacteria associated with food poisoning in man. This sponge may not be intended to disinfect surfaces on which it is used but simply to prevent it from becoming a reservoir of such bacteria in a food preparation environment.

Clearly, there are some complex situations when the effects intended by treated articles/treated materials are to be considered and this will impact on the suitability of the methods used to measure them. In general however, the effect of a treated item/treated material can be considered to be external to it. The effect is not concerned with either preservation or protection of the material/item itself and is not achieved by the application of a disinfecting agent after the material has entered service.

Finally, when considering suitable test methodologies, the scale and duration of the effect may need to be considered with respect to the claim made. For

example, will the material/item be able to exert the effect claimed for the effect to have any realistic benefit? Similarly, will the scale of the effect be sufficient to provide the benefit either claimed or implied? It is unlikely that data to support such claims would be available from a single test and it is likely that ageing and weathering studies would be needed in addition to tests which provide basic proof of principle and demonstrate performance under conditions which simulate actual use.

Biocidal Activity

Biocidal activity is a generic term but in the context of this chapter we are essentially considering microbiocidal, insecticidal, acaricidal and molluscicidal activity and is considered in more detail in [14.5]. In actual use this activity is further sub-divided to represent activity against one or more groups within the various classes. For example, in the case of microorganisms, this will be impacted on by the microbial types/species which are employed in testing and, to a certain extent, the type of test required and this is considered in detail in other chapters in this section. The scale of the effect will often be important in some applications but the outcome of biocidal activity will result in a reduction in the number of test microorganisms as a result of an interaction with the material through an irreversible, killing effect. Such effects may be described as:

1. **Bactericidal:** the effect is limited to a reduction in the size of a vegetative bacterial population.
2. **Fungicidal:** the effect is limited to fungi. This effect may be attributed to activity against vegetative growth, spores/dormant structures or both and may require clarification depending on the intended use of the product.
3. **Sporicidal:** the effect is against the spores/dormant structures of bacteria.
4. **Virucidal:** the effect is limited to virus particles;
5. **Protosticidal:** the effect is exhibited against protozoa and their dormant stages.
6. **Algicidal:** the effect is exhibited against algae and their dormant stages.

Biostatic Activity/Repellency

In many of the cases of the protection/preservation of materials the effects required are not associated with killing a population but of either preventing its growth or preventing it coming into contact with the material. In this context most interactions between a 'biocide' and microbial populations are biostatic ones. As with bio-

cidal activity, this will be impacted on by the species which are employed in testing and, to a certain extent, the type of test required but obviously, the prevention of growth/metabolism/colonization of/by the target species should be demonstrated. It may be sufficient to demonstrate that growth is either slower or reaches a lower level than on an equivalent control material to either substantiate a claim or demonstrate a benefit. In many cases chemical microbicides exhibit both biostatic and biocidal activity with the initial impact on a microbial population being biostatic and sustained contact resulting in biocidal action. Similar relationships are found with molluscicides where presence of a toxic agent is sufficient to deter attack. In some cases limits to the efficacy of biostatic and repellency action are not related to the potency of the agent but to the durability of the effect in combination with a material (e.g., leach resistance of a fungicide preventing the germination of fungal spores that have alighted on a coating applied to the facade of a building). As with biocidal activity an equivalent subdivision of the type of activity exists, e.g.:

1. **Bacteriostatic:** the effect is limited to the prevention of growth/metabolism of bacteria and possibly the germination of bacterial endospores and other dormant structures.
2. **Fungistatic:** the effect is limited to the prevention of growth of fungi and possibly the germination of fungal spores and other dormant structures.
3. **Algistatic:** the effect is limited to the prevention of growth of algae and possibly the germination of dormant structures.

Summary

Although the intrinsic activity of biocidal agents is important, of more concern is the interaction between them and the material/system which they are designed to protect. The spectrum of activity must be appropriate to the challenge the materials is likely to endure and the biocide must be compatible with the material as well as be able to provide protection for a suitable period of service. Although many of the tests described in this section are designed to examine the susceptibility of materials to biological attack, many can be adapted to examine the impact a biocidal treatment can have on that attack. With careful consideration, reliable prediction of the performance of a material equipped with a biocide can be made and this is often the main challenge when considering the negative interaction of biological systems with materials.

14.2 Biological Testing of Wood

Section 14.2 deals with the degradation of wood, wood products and wood treated with preservatives, by insects and microorganisms. It introduces the test methodology used to simulate such attack and how to estimate its impact on the material. The approach to testing differs in detail throughout the world. However, certain basic principles are commonly accepted. The approach taken in Europe will mainly be used to illustrate these principles.

Before elaborating on the specifics of attack by microorganisms (Sect. 14.2.1) and insects (Sect. 14.2.2) some general aspects concerning the testing of wooden materials will be considered.

Wood is one of the oldest construction materials. Its natural availability and omnipresence had made it the most obvious choice to build bridges, houses, ships etc. for millennia. It is relatively easy to process, has good insulating properties, has a high elasticity (compared e.g. to concrete, steel, stone) and wood with a high density is amazingly fire resistant (e.g. oak, teak).

Wood can be cut and bent to the desired size and shape. However, as a typical organic matter, its basic components and its constituents provide a nutrient source for microorganisms, molluscs, insects and other arthropods. Because of this, many species have developed natural defence systems. For example, some tree species (e.g. bongossi, teak) often produce phenolic substances which are deposited in the cells of the heartwood. These substances can considerably delay the attack by microorganisms and lend the material a degree of natural durability. Laboratory and outdoor tests have been developed to assess this natural durability for the commercially most interesting wood species used in Europe (see later: European Standard EN 350, Durability of wood and wood based products). In contrast, other wood species (e.g. pine, beech) can be rapidly degraded. To make long-term use of them in construction etc. they have to be preserved chemically with a wood-protecting biocide. Therefore, the test standards described in the following mainly deal with preservative-treated wood/wooden materials to determine the efficacy and performance of this material.

However, to determine the virulence of the microorganisms used in the different test setups, untreated wood is always incorporated. Some methods also employ so-called “reference products” which include preservatives that have shown their preserving effects on wood for decades. With the help of a reference product the severity of a method can be estimated and the results for a new preservative under test can be put into context.

Ideally, methods for determining the protective efficacy and the performance of treated or untreated timber should:

- reflect the environmental conditions to which the treated timber is subjected in service;
- cover all relevant organisms and their succession during the time of use of the wooden commodity or construction;
- take into account the possible methods of treatment for the wood preservative;
- provide reproducible results rapidly;
- be uncomplicated and easy to handle;
- involve minimal costs.

Obstacles are:

- the environmental conditions and the decaying organisms to which the timber is subjected are extremely diverse,
- the sensitivity of the decay organisms is different towards different biocides,
- the biocides applied are stressed not only by physical factors like evaporation, leaching and diffusion but;
- in the case of organic biocides, these compounds can also be utilized by organisms that are not the target of the chemical wood preservation and which may deteriorate the biocides or even use them as a nutrient source;
- not all timber species are equally treatable.

Therefore it is necessary to simplify and to develop methods which nevertheless give sufficient certainty for the assessment of treated and untreated wood under test.

General Requirements for Resistance Against Biological Attack

More general requirements for testing procedures are outlined in the European Standard EN 350 for a natural resistance against wood-destructing organisms and in EN 599 for a wood preservative derived resistance.

- European Standard EN 350-1:
Durability of wood and wood-based products – Natural durability of solid wood – Part 1: Guide to principles of testing and classification of the natural durability.
- European Standard EN 350-2:
Durability of wood and wood-based products – Natural durability of solid wood – Part 2: Guide to

natural durability and treatability of selected wood species of importance in Europe.

- European Standard EN 599-1:
Durability of wood and wood-based products – Performance of wood preservative as determined by biological tests – Part 1: Specification according to use class.
- European Standard EN 599-2:
Durability of wood and wood-based products – Performance of wood preservative as determined by biological tests – Part 2: Classification and labelling.

The likelihood for a biological attack of wooden materials also strongly depends on the environment in which the material is used. These potential environments can be categorized into use classes, formerly known as hazard classes, according to the European Standard EN 335.

- European Standard EN 335-1:
Durability of wood and wood-based products – Definition of use classes of biological attack – Part 1: General
- European Standard EN 335-2:
Durability of wood and wood-based products – Definition of use classes of biological attack – Part 2: Application to solid wood.
- European Standard EN 335-3:
Durability of wood and wood-based products – Definition of use classes of biological attack – Part 3: Application to wood-based panel.

EN 335-1 defines the environmental compartments in which wood can be used and describes the main hazards wood is exposed to. The standard defines five hazard

classes of biological attack, recently renamed use classes (Table 14.1). Other countries developed similar classifications. An ISO standard titled “Durability of wood and wood based products – Definition of use classes” is basically following this principle and is currently under preparation.

Preconditioning Methods Before Durability Testing of Treated and Untreated Wood

In order to evaluate the effectiveness of a wood preservative over time, artificial ageing of protected wood is performed before a standard test method against microorganisms or insects is carried out.

- European Standard EN 73:
“Accelerated ageing tests of treated wood prior to biological testing – Evaporative ageing procedure” describes an evaporative ageing procedure, applicable to test specimens of wood which have previously been treated with a preservative, in order to evaluate any loss in effectiveness when these test specimens are subsequently subjected to biological tests, as compared with test specimens which have not undergone any evaporative ageing procedure.
- European Standard EN 84:
“Accelerated ageing tests of treated wood prior to biological testing – Leaching procedure” describes an ageing procedure by leaching, applicable to test specimens of wood which have previously been treated with a preservative, in order to evaluate any loss in effectiveness when these test specimens are subsequently subjected to biological tests, as compared with test specimens which have not undergone any ageing procedure by leaching.

Table 14.1 European Standard EN 335-1:1992 “Durability of wood and wood-based products – Definition of hazard classes¹⁾” of biological attack

Hazard classes ¹	General service situations	Description of expose to wetting in service	Fungi	Beetles ²	Termites	Marine borers
1	Above ground, covered (dry)	None	–	U	L	–
2	Above ground, covered (risk of wetting)	Occasionally	U	U	L	–
3	Above ground, not covered	Frequently	U	U	L	–
4	In contact with ground or fresh water	Permanently	U	U	L	–
5	In salt water	Permanently	U	U	L	U

U = Universally present within Europe.

L = Locally present within Europe.

¹ According to a decision of CEN/TC 38 now named **use classes**.

² The risk of attack can be insignificant according to the specific service situation.

- European Technical Report CEN/TR 15046 “Wood preservatives – Artificial weathering of treated wood prior to biological testing – UV-radiation and water-spraying procedure”: This method describes an ageing procedure which simulates intervals of rain and UV-radiation. Because it works with elevated temperatures, to some extent also evaporation is included with this method. The method combines the main stresses by physical factors on the wood preservative in treated wood specimens prior to fungal or insect tests.

Modern organic fungicides and insecticides are susceptible to microbiological degradation. Therefore, the above-mentioned ageing standards are not always sufficient to determine the longevity of wood preservatives formulated with these biocides. A European Technical Specification (CEN/TS) titled “Wood preservatives – Method for natural preconditioning out of ground contact of treated wood specimens prior to biological laboratory tests” is under preparation. This method combines natural physical stress factors with the possible succession of naturally occurring microorganisms. This Technical Specification is intended to overcome the difficulties caused by the non-target microorganisms at least for wood exposed to the general service situations defined for European hazard class 3.

14.2.1 Attack by Microorganisms

Microorganisms can only attack wood when water is present in its cell lumina. This state is described as “wood moisture above the fiber-saturation-point”. As a rule of thumb this state is reached at about 30% wood moisture content (related to the dry weight of the wood). Dry wood cannot be metabolized by microorganisms and needs no preservatives to protect it against them.

Above fiber saturation the main components of wood – cellulose, hemicelluloses and lignin – can be degraded by a vast number of microorganisms.

Wood-destroying fungi are the most evident and powerful wood degraders. Their species belong to the

- basidiomycetes, causing brown rot or white rot,
- ascomycetes and fungi imperfecti, causing soft rot and stains.

Wood-destroying bacteria can be present in extremely wet environments, but the speed at which they degrade

wood is normally very slow and they can be neglected as metabolizing organisms of wood components. Nevertheless, with wood preservation moving away from inorganic, undegradable components towards organic compounds, the deterioration of these substances might be influenced by bacteria, leading to a failure of the wood preservative and therefore opening pathways for wood-metabolizing organisms to attack.

In relation to wood destruction mass loss and therefore strength loss of the wood are the primary issues. However, wood can also lose value through discoloration by microorganisms through molds and blue-staining fungi that cause no loss of cellulose, hemicellulose or lignin.

Detecting Wood-Destroying Fungi by Visual Means

The above-mentioned types of rot cause different appearances of the attacked wood. In many cases this can even be detected by the bare eye and can be confirmed by microscopic work. For macroscopic evaluation the wood should be dry, because checks and cracks become more obvious this way. For cutting sections to be analyzed microscopically the wood moisture should be above the fiber saturation point (above 30% wood moisture), because all strength properties of wood decrease with increasing moisture content of the wood until the fiber saturation point is reached. In other words: cutting becomes easier.

Visual Distinction of the Main Types of Wood Decay

Figures 14.2a, 14.3a show brown rot and white rot on wood macroscopically (here the wood has been cut longitudinally). Figure 14.1a shows undecayed, Figs. 14.2b, 14.3b decayed cross sections of wood as it can be seen under the microscope at a magnification of 150× to 200×. Further macroscopic and microscopic examples of wood decay can be found in [14.8].

Soft Rot. These fungi degrade cellulose and hemicelluloses. Macroscopically they cause a greyish-black rot with small cubicle cracks. Microscopically this form of decay is characterized by cavity formation inside the cell wall (Fig. 14.1b).

Blue Stains. Blue stains do not degrade lignin, cellulose or hemicelluloses and therefore cause no loss in mass or stability of the timber. They metabolize sugars deposited in the parenchymatic tissue of the wood. Blue stain fungi grow through the parenchymatic cells and spread in the

Fig. 14.1 (a) Cross section of sound undecayed wood (*Picea sp.*). (b) Cross section of wood (*Picea sp.*) decayed by soft rot causing (Courtesy of Swedish University of Agricultural Science, Uppsala, Sweden)

wood. They stain the wood through their black-bluish hyphae and spores.

Brown Rot Fungi. Brown rot fungi metabolize cellulose and hemicellulose of the wood. Lignin can not be degraded by these fungi. The rot leaves behind cubic cracks (Fig. 14.2a) and a dark brownish tinge to the wood. The microscopic features are shown in Fig. 14.2b.

White Rot Fungi. White rot fungi metabolize all three main components of wood: lignin, cellulose and hemicelluloses.

Macroscopically white rot fungi generally lighten the color of the wood. Two types of white rot can be distinguished: a) simultaneous rot, where in pockets of decay the cellulose, hemicelluloses and lignin are completely degraded and b) the selective lignin degra-

Fig. 14.2 (a) Longitudinal cut of wood (*Picea sp.*) decayed by brown rot causing fungi; wood surface shows cubicle cracks in wood decayed by brown rot, in the lower part of the picture mycelium of the brown rot causing fungus can be seen. (b) Cross section of wood (*Picea sp.*) decayed by brown rot causing fungi (Courtesy of Swedish University of Agricultural Science, Uppsala, Sweden)

dation. Whereas the pockets of decay can be easily detected (Fig. 14.3a) the selective degradation of lignin, which is the more common form of white rot, can not be determined by changes of the wood surface like cracks or holes. Mass loss and change to a lighter color of the wood compared to the undecayed timber are the first signs of such an attack. The microscopic features for lignin degraders are shown in Fig. 14.3b.

Lignin-degrading fungi can be detected by the presence of a phenolic oxidase enzyme based on the Bavendam-Test. This test allows to biochemically distinguish brown from white rot fungi.

Sap Stains. Fungi grow only on the surface of freshly cut timber. They do not metabolize the wood itself, but

Fig. 14.3 (a) Longitudinal cut of wood (*Picea* sp.) decayed by white rot causing fungi; this picture shows an example for so called “pocket rot”, because white pockets of decay can be seen on the wood surface. (b) Cross section of wood (*Picea* sp.) decayed by white rot causing fungi (Courtesy of Swedish University of Agricultural Science, Uppsala, Sweden)

the sugars deposited in the parenchymatic tissue of the wood. The fungi can access these sugars only in cells that have been damaged (by force: felling or processing). By their metabolic products and colored spores they stain the wood and lead to loss in value.

A good overview on different forms of decay is also given by Wilkinson [14.9], and a more detailed description of macro- and microscopic observations can be found, e.g., in *Anagnost* [14.10].

As outlined above (see on *sap stain*, *blue stain*) some microorganisms cause only discoloration of wood while others also lead to mass loss of the wooden substance. Mass loss and therefore density loss is the more critical parameter since it is related to strength loss [14.11] which is especially undesirable for a construction and

building material. Therefore laboratory methods determine the mass of a wooden specimen before and after exposure to fungi which have been selected as aggressive wood-deteriorating organisms under laboratory conditions.

To measure mass loss at a set point in time requires the drying of the wooden material to 0% wood moisture content. This drying process kills living fungal cells and can lead to severe cracking of the wood structure. The rheological properties of the wood also lead to irrevocable physicochemical changes while drying. Therefore the determination of mass loss by weighing is not a nondestructive method.

Nondestructive Testing Methods to Detect Fungal Decay

Nondestructive methods are required when the changes of wood structure have to be monitored over a longer time period or when the timber to be tested is already part of a construction. *Bodig* [14.12] listed the following nondestructive methods as examples:

- **Sonic Stress Wave**
Stress waves are generated either through an impact or by a forced vibration. Usually, with this method either the speed of sound or the vibration spectrum is measured. The dynamic modulus of elasticity (**MOE**) can be calculated from these measurements.
- **Deflection Method (Static Bending Technique)**
The deflection is measured at a safe load level which does not lead to rupture of the test piece. The static **MOE** can be calculated from these measurements.
- **Electrical Properties**
The products of fungal metabolism are carbon dioxide and water of which the latter leads to a higher moisture content in the wood. This method is based on the relationship between moisture content and electrical resistance of wood.
- **Gamma Radiation**
is tool for quantifying decay. It is also employed as a tracing method for quantifying the distribution of preservatives in wood. One of the limitations of this method is the regulations associated with the use of a radioactive source.
- **Penetrating Radar**
this method is currently being developed for wood products. The method bears the potential to detect and quantify degradation at inaccessible locations.

- **X-ray Method**
is mostly used in the laboratory or in production lines due to the bulky nature of the X-ray source and the measuring equipment.

Similar techniques (transverse vibration techniques, static bending techniques) are listed in a review on non-destructive testing for assessing timbers in structures by *Ross and Pellerin* [14.13].

Also infrared, X-ray and gamma-ray computerized tomography has been employed to visualize microbiological attack in timber. However, the techniques are mostly very cost intensive.

The oldest nondestructive test method is the visual estimation with the bare eye followed by rating the decay or discoloration of the specimens. This inexpensive method provides the expert with a lot of information. It is mainly applied when large numbers of specimens in a test field have to be assessed. An experienced evaluator will be able to rate the intensity of decay as well as to determine which type of decay has infested the wood.

Testing Wood for Different Use Classes

While the environmental conditions in use class 1 and 2 do not provide the necessary amount of water to allow growth of microorganisms, the use classes 3 and 4 are the more relevant for testing microbiological decay above ground and in ground contact.

Testing wood for use class 3.

Field tests

Use class 3 is a very complex class. Depending on the local climatic conditions, the dimensions of the cross section of construction parts and their actual location (near to the ground, mostly covered under a roof etc.) it may reach from nearly use class 2 to use class 4. Many test methods have been developed for use class 3, intended to accelerate the attack by microorganisms and thus to give results in relatively short times. Some of them even use additional artificial wetting regimes. But all of them are simply reflecting different situations in use class 3. They are not accelerated test methods, except when they are used under extremely severe tropical conditions.

Three of these methods shall be described exemplarily:

- EN 330:1993 “Wood preservatives – Field test method for determining the relative protective effectiveness of a wood preservative for use under

a coating and exposed out of ground contact: L-joint method.” With slight modifications the AWP standard E9:87 is comparable to this method. Stylized corners of window frames with mortise and tenon (L-joints) are treated with a wood preservative by a method recommended by the supplier of the preservative (double vacuum, dipping or others). After drying of the preservative the mortise members are sealed at the cross section opposite to the mortise and the whole L-joints are coated with an alkyd reference paint or a paint system provided by the supplier of the preservative. Then the specimens are exposed in the field on racks in a position slightly leaned backwards. Prior to exposure the top coat will be broken at the joint by opening and reclosing the joint. In at least annually intervals the L-joints are visually examined for occurrence of wood-disfiguring and wood-destroying fungi. For the assessments the joints are taken apart in order to check the situation within the joint. The fungal attack is rated according to a 5-step rating scale reaching from 0 (sound) to 4 (failure). After 3 and 5 years of exposure additionally exposed specimens are assessed destructively by cutting the joint members lengthwise as to detect interior rot in the wood. The mean service-life of a series of L-joints will be determined by adding the service-life of the individual members of the series after the last member is rated “failure” and dividing that number by the number of parallels in the test.

- ENV 12037:1996 “Wood preservatives – Field test method for determining the relative protective effectiveness of a wood preservative exposed out of ground contact – Horizontal lap-joint method.” AWP Standard E16-98 uses the same method with only slight modifications. Objective of the method is to evaluate the relative effectiveness of the preservative, applied to jointed samples of pine sapwood by a treatment method relevant to its intended practical use. In contrast to the L-joint method, the wood preservative is applied without subsequent surface coating. Bound together with cable straps the jointed specimens are exposed on racks outdoors not touching the ground. The joint functions as a water trap, thus providing optimal wood moisture conditions for the attack by wood-destroying fungi for relatively long periods. Again the specimens are examined visually at least annually using a rating scale for the fungal attack.
- AWP E18-04 “Standard field test for evaluation of wood preservatives intended for use in cate-

gory 3B applications exposed, out of ground contact – Uncoated ground proximity decay method.” Test specimens of pine or other softwood species, measuring $125 \times 50 \times 19 \text{ mm}^3$ are treated with a wood preservative according to the recommendation of the supplier of the preservative. After drying of the preservative the specimens are exposed outdoors, lying horizontally on concrete blocks measuring $40 \times 20 \times 10 \text{ cm}^3$ which are placed on the ground. The arrangement is covered by an open frame with a horticultural shade cloth on top. The distance between specimens and cloth is about 3 cm. The cloth is intended to protect the specimens from direct sunlight. It also reduces the drying of the specimens and provides an increased relative humidity within the frame. The specimens are checked for fungal attack at fixed intervals. The attack is rated according to a rating scale.

The purpose of these methods is to expose the treated specimens to the complete range of microorganisms occurring under natural conditions. That means, all possible microorganisms, like bacteria, yeasts and fungi get to attack the wood. According to the local climatic conditions the specimens are subjected to changing temperatures, precipitations and relative humidity. All microorganisms metabolizing wood have their specific optimum temperatures and wood moisture content. Therefore a natural succession of microorganisms occurs which cannot be achieved in the laboratory. To some of the organisms the active ingredients of the wood preservatives may be poisonous, while other microorganisms may detoxify them or in the case of organic substances may even use them as a nutrient source.

All these methods provide data on the performance of wood preservatives. But as the local conditions of temperature and precipitation of the exposure sites can be extremely different even at relatively small distances, the performance data can also vary extremely. As experiments in a European research project (FACT project) have shown, even untreated lap-joints may not be attacked in northern Europe within three years but be heavily attacked within one year in the tropics. And because it is more or less accidental which decay organism attacks the specimens at which time, the tests are not sufficiently reproducible. Therefore the results cannot be used for approvals of wood preservatives, where reproducible efficacy data are needed which give a certain overall reliability for the consumer [14.14–16].

Laboratory tests

- EN 113 “Wood preservatives – Method of test for determining the protective effectiveness against wood destroying basidiomycetes – Determination of the toxic values” works with pure cultures of different basidiomycetes that cause brown or white rot. The preservatives are incorporated into the wood at different concentrations under vacuum conditions. The treated specimens are then exposed to the fungi for 16 weeks at an optimum temperature. The mass loss (%) is determined at the end of the test.
- TS (Technical Specification) 839 “Wood preservatives – Determination of the protective effectiveness against wood destroying basidiomycetes – Application by surface treatment” is designed to assess whether a wood preservative is suitable to protect the surface of timber constructions from decay and to prevent the penetration of fungi into the interior parts of timber which are not impregnated with the wood preservative.
- EN 152-1 “Test methods for wood preservatives; laboratory method for determining the protective effectiveness of a preservative treatment against blue stain in service; part 1: brushing procedure” and
- EN 152-2 “Test methods for wood preservatives; laboratory method for determining the protective effectiveness of a preservative treatment against blue stain in service; part 2: application by methods other than brushing” are methods that are applied partly in the field as well as in the laboratory. After a natural weathering period of 6 months (between April to October) on outdoor racks the timber specimens are taken into the laboratory where they are inoculated with blue stain fungi. After 6 weeks of incubation the discoloration of the brushed/coated timber surfaces is evaluated. Optionally the outdoor weathering can be replaced by an artificial weathering in a weathering device with UV-light, condensation and rain periods (see: Preconditioning methods before durability testing of treated and untreated wood).

Testing wood for use class 4.

Field tests

While in use class 3 the local climates play the decisive role in start and progression of microbial attack of wood, the type of soil is the decisive factor in use class 4.

An example for a test method for this use class is

- EN 252 “Field test method for determining the relative protective effectiveness of a wood preservative

in ground contact.” The AWP A E7-93 “Standard method of evaluating wood preservatives by field tests with stakes” follows the same principle.

EN 252 uses stakes of Scots pine sapwood (dimensions: $500 \times 50 \times 25 \text{ mm}^3$) which are treated with the preservative under test by a vacuum-pressure process. The stakes are exposed in the test field, buried half of their length in the ground. Annually the stakes are examined visually for fungal decay using a rating scale. In addition, the remaining strength of the stakes is probed by a gentle kick against the stakes when still buried in the ground. Stakes treated with a well-known reference preservative are exposed simultaneously. The efficacy of the test preservative is determined by comparing the performance of the test preservative with the performance of the reference preservative.

Methods of nondestructive testing (see above) can also be applied at this point. For instance, measuring the MOE in a static or dynamic manner of the wooden stakes before they are exposed in the field and once every year does give an indication of the performance of the preserved or unpreserved material over time [14.17].

Laboratory tests

- Prestandard ENV 807 “Wood preservatives – Determination of the effectiveness against soft rotting micro-fungi and other soil inhabiting microorganisms” gives a basis for assessing the effectiveness of a wood preservative against soft rot-causing fungi. The source of infection is the natural micro-flora of biologically active soil, which may also contain other microorganisms such as bacteria and other fungi. The data obtained from this test provides information by which the value of a preservative can be assessed. Nevertheless it has to be supplemented with other test data for use class 4 to provide a more complete picture.

Testing wood in aquatic environments (part of use class 4 and use class 5). The fresh water (use class 4) or marine (use class 5) environment, is a very complex environment in which bacteria, fungi and molluscs can lead to wood destruction. Other organisms like algae might settle on the wood and will help to establish a biofilm on the wood that enhances fouling. Standardized laboratory methods for wood treated with preservatives or tested for their natural resistance against decay are not known to the author. The methods known are all field tests, which

implies the setup of the test specimens into open waters.

Only a few marine organisms shall be mentioned in this context specifically: The mollusc borers *Toredo navalis*, and *Bankia sp.*, commonly called “shipworms” and the crustacean borers *Limnoria*, *Cherula* and *Sphaeroma*. These organisms actively bore into the wood and therefore affect wood stability.

14.2.2 Attack by Insects

Several industrial and household materials and construction devices of organic matter, especially those of biogenic origin, are endangered by pest insects. Susceptible to insect attack are mainly materials of plant origin made up of lignin and cellulose, namely wood, or products of wood origin [14.8]. These materials provide a habitat with shelter, food, and breeding sites for a manifold of different pest insect species [14.18]. Most are beetles (*Coleoptera*) (Figs. 14.4 and 14.5) and termites (Fig. 14.6). In most cases the developmental stages of the pests feed on the materials causing their destruction or contaminate it in such a way that their intended function is irreversibly altered.

The rate of destruction caused by insects is strongly influenced by various factors like climate, moisture content of the material, its nutritional value, and the infestation density. Additionally, the respiratory activity of a heavy insect infestation generates heat and moisture and affects the microclimate, favoring the growth of fungi, yeasts, and bacteria which further increase the overall decay rate of the material.

Preventive protection and, more important, regular inspections of potentially endangered materials are essential to guarantee the safety and the serviceability of, for example, wooden constructions, paper-based insulation materials, tools, furniture, and historic artefacts. The sooner an infestation is detected, the better is the chance for a remedial measure. The signs of destruction are generally material specific but may also be pest specific, allowing target-specific corrective and control actions.

However, the degree of damage, especially the one caused by wood-destructing insects, can easily be overseen, for larvae of wood-boring beetles and some termite species excavate wood only from the inside and leave a shallow surface layer fully intact. Nevertheless, a number of indices may point to a pest infestation, and no particular equipment for the detection is necessary.

Preventative control action against material insect pests is usually achieved through the application of resid-

Fig. 14.4a–d Development stages of wood boring beetle using the old house borer *Hylotrupes bajulus* as an example. All stages except adult beetles are inside the wood and usually not visible from the outside. **(a)** Egg laying female; **(b)** full grown larva (3 to 6 years old) **(c)** pupa; **(d)** adult beetles (female left, male right)

ual pesticides. The effectiveness of these insecticides can be evaluated in several laboratory test methods.

Methods for Detecting Insect Attack

The most important types of insects that attack constructive timber are beetles and termites. Occasionally, a few ant species, wood wasps or horntails, wood-boring moths and a solitary bee may be of some relevance. Numerous indices on the surface wood may directly point to an attack by wood-feeding insects. Prominent signs allow differentiating between the possible pests.

Various inspection methods are available to check for the presence of wood-boring insects: visual, auditory, X-ray, infrared, and even the use of tracker dogs.

Visual Inspection. The simplest check-up of materials potentially endangered by insect attack is visual inspec-

tion of the material's surface, streaming debris from the material and all signs of insect presence Table 14.2.

Flight holes: Flight or emergence holes are the exit sites of emerged adult insects after having completed their larval stage inside the wood. They appear round or oval and sharp-edged, not to be confused with screw- or nail holes. Broadly oval holes are characteristic for cerambycid beetles, whereas a round shape of these holes points to powder-post or anobiid beetles. However, the mere existence of flight holes is no final proof for an ongoing attack, since the completion of beetle development and the infestation may have occurred a long time previous. Additional information is required. New emergence holes appear bright to light yellow in color, like freshly-sawed wood, and indicate recently emerged beetles with possibly more larvae in the material to complete their development. The longer an infestation is extinct

Fig. 14.5 Wood boring beetles *Anobium punctatum* adult

the more dust is accumulated and oxidation processes darken the powdery inner edges of the holes over time. Paint sealed holes from a previous coating may also indicate an already extinct infestation when no fresh holes are evident. In case of doubt, existing emergence holes should be marked and the material be rechecked after time for additional holes to have occurred. The material may also be tightly wrapped or sealed with paper, for new emerging beetles will penetrate the wrap and indicate developmental activity by leaving their exit holes in the wrap.

The flight holes of dry-wood termites, which may be confused with the exit holes of anobiid beetles, are first signs of their presence. They live in small colonies of up to some hundred individuals entirely in wood that is moderately to extreme dry. They require no contact with the soil. Because of their concealed life, colonies can go undetected for many years inside timber. Often it

Fig. 14.6 Termite *Mastotermes darwiniensis*; 2 worker termites at the bottom and 3 soldier termites at the top

becomes visible only when already considerable damage was produced.

Big round holes, 12 mm wide, mainly outdoors, are the nest entrances of carpenter bees. The wood below the hole often shows yellowish fecal streaks. The entrance is usually guarded by the male bee, giving a humming sound.

Horntails also emerge through round-shaped flight holes. Their size can vary between 4 to 6 mm in cross section and fresh holes occur exclusively in recent cut and build-in timber during the first three years. This is because development is completed from eggs which had been laid by female horntails in the forest on trees declining or dying from fire, disease or insect damage or other natural causes. They also infest newly felled and freshly sawed lumber. Reinfestation of dry structural timber is most unlikely.

Appearance of the wood surface: The larvae of wood-boring insects usually start their tunnelling in the most peripheral parts, leaving a paper-thin layer of the wood surface untouched. The frass produced by growing larvae occupies a greater volume than the wood from which it was produced, and this causes the surface of the infested wood to have a blistered or rippled appearance. Occasionally the surface will break, and frass may fall out through the fine cracks and accumulate on the floor beneath.

Little mud tubes, so-called galleries, extending from the ground over exposed surfaces to a wooden food source are good indicators of the presence of subterranean termites. The tubes are either round or flat and usually measure at least 8 mm. These termites live in colonies which can contain thousands to millions of individuals and are closely associated with the soil habitat where they tunnel to locate water and food, namely wood.

Termites excavate galleries or tunnels in wood as they consume it, leaving nothing more than a thin wooden layer. These areas are easily crushed with a hard object (knife, hammer or screwdriver). In the case of extreme damage partly collapsed wood at bearing points may pinpoint to internal excavation. Noninfested wood gives a sound resonance when pounding the surface, damaged wood sounds hollow.

Slitlike openings called “windows” with some frass directly beneath are positive signs for carpenter ant activity. Usually this frass contains fragments of ants and other insects mixed with the wood fibers, because unlike termites that consume wood, carpenter ants scavenge on dead insects, insect honeydew and other materials.

Table 14.2 Characteristics damage by wood infesting insects (modified from [14.18])

Infested Material	Signs of infestation frass	holes	galleries, tunnels, feeding tubes	Most likely pest
seasoned sapwood of hardwoods or softwoods (rarely in heartwoods)	fine powder with elongate lemon-shaped pellets, loosely packed	exit holes circular 1.6 to 3 mm	up to 3 mm circular in cross section, numerous and random	anobiid powderpost beetle
sapwood of hardwoods primarily, minor in softwoods	fine to coarse powder, tightly packed, tend to stick together	exit holes circular 2.5 to 7 mm	1.6 to 10 mm circular in cross section numerous and random	bostrichid powderpost beetle
sapwood of ring and diffuse porous hardwoods only	fine flour-like, loosely packed in tunnel	exit holes circular 0.8 to 1.6 mm	1.6 mm circular in cross section, numerous, random	lyctid powderpost beetle
seasoned sapwood of softwoods	very fine powder and larger cylindrical pellets, tightly packed in tunnels	exit holes oval 6 to 10 mm	10 mm oval in cross section, numerous in outer sapwood, ripple marks on walls	Hylotrupes bajulus
unseasoned wood under bark only, inner bark and surface of sapwood only	coarse to fine powder, bark coloured, tightly packed	exit holes circular 1.6 to 2.5 mm	up to 2.5 mm circular in cross section, random	bark beetles
seasoned dry soft- or hardwood	hard elongate pellets of uniform size, less 1 mm, six flattend or concavely depressed sides	none	hollow tunnels beneath a thin wooden layer, sometimes filled with fine frass	dry wood termites
wood coated with mud galleries	fine lamellae of late wood remain intact	none	hollow tunnel beneath a thin wooden layer, mud tubes leading to the wood	subterranean termites
seasoned wood	piles of coarse wood shavings with insect parts	slitlike “windows”	clean smooth galleries	ants, carpenter ants
softwood or softer hardwood with no bark	fine wooden debris with yellowish faecal streaks	entrance holes large and circular 12 mm	smooth walled 12 mm circular in cross section, very regular	carpenter bees
fresh to slightly seasoned softwood, very rarely hardwood	fine coarse, usually not outside the wood	exit holes circular 4 to 6 mm	strong variation in size, circular in cross section, tightly packed with frass	horntails
unseasoned wood or occasionally damp	fine in texture with granules being circular	narrow oval ragged margins	Indistinct, less than 3 mm in cross section	weevils
unseasoned wood with bark or occasionally damp	Fine, stacked between bark and sapwood	Numerous small entrance and larger exit holes	bark is lifted up by frass deposits	warf beetles

Lamellar degradation of the cut end of foundation beams point to the activity of the wood ant *Lasius fulliginosus*. This small ant in general starts to attack wood at the ground level, where it is in contact with moisture and therefore is susceptible for fungus decay. This is a precondition for an initial attack. Later, by autonomous moisture intake, together with this symbiotic fungus the ants progress deeper into the wood thus possibly causing substantial damage.

Occurrence of frass (bore dust): While feeding, beetles often push out powdery frass from holes which they have constructed in the infested wood. The frass is piled below the holes or in cracks of the structures. However,

those piles are not indicative off an active attack, as concussions can cause a release, after an infestation has already ceased. Furniture or other wooden objects with past infestations will sometimes be suspected to be re-infested when frass or insect parts fall out in the process of handling or moving. By placing a dark paper beneath nonmoved objects to detect the appearance of fresh frass will clarify whether the infestation is active or not.

If the wood surface is probed where tunnelling is suspected, the powdery borings may be located. The consistency of the frass ranges from very fine to coarse, depending on the pest. The size and shape of larval frass are often species specific. Larger cylindrical frass pellets

like those produced by the old house borer, *Hylotrupes bajulus*, are typical for cerambycid beetles, whereas round frass pellets with tip-point edges indicate the presence of anobiid larvae like *Anobium punctatum* for example. Flour or talc-like frass points to the presence of powderpost beetles. This will fall out of the emergence holes while tapping the wood with a hammer. A magnifying lens should be used for a reliable inspection of frass pellets.

Small fecal pellets generally found in the close vicinity of their wooden habitat are good indicators for the presence of drywood termites. The pellets can vary in color, depending on the wood that has been consumed. They appear hard, elongate, of uniform size, less than 1 mm in length, with round ends and six flattened or concavely depressed sides. The piles do not contain any other debris such as insect parts or fiber.

A pile of wood shavings outside a hole or opening is a hint for the presence of carpenter ants. The wood shavings are coarse and insect parts and bits of insulation will be mixed among them. These shavings may also be found in spider webs and window sills close to the nest site.

The frass produced by carpenter bees is very similar to those of carpenter ants regarding color and size. It usually lacks insect fragments.

Damaged wood: The larvae of most wood-boring beetles develop for several years inside the inner portion of seasoned wood. Tunnelling is most extensive in sapwood, but it may extend into the heartwood, especially when it is partly decayed. The size and shape of feeding tunnels may be a good indication for the causing pest. However, small tunnels produced by young larvae of cerambycid beetles at an incipient decay can easily be confused with those from an old infestation by anobiid beetles. Therefore, other indices like the shape of frass pellets are needed for a final proof. The frass in the tunnels may be loosely to tightly packed and does not tend to fall out freely from the wood. Some wood-boring species only attack softwoods, like the old houseborer, others specifically infest hardwoods like most bostrichid and lyctid beetles. Some anobiid species will attack both hardwoods and softwoods. Defrassing of suspected infested timber may expose the feeding tunnels and thus ease inspection.

Unseasoned hardwood with bark or wood in damp environments like pit-shafts or seashores may be attacked by wood-boring weevils or wharf beetles (also known as wharf borers). Weevil infestation can be differentiated from those of anobiids by the bore dust and frass which are finer in texture and the individual granules being

more circular. The feeding tunnels are smaller and the exit holes are narrow oval with ragged or indistinct margins. Wharf beetles usually deposit the frass between the bark and the outer sapwood portion, which lifts and loosens the bark. The larval feeding tunnels are covered with ambrosia fungi staining the wood slightly dark. The wood surface may be covered with circular small larval entrance and larger adult emergence holes. Wharf beetles are, next to submerged marine wood degraders like shipworms and certain crustaceans (which do not belong to the insects and are therefore dealt with elsewhere), economically the most important pests in the ship-building industry.

Wood damaged by carpenter ants (*Camponotus spp.*) contains galleries that are very clean and smooth. Ants do not eat wood, but tunnel into wood to make a nest. Wood ants like *Lasius spp.* preferentially excavate the early wood layers, leaving a lamellar set of late wood untouched.

Some soil-inhabiting termites (e.g., those of the genus *Coptotermes*) decay wood from the surface (erosive decay). They coat it with wide mud galleries usually underneath and feed on the early wood. Fine lamellae of the late wood remain almost untouched. Others (e.g., of the genus *Reticulitermes*) intrude into the wood and hollow out all but a thin surface layer. Drywood termites simply excavate tunnels and chambers within the timber, which can be filled with frass. They prefer softwoods and the sapwood of hardwoods, but they have been recorded to attack heartwoods as well.

Technical devices can assist in the inspection of possible infestation sites: the use of an endoscope supplies additional information about the degree of damage; a moisture-meter is especially useful for detecting termites in their cavities.

Insects, insect parts: Occasionally, the obvious presence of adult beetles, wasps, bees or termites will be noted. As adult beetles emerge in confined structures, they often are attracted to lights or windows. Membranous insect wings in great number around windows or beneath lamps are an indication for termite activity. Insect manuals and determination keys may allow the identification of the pest. Sometimes insect fragments found in the tunnelled wood or in the frass (wings, legs, cuticle fractions) may be sufficient for identification, however, professional entomological education and good magnifying devices are required.

X-ray and infrared: Hidden infestations inside the wood or concealed parts of a building may be recorded with X-ray machines or infrared cameras. However, the use of X-ray is very limited due to the lack of safe-

to-use portable X-ray devices and the high costs of this technique when applied stationary. Infrared cameras record the heat generated by living organisms. They may be very useful to pinpoint large cryptic infestation hotspots by termites. The accuracy of the recording, however, depends on the building insulation and other potential heat sources. In most cases, cost-benefit considerations do not justify the use of the infrared technique.

Auditory Inspection. Sounds, generated by the insects' interactions with their substrate, may be a hint for an active infestation. Under certain circumstances, especially during the quiet nightly hours, auditory inspection and acoustic detection of wood-infesting insects is possible. Computer-based devices have been developed to facilitate the prospect of success [14.?, 19].

Gnawing sounds of beetle larvae: Even in the early stages of an infestation, the rasping or ticking sounds made by the larvae while boring can be heard. This sound may be detected from a distance of 1–2 meters, day and night, at infrequent intervals. The amplitude and frequency spectra of the feeding sound appear to be species specific.

Tapping sounds of adult beetles: Adult beetles of the death-watch beetle tap their heads on the wood as mating signals. The tapping noise is made by both sexes and can be heard unaided. It can be imitated tolerably well, at least to the extent of stimulating surrounding beetles to themselves start tapping.

Running termites: With the help of high-resolution contact microphones attached to the wood to be tested the sound of termites running in their tunnels may be detected.

Alarm signals of carpenter ants: An active colony may produce a dry rustling sound, similar to the crinkling of cellophane. After identifying a potential nest site, tapping against it with a screwdriver may cause a response clicking of alarmed ants. A listening device, such as a stethoscope, may be useful when conditions are quiet and outside noises are at a minimum.

Swarmers. The occurrence of swarming insects is evidence for the presence of ants or termites. Because of the consequences for possible remedial action, it is essential to know the major differences between those two insect groups. Ants, like most hymenoptera, have much larger forewings than hind wings. Termite wings all are of the same size; they break off easily. The antennae of ants are kinked, those of termites are straight. The thorax including the first abdominal segment (first abdominal

tergum) and the rest of the abdomen in ants are joined by a narrow waist, while the thorax of termites is broadly joined to the abdomen.

Swarming termites in the exterior only indicate a termite infested area and not necessarily a termite attack. If, however, the swarmers are observed flying out of the structure from around windows, doors, porch columns or other wood constructions, then there might be some concern. Indoor swarmers point to the presence of either soil-inhabiting termites underneath the structure or drywood termites, which live in the house framework or in wooden furniture. An entomologist should be consulted for identification of the pest species, because control measures are specific for the different insect groups.

Termite Dog. Specialized dogs, trained to smell the trail odors of termites, are used to detect termites in- and outside of properties. According to an investigation at the University of Florida, the success rate is up to 96% [14.20].

Sticky Traps. Sticky traps, baited with the female sex pheromone, mostly used for detecting and monitoring beetle populations, are marketed for *Anobium punctatum*. It only has limited use for mass-trapping by setting out large numbers of traps in infested areas to catch a large number of beetles and thus reduce the population. As the traps only attract males and trap attractiveness has to compete with the natural pheromone of female beetles, the number caught may be too low to prevent mating. Therefore, pheromone traps are mostly used for detecting and monitoring beetle populations only.

Control. Knowledge about the particular insect species responsible for the impact may determine the control measure. Even prior to a thorough investigation of the dwelling and probable consequent treatments, the significance of a possible infestation has to be considered. A differentiation between wood-feeding and wood-breeding insects can assist in estimating the degree of a damage.

The impact on timber by wood-breeding insects can mostly be neglected, as they only attack wood for completing their development. They are only active in green timber. Debarked wood and seasoned lumber is never infested. Prominent examples are the following:

- **Green wood beetles:** Their larvae feed in the cambium, the thin layer of plant tissue between bark and wood. They usually groove the sapwood. At

the end of their development, old larvae tunnel into the wood and pupate. The emerging beetles leave through those tubes. On the surface of plane timber the flight holes may be visible, which can be confused with those from wood-feeding species.

- **Bark beetles:** Their larvae also feed in the cambium zone of living trees, fallen trees and logs. They excavate a characteristic tunnel called a gallery usually parallel to the grain and may penetrate superficially into the sapwood. Timber is not attacked unless of a high moisture content.
- **Wood wasps:** Wood wasps, also known as horntails, are capable of penetrating solid wood, especially of debilitated, dying and freshly felled trees, in which the eggs are laid. The damage is characterized by round boreholes densely packed with frass. Emergence holes are circular in cross section and up to 8 mm in diameter.

Methods for Testing Insect Resistance

The resistance of wooden materials against insect attack can be material-specific or generated through the modification of the wooden matrix or the application of wood preservatives, namely insecticides. Several general and specific standard testing procedures are available which allow resistance data obtained in the laboratory to be transferred to field situations. Specific standards may differ for either preventive or curative measures. The test organisms used in these testing standards represent the economically most important pests. *Hylotrupes bajulus* represents a softwood-infesting cerambycid beetle, *Lyctus brunneus* an exclusively hardwood-infesting beetle, and *Anobium punctatum* an opportunist. Tests with termites are usually carried out with subterranean species like *Reticulitermes santonensis* or *Coptotermes formosanus* or others.

Specific Tests for Resistance Against Wood-Boring Beetles (Preventive Measures). The eggs of wood-boring beetles are deposited in cracks and crevices of the wood. Larvae of wood-boring beetles therefore hatch inside the wood and begin tunnelling immediately. This fact was generally taken into account when test procedures were designed. The natural resistance of wood against insect attack may also be tested applying the following standards.

- **European Standard EN 20:** Determination of the preventive action against *Lyctus brunneus* (Stephens) – Part 2: Preservatives application fully impregnated wood treatment (laboratory method).
- **European Standard EN 21:** Determination of toxic values against *Anobium punctatum* (De Geer) by larval transfer (laboratory method). This standard describes a laboratory test method which gives a basis for assessment of the effectiveness of a wood preservative against *Anobium punctatum*. It allows the determination of the concentration at which the product prevents the survival of *Anobium punctatum* larvae in impregnated wood of a susceptible species. Although an infestation normally starts from egg-laying, a larval transfer test is applicable when considering the situation of treated wood being put into contact, during repair work, with wood that might be infested.
- **European Standard EN 46:** Wood preservatives – determination of the preventive action against recently hatched larvae of *Hylotrupes bajulus* (Linnaeus) (laboratory method). This standard makes it possible to determine whether recently hatched larvae are capable of boring through the treated surface of a susceptible wood species and of surviving in the untreated part of the test specimen. For this purpose, the procedure seeks to reproduce normal egg-laying conditions existing in cracks in the wood, which provide the principal egg-laying sites. It takes account of the fact that, if larvae pass through the treated surface, they will then tunnel in the direction of the least protected regions of the wood.
- **European Standard EN 47:** Determination of the toxic values against recently hatched larvae of *Hylotrupes bajulus* (Linnaeus) (laboratory method). This standard specifies a laboratory test method which gives a basis for the general assessment of the effectiveness of a wood preservative against *Hylotrupes bajulus* by determination and comparison of the concentration at which the product prevents their survival in totally impregnated wood of a susceptible species.
- **European Standard EN 49-1:** Determination of the protective effectiveness against *Anobium punctatum* (De Geer) by egg-laying and larval survival – Part 1: Application by surface treatment (laboratory method). This part of EN 49 describes a laboratory test method which gives a basis for assessment of the effectiveness of a wood preservative, when applied as a surface treatment, against *Anobium punctatum*. It allows the determination of the concentration at which the product prevents the development of infestation from egg laying. The method simulates conditions which can occur in practice on timber which has been treated some time previously with

wood preservative applied by dip, brush or spray and on which eggs of *Anobium punctatum* are laid.

- European Standard EN 49-2: Determination of the protective effectiveness against *Anobium punctatum* (De Geer) by egg-laying and larval survival – Part 2: Application by impregnation (laboratory method). In contrast to part 1 of this standard, this method simulates conditions which can occur in practice on timber which has been treated some time previously with a deeply penetrating wood preservative and on which eggs of *Anobium punctatum* are laid.

Specific Tests for Resistance Against Wood-Boring Beetles (Curative Control Measures). When susceptible wood is infested with beetle larvae at low density, the infestation can be cured before structural damage occurs. This work requires to be done by experts only. The wood preservative is usually applied by surface application through brushing or spraying and has to penetrate deep enough for contact with tunnelling larvae.

- European Standard EN 22 (henceforth replaced by EN 1390): Determination of the eradicator action against *Hylotrupes bajulus* (Linnaeus) larvae (laboratory method). This standard describes a laboratory test method which gives a basis for assessment of the eradicator action of a wood preservative against *Hylotrupes bajulus*. It allows determination of the lethal effect of a surface application of a preservative product on a population of large larvae previously introduced into the test specimens. The method simulates conditions in practice where a stake is treated which is only slightly attacked and where insect tunnels have been exposed by cutting away. This represents a valid test of the product.
- European Standard EN 48: Determination of the eradicator action against larvae of *Anobium punctatum* (De Geer) (laboratory method). This standard describes a laboratory test method which gives a basis for assessment of the eradicator action of a wood preservative against *Anobium punctatum*. It allows the determination of the lethal effect of a surface application of the preservative on a population of larvae already established in the test specimens. The method simulates conditions which can occur in practice where a length of wood such as an affected stair tread is treated, which is still free from exit holes and in which certain of the faces are inaccessible, thus constituting valid test conditions.
- European Standard EN 370: Determination of eradicator efficacy in preventing emergence of *Anobium punctatum* (De Geer). This standard describes a laboratory test method which gives the basis for the assessment of the eradicator efficacy of a wood preservative in preventing emergence of *Anobium punctatum*. It determines the lethal effects, on beetles attempting to emerge through treated wood surfaces, of an insecticidal product deposited by surface application.

Specific Test for Resistance Against Termites. Termite control is not achievable by curative treatment of infested wood. Usually, the damage caused by termites is already too severe by the time termite-infested wood is detected. Wood preservative action against termites focuses on preventive treatment of the endangered material or the creation of biocidal or physical soil barriers. The test species may vary depending on the geographical situation.

- European Standard EN 117: Determination of toxic values against European *Reticulitermes* species (laboratory method). This standard describes a laboratory test method which gives a basis for assessment of the effectiveness of a wood preservative against *Reticulitermes* species. It allows the determination of the concentration at which the product completely prevents the attack by this insect of impregnated wood of a susceptible species.
- European Standard EN 118: Determination of preventive action against European *Reticulitermes* species (laboratory method). This standard describes a laboratory test method which gives a basis for assessment of the effectiveness of a wood preservative, when applied as a surface treatment, against *Reticulitermes* species.
- American Society for Testing and Materials ASTM D 3345: Laboratory evaluation of wood and other cellulosic materials for resistance to termites. This method covers the laboratory evaluation of treated or untreated cellulosic material for its resistance to subterranean termites. This test should be considered as a screening test, for treated material and further evaluation by field methods is required.
- American Wood-Preservers' Association Standard E1-72: Standard method for laboratory evaluation to determine resistance to subterranean termites. This method provides for the laboratory evaluation of treated or untreated cellulosic material for its resistance to subterranean termites. This test should

be considered as a screening test for treated material and further evaluation by field methods is required.

- Australian Standard 2178: Protection of buildings from subterranean termites – detection and treatment of infestation in existing buildings. This standard sets out methods for the detection and treatment of subterranean termite infestation in existing buildings and also sets out methods for the prevention of reinfestation.
- Japan Wood Preserving Association Standard 11(2): Method for testing the effectiveness of surface treatments of timber (brushing, spraying and dipping) with termiticides against termites (2) field test. This standard describes a field test method for evaluating effectiveness of surface treatments of timber such as brushing, spraying and dipping with termiticides against termites.
- Japan Wood Preserving Association Standard 12: Method for testing the effectiveness of pressure treatment of timber with termiticides against termites. This standard describes laboratory and field test methods for evaluating effectiveness of pressure treatment of timber with termiticides against termites.
- Japan Wood Preserving Association Standard 13: Method for testing the effectiveness of soil treatment with termiticides against termites. This standard describes a test method for evaluating effectiveness of soil treatment with termiticides against termites.
- Japan Wood Preserving Association Standard 14: Qualitative standards for termiticides, preservative/termiticides and soil-poisoning termiticides. This standard describes qualitative standards for termiticides, preservative/termiticides and termiticides for soil treatment.

14.3 Testing of Organic Materials

Polymeric materials (plastics) are used in all sectors of life as very durable products with tailor-made properties. They provide a combination of easy thermoforming (most plastics, if not cross-linked) and excellent use properties. For some applications, such as paints, items in the automobile industry or for use in buildings, they have to maintain their properties for a long period of time, often decades. The long-lasting exposure to environmental factors often results in a change of material properties such as roughening of the surface, embrittlement, a loss in mechanical strength or just a discoloration. It has been observed in some cases that also the presence of microorganisms such as bacteria, fungi or algae can cause or enhance changes in plastics, although most plastics are supposed to be inert to attacks of microorganisms (“they do not rot”). All these effects usually are not desired and are denoted generally as biocorrosion or as biodeterioration, if the material falls apart due to the ageing process. A number of test methods have been developed to characterize these phenomena.

However, the increasing stability of many plastics against environmental ageing in combination with the intense use of modern plastics generated serious problems with plastic waste in the last decade, especially from plastic packaging. Alternative waste management strategies to landfilling such as incineration or plastics recycling are not always optimal and the subject of very controversial discussions. On this background intensive attempts were made since the

early nineties to develop novel plastics which combine a good performance, comparable to conventional polymers, with a controlled susceptibility to microbial degradation. This new class of materials is usually called “biodegradable plastics”. Applications of these materials are, e.g., bags for collecting biowaste, packaging (disposed via composting), or mulch films in agriculture.

For these novel materials which are claimed to be environmentally friendly, it is demanded to prove their environmentally safe biodegradation using scientifically based and generally accepted methods. Concerning the parameters used for monitoring biodegradation, the testing procedures applied and the evaluation criteria for biodegradability of plastics significantly differ from testing biocorrosion phenomena of plastics. Hence, an own system of test methods and evaluations criteria is being developed for this kind of materials.

14.3.1 Biodeterioration

In contrast to the biodegradation of plastics, where a near complete conversion of the material components into naturally occurring metabolic products of microorganisms (e.g., water, carbon dioxide, methane, biomass etc.) occurs (see later), for biocorrosion or biodeterioration processes only a change in the polymer structure or the plastics composition is observed in many cases [14.21].

General Mechanism of Biodeterioration

Since usually mechanical properties of plastics are predominantly determined by the length of the polymer chains in the material, scission of polymer chains (reduction of the average molar mass) is one major reason for changes in mechanical properties. This effect is especially dramatic if the cleavage of the polymers occurs statistically along the chains (endo-degradation) and not at the ends (exo-degradation). Even just a single endo-cleavage in a polymer chain can reduce the molar mass to 50%, and hence cause significant changes in mechanical properties.

Embrittlement (= loss in elasticity), however, can also occur when plasticizers are removed from the plastic materials by microorganisms. Especially for polyvinylchlorides (PVC), which in some cases contain high amounts of plasticizers (e.g., low-molecular-weight esters), biocorrosion due to this phenomenon has been reported in earlier times [14.22–24]. A similar effect is observed in polymer blends or (block)-copolymers when single components are selectively degraded by microorganisms. An example for this mechanisms of biodeterioration are mixtures of (unmodified) polyethylene and starch. Here the starch basically can be metabolized by microorganisms, leading to a weakening of the entire material and finally result in fragmentation [14.25].

If the attack of microorganisms only concerns side groups attached to the polymer main chains, this usually results in a change of the chemical characteristic and hence, in the material properties. The cleavage of ester bonds in side chains of cellulose esters (e.g., cellulose acetate) results in the formation of charged chemical groups (at suitable pH values) increasing the

hydrophilicity of the material (this can be followed by an increased water uptake and swelling of the material). If a sufficiently high amount of esters has been transformed into hydroxyl groups the entire material can become accessible to direct microbial attack [14.26, 27]. Similar effects can be caused by oxidation phenomena, where new polar carbonyl and carboxyl groups are formed in the polymer (or at the surface of the polymer).

Coloring of plastics can be caused due to the formation of new chromophoric chemical groups, but also the release of pigments from microorganisms can cause changes in the color of plastic materials.

Strictly speaking, real biodegradation involves the direct action of enzymes (biocatalysts) on the plastic material itself. The hydrolysis of ester bonds in polyesters by hydrolases is such a case [14.28–30]. However, in biodeterioration processes microorganisms mostly indirectly contribute to changes in the plastic materials. During microbially induced oxidative degradation of plastics (in nature, for instance present in degradation of lignin or latex [14.31]), the oxidative enzymes do not directly act on the polymers, but produce low-molecular-weight oxygen compounds which diffuse into the polymer material and there cause chemical reactions. Microorganisms can also indirectly induce hydrolytic degradation processes by changing the pH in a microenvironment at the surface of the material (e.g. in biofilms, see below) or through the excretion, e.g., of organic acids such as lactic acid or acetic acid as products of their metabolism.

In real environments, however, corrosion phenomena of plastics are often a mixture of physical, chemical and biological processes. Chemical hydrolysis caused by water which has been diffused into the polymer and oxidation induced by light (photo-oxidation) or by increased temperatures (“thermal oxidation”) in many cases play an important role during biocorrosion and biodeterioration. In fact, the expression “environmental corrosion” would be an expression, better meeting the point than “biocorrosion”.

The mechanism and the impact on the plastics differ basically between chemical or physical processes and the direct action of enzymes on the polymer. While water and oxygen are small molecules which are in principle able to penetrate into the entire plastic material, enzymes are too large to diffuse into the polymer bulk, and thus, can only act at the surface, causing a typical erosion process, where the material is affected layer by layer from the surface. This is illustrated in Fig. 14.7 for the chemical (bulk degradation) and enzymatic hydrolysis (surface erosion) of e.g. a polyester.

Fig. 14.7a,b Influence of surface erosion (a) and bulkdegradation (b) on the material properties of plastics

While for the enzymatic action only a small part of the material at the surface “knows” about the degradation which proceeds slowly from the surface, chemical hydrolysis caused from water contained in the plastics, affects the entire material right from the beginning. As a consequence, changes in mechanical properties and mass loss due to degradation run in parallel for the enzymatic degradation. In contrast, chemical hydrolysis causes chain scissions in all polymer chains simultaneously, resulting in an instant decrease in mechanical strength, while a mass loss of the material is only observable at a later stage of degradation, where polymer chains become so short to be water soluble.

Biofilms

One important phenomenon in correlation with biodeterioration and biocorrosion is the forming of biofilms on material surfaces, also known as biofouling [14.21]. Formation of biofilms is not only restricted to polymer materials, but also plays a central role in corrosion of, e.g., concrete, stones (buildings) and metals. Such biofilms consist of a combination of various microorganisms which is highly complex and variable in time and includes the microorganisms themselves and additionally a number of extracellular polymeric substances, e.g., polysaccharides. Biofilms represent an own microenvironment at the surface of the materials providing optimal living conditions (humidity, pH, nutrient concentrations) for the microorganisms inhabiting the biofilm and protecting them from external attacks, e.g., from other bacteria or fungi, and also to a certain extent from biocides.

In biofilms the concentration of polymer-degrading enzymes, but also, e.g., of oxidating agents formed by the microorganisms can substantially be higher than in a liquid environment, where such substances can diffuse away from the surface. Also concerning the pH value, biofilms can present totally different conditions to the material surface than be measured in the liquid environment. Thus, the presence of such biofilms on polymer surfaces can substantially influence biodeterioration phenomena of plastics.

Standards for Evaluation of Biodeterioration

As mentioned above biodeterioration is usually a very complex process, involving the direct or indirect action of diverse microorganisms forming often a biofilm on the material surfaces and also including in many cases nonbiotic actions such as irradiation or thermal oxidation. As a consequence, the corresponding standard procedures for testing biodeterioration and biocorrosion

phenomena of plastics are correlated to different topics. On the one hand, a number of materials different from plastics such as steel, concrete, textiles or paints are covered, on the other hand, also nonbiotic factors (light, heat, oxygen, moisture, chemicals) are regarded in such tests exclusively or in combination with biotic influences. Thus, only a limited number of tests strictly deal with “pure” biocorrosion or biodeterioration mechanisms of plastics. Those tests, only focussing on biotic effects usually use a number of defined test organisms (Table 14.3). However, in many cases simulation or field tests are used which combine the action of biotic and nonbiotic factors. These standards often are correlated with the expression “weathering” – a selection of such standards is also included in Table 14.3.

14.3.2 Biodegradation

At the beginning of the nineties a novel group of polymers were developed which were intended to be degradable by microorganisms in a controlled manner, but at the time were no adequate methods and criteria available to evaluate the property of biodegradability. First tests carried out at that time (e.g., by using the growth of microorganisms on the surface or a certain loss in mechanical properties such as the tensile strength as indicators for biodegradation) originated from the field of plastics biocorrosion and biodeterioration (see above). However, these evaluation methods proved to be unsuitable to characterize biodegradable materials. A first generation of modified polyethylenes, claimed to be biodegradable based on these tests, did not meet the expectations of the users and caused to some extent a general negative image of biodegradable plastics at the time. As a consequence, the development of suitable testing methods and evaluation criteria for biodegradable plastics started and resulted in a number of standards of various national and international standardization agencies during the past 15 years. This process still continues, since the number of different environments, where plastics can be degraded, make it necessary to establish a quite complex and extended system of testing methods and evaluation criteria for biodegradable plastics.

General Mechanism of Biodegradation

When talking about biodegradation of plastics usually one is referring to the attack of microorganisms on water-insoluble polymer-based materials (plastics). Because of the lack of water-solubility and the length of the polymer molecules, microorganisms are not able to transport the

Table 14.3 Standard test methods for biocorrosion phenomena on plastics

Action of microorganisms on plastics	
ISO 846 – 1997	Plastics – Determination of behaviour under the action of fungi and bacteria. Evaluation by visual examination or measurement of changes in mass or physical properties
ISO 16869 – 2001	Plastics – Assessment of the effectiveness of fungistatic compounds in plastics formulations
EN ISO 846 – 1997	Plastics – Evaluation of the action of microorganisms
ASTM G21-96	Standard practice for determining resistance of synthetic polymer materials to fungi
ASTM G29-96	Standard practice for determining algal resistance of plastic films
DIN IEC 60068-2-10 – 1991	Elektrotechnik; Grundlegende Umweltprüfverfahren; Prüfung J und Leitfaden: Schimmelwachstum; (Identical with IEC 60068-2-10:1988)
IEC 60068-2-10 – 1988	Elektrotechnik; Grundlegende Umweltprüfverfahren; Prüfung J: Schimmelwachstum
Weathering of polymers	
ISO 877:1994	Plastics – Methods of exposure to direct weathering, to weathering using glass-filtered daylight, and to intensified weathering by daylight using Fresnel mirrors.
ISO/AWI 877-1	Plastics – Methods of weathering exposure – Part 1: Direct exposure and exposure to glass-filtered daylight.
ISO/AWI 877-2	Plastics – Methods of weathering exposure – Part 2: Exposure to concentrated solar radiation
ISO 2810:2004	Paints and varnishes – Natural weathering of coatings – Exposure and assessment
ISO 4582:1998	Plastics – Determination of changes in color and variations in properties after exposure to daylight under glass, natural weathering or laboratory light sources
ISO 4665:1998	Rubber, vulcanized and thermoplastic – Resistance to weathering
ASTM D1435-99	Standard practice for outdoor weathering of plastics
ASTM D4364-02	Standard practice for performing outdoor accelerated weathering tests of plastics using concentrated sunlight

polymers directly through their outer cell membranes into the cells where most of the biochemical processes take place. To be able to use such materials as a carbon and energy source, microorganisms have developed a special strategy. The microbes excrete extracellular enzymes which depolymerize the polymers outside the cells. This means that biodegradation of plastics in its first step is usually a heterogeneous process.

If the molar mass of the polymers has been sufficiently reduced and water-soluble intermediates have been generated, these small molecules can be transported into the microorganisms and introduced there into the metabolic pathways. As a final result new biomass and natural metabolic end-products such as water, carbon dioxide and methane (for degradation processes in the absence of oxygen = anaerobic degradation) are formed.

The excreted extracellular enzymes usually have a molar mass of some ten-thousand Daltons and hence, are to large to penetrate deeper into the polymer material. In consequence, the enzymes only can act on the polymer surface of the plastics and erodes the material layer by layer – biodegradation of plastics is usually a surface erosion process, only affecting a relative small fraction of the entire polymer material at one time. In many cases the enzymatic catalyzed chain length reduc-

tion of the polymers is the process in biodegradation determining the rate of the entire process.

In parallel to the enzymatic attack, nonbiotic chemical and physical processes such as oxidation, irradiation (photodegradation), thermal degradation or chemical hydrolysis can affect the polymer and contribute to the degradation process. In some cases an abiotic degradation mechanism is exclusively responsible for the first step of molar mass reduction.

Some materials, claimed to be biodegradable, directly used such effects to induce the biodegradation process. For instance, poly(lactic acid) is at first hydrolyzed into oligomeric esters by an autocatalytic chemical hydrolysis or sunlight in combination with heat then generates in pro-oxidant-modified polyethylene short hydrophilic intermediates which are considered to be assimilated by microorganisms. Because of the coexistence of biotic and nonbiotic processes in many cases the entire mechanism of polymer degradation could also be called an environmental degradation. Both, biotic and abiotic processes have to be considered in tests evaluating biodegradation of polymers.

Environmental factors do not only influence the plastics themselves, but have also a crucial impact on the microbial population and on the activity of the different microorganisms involved in the polymer degradation.

Parameters such as humidity, temperature, pH, concentration of salts, the presence or absence of oxygen and the supply with different nutrients have an important effect on the microbial degradation of polymers and must be adequately considered when testing the biodegradability of plastics.

A further complicating factor when dealing with biodegradation of plastics is the complexity of plastic materials with regard to their possible compositions, structures and morphologies (Fig. 14.8).

Different monomers can be combined in one polymer chain, where these elements can be distributed statistically along the polymer chains (random copolymers), strictly alternate (alternating copolyesters) or build longer blocks of each structure (block copolymers). Different polymers can be mixed physically in the melt or solution forming polymer blends. Depending on the chemical structure of the components and the formation process, mixtures of different characteristics can be formed (e.g., homogeneous mixtures for miscible polymers, small domains of component A in a continuous phase of component B or penetrating networks of both components). Furthermore, in many cases low-molecular-weight additives (e.g., plasticizer, antiblock agents, nucleation agents) are added to a polymer to adjust properties such as flexibility or processibility.

Different structures, even with the same overall composition of a polymer, can directly influence the accessibility of the material to the enzymatically catalyzed polymer chain cleavage significantly. Another important structural characteristics of polymers are their average

molar mass, their molar mass distribution and possible branching of the chains or the presence of networks (crosslinked polymers).

The structural characteristics of the polymer have a crucial impact on higher ordered structures of the material (crystallinity, crystal morphology, melting temperature or glass transition temperature) which in some cases have been shown to control predominately the degradation behavior of many polymers [14.29, 30]. Finally, the crystallinity and crystal morphology depends on the processing conditions and can change with storage time of the material.

All these factors described above have to be taken into account when measuring biodegradation of plastics and interpreting the results. This makes testing of biodegradable plastics a typical interdisciplinary work. General statements such as “polymer xyz is biodegradable” can not be made since the specific properties of the polymer have to be taken into account. Thus, a detailed description and identification of a material to be tested must be a basic prerequisite for any testing protocol.

Definitions

Standardized evaluations of biodegradable plastics must always be based on definitions as to the meaning of the term biodegradation with regard to plastics. The various national and international standardization agencies and organizations have published a number of different definitions (Table 14.4) which vary significantly. While the definition for “biodegradable plastics” established by the ISO only refers to a chemical change of the material

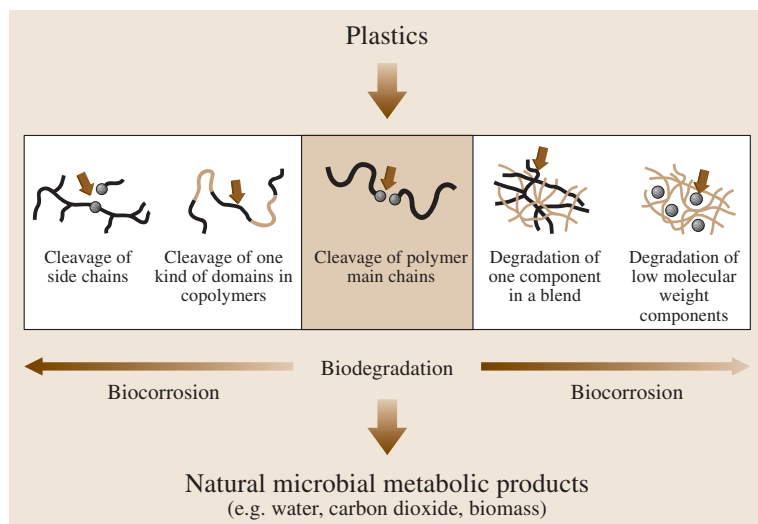

Fig. 14.8 Biodegradation- and biocorrosion phenomena in plastics

Table 14.4 Biodegradation and biodegradable plastics – Definitions established by different standardisation organisations

Definitions of “Biodegradation”	
DIN	Biodegradation is a process, caused by biological activity, which leads under change of the chemical structure to naturally occurring metabolic products.
CEN	Biodegradation is a degradation caused by biological activity, especially by enzymatic action, leading to a significant change in the chemical structure of a material.
Definitions of “Biodegradable plastics”	
DIN	A plastic material is called biodegradable if all its organic compounds undergo a complete biodegradation process. Environmental conditions and rates of biodegradation are to be determined by standardized test methods.
ASTM	A degradable plastic in which the degradation results from the action of naturally occurring microorganisms such as bacteria, fungi and algae.
JBPS	Polymeric materials which are changed into lower molecular weight compounds where at least one step in the degradation process is through metabolism in the presence of naturally occurring organisms.
CEN	A degradable material in which the degradation results from the action of microorganisms and ultimately the material is converted to water, carbon dioxide and/or methane and a new cell biomass.
ISO	A plastic designed to undergo a significant change in its chemical structure under specific environmental conditions resulting in a loss of some properties that may vary as measured by standard test methods appropriate to the plastic and the application in a period of time that determines its classification. The change in the chemical structure results from the action of naturally occurring microorganisms.
Definition of “Inherent biodegradability”	
CEN	The potential of a material to be biodegraded, established under laboratory conditions
Definition of “Ultimate biodegradability”	
CEN	The breakdown of an organic chemical compound by microorganisms in the presence of oxygen to biodegradability carbon dioxide, water and mineral salts of any other elements present (mineralization) and new biomass or in the absence of oxygen to carbon dioxide, methane, mineral salts and new biomass.
Definition of “Compostability”	
CEN	Compostability is a property of a packaging to be biodegraded in a composting process. To claim compostability it must have been demonstrated that a packaging can be biodegraded in a composting system as can be shown by standard methods. The end product must meet the relevant compost quality criteria.

(e.g. oxidation) by microorganisms, the European Standardisation Organisation CEN and the German DIN, in contrast, consider biodegradation of plastics as a final conversion of the material into microbial metabolic products. Other definitions listed in Table 14.4, such as “inherent biodegradability” or “ultimate biodegradability”, are adapted from according considerations for the degradation of low-molecular-weight chemicals, but can also be applied for polymers. Generally, the definitions do not specify any particular environment nor time frames; these are defined in corresponding standards specifying different degradation environments and processes.

Additional definitions have been set up for plastics classified as “compostable”. In the definition of “compostability” biodegradation of the polymeric material is only one requirement and further demands such as a sufficient compost quality after the composting process with plastics are included in the definition.

However, despite of the quite inconsistent definitions the different standards and evaluation schemes are surprisingly congruent.

General Test Methods
for Biodegradable Plastics

The evaluation of the degradability of chemicals in the environment has become important as one crucial aspect of their ecological impact. First regulations and according test methods were established for products reaching the wastewater and for pesticides. In this respect a large number of standardized tests have been developed for different environments applying different analytical methods [14.32]. Nowadays, the evaluation of biodegradability, as one aspect of an environmental risk assessment, has become a standard procedure for any new chemical product intended to be marketed. However, testing methods developed for this purpose do not consider the special features (see above) of plastics materials.

Testing methods focussed on the effect of microorganisms on polymers already existed long time before biodegradable plastics started to be developed. It had been shown that conventional plastics, although they are quite resistant to environmental influences, can be attacked in some cases by microorganisms, causing

undesired changes in their material properties, e.g. in the color or in mechanical properties such as flexibility or mechanical strength and according tests were developed [14.33, 34]. However, for these biocorrosion phenomena a generally different question underlies the corresponding test compared to the process of real biodegradation (as e.g. defined in CEN definitions listed in Table 14.4). While biocorrosion tests aim to characterize changes in the material properties (which can even be caused by minor chemical changes in the polymers such as extraction of plasticizer or oxidation, etc.), biodegradation tests for plastics have to prove that the plastic material is finally transformed into natural biological products.

Despite the large number of standardized degradation tests it turned out to be necessary to develop special testing methods when dealing with biodegradable plastics.

The testing methods published for biodegradable plastics during the last decade [14.35] are predominantly based on principles used for the evaluation of low-molecular-weight substances, but have been modified with respect to the particular environments that biodegradable plastics are exposed to and with respect to the fact that plastics are often complex materials and degrade mainly by a complicated surface mechanism.

The Dilemma in Choosing the Right Degradation Test

When testing degradation phenomena of plastics in the environment one has to face a general problem concerning the kind of tests applied and the conclusions which can be drawn. In principle the degradation tests can be

classified into three categories: field tests, simulation tests and laboratory tests (Fig. 14.9).

Field tests such as burying plastic samples in soil, to place samples in a lake or river, or full-scale composting performed with the biodegradable plastics represent ideal practical environmental conditions, but there are some serious disadvantages of such kinds of tests. One is that environmental conditions such as temperature, pH, or humidity, can not be efficiently controlled in nature and secondly, analytical methods for monitoring the degradation process are very limited. In most cases it is only possible to evaluate visible changes of the polymer samples or to determine the disintegration by measuring the weight loss, and even that may not be feasible if the materials disintegrate into small fragments which have to be quantitatively recovered from the soil, the compost or the water. Analysis of residues and intermediates is complicated due to the complex and undefined environment. Since a pure physical disintegration of a plastic material is not regarded as biodegradation in the sense of most definitions (see above), these tests alone are not suitable to prove whether a material is biodegradable or not.

To overcome these problems at least partially, various laboratory simulation tests have been developed. Here, the degradation takes place in a real environment (e.g. compost, soil or sea water), but the exposure to the environment is performed in a laboratory reactor. This environment is still very close to reality, but important external parameters which can affect the degradation process (e.g. temperature, pH, humidity, etc.) can here be controlled and adjusted, and analytical tools are better than in field tests (analysis of residues and intermediates, determination of CO₂ production or O₂ consumption).

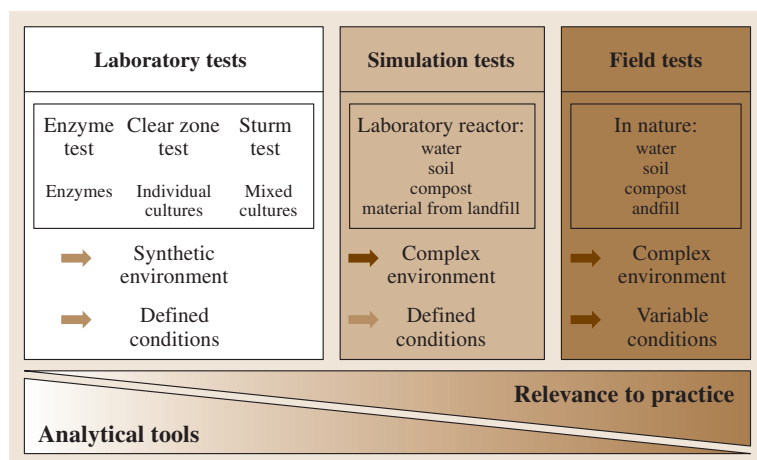

Fig. 14.9 Classification of test methods for biodegradable plastics

Examples for such tests are the soil burial test [14.36], the so-called controlled composting test [14.37–41], test simulating landfills [14.42–44], or aqueous “aquarium tests” [14.45]. To increase the microbial activity, nutrients are sometimes added in these tests with the aim to accelerate degradation and to reduce the duration of the degradation tests.

The most reproducible biodegradation tests are laboratory tests, where defined (often synthetic) media are used which then are inoculated with a mixed microbial population (e.g., from waste water or compost eluate). In some cases individual microbial strains or mixtures of some strains are used for inoculation. The organisms sometimes have been especially screened for the degradation of the particular polymer. Such tests often take place under conditions optimized for the activity of the particular microorganisms (e.g. temperature, pH etc.) with the effect, that polymers often exhibit a much higher degradation rate in laboratory tests than observed under natural conditions.

The most reproducible degradation tests directly use the isolated extracellular enzymes of the microorganisms which are responsible for the first step of the degradation process, the molar mass reduction of the polymers by depolymerization [14.28–30, 46, 47]. Also with this system it is not possible to prove biodegradation in terms of metabolization by microorganisms.

However, the shorter test durations and the reproducible test conditions make laboratory tests especially useful for systematic investigation when studying basic mechanisms of polymer biodegradation. However, conclusions on the absolute degradation rate in a natural environment can only be drawn to a limited extent.

Besides reproducibility, the shortening of test durations and minimization of the material needed is a crucial point when performing extended systematic investigations or for biodegradation testing as a tool for supporting the development of an industrial material. While degradation experiments in compost or soil often take up to one year, tests with especially screened organisms may only require several weeks and enzymatic degradation can be performed even within a few hours or days. Recent reports applying polymer nanoparticles (increased surface area) indicate that enzymatic degradation tests with polyesters can be performed within seconds [14.48, 49].

As a consequence of the principle discrepancy between the analytical tools applicable in the different tests and the relevance of the test to practical degradation conditions, it will be in most cases necessary to combine

different tests to completely evaluate the biodegradation behavior of a plastic in a certain environment.

Analytical Methods to Monitor Biodegradation

The analytical tools used to follow the degradation process depend on the aim of the work and the test environment used. In the following, some analytical methods are presented.

Visual Observations. The observation of visible changes of plastics can be performed in many tests. Effects which were used to describe degradation are, e.g., the formation of biofilms on the surface, changes in the material color, roughening of the surface, formation of holes or cracks or the occurrence of defragmentation. As already mentioned, these changes do not prove a biodegradation process in terms of conversion of the polymer mass into biomass and natural metabolic products (see definitions), but the parameter of visual changes can be used as a first indication of a microbial attack. More detailed information on the degradation process can be obtained from SEM- or AFM-techniques [14.50]. An example is presented in Fig. 14.10, showing SEM micrographs of a surface of a poly(β -hydroxy butyrate) (PHB) film before and after incubation in an anaerobic environment [14.51]. In the course of the degradation crystalline spherulites appear on the surface. This is caused by a preferential degradation of the amorphous polymer fraction, etching the slower degrading crystalline parts out of the material.

Especially recent developments of the AFM technique allow very detailed investigations on the degradation mechanism of polymers [14.52].

Changes in Polymer Chain Length and Mechanical Properties. Comparable to visual observations changes in material properties do not allow an evaluation of polymer degradation, since these measurements do not directly prove the metabolization of the plastic material. However, changes in mechanical properties are often used when only small effects on the material due to the degradation process have to be monitored. Properties such as tensile strength are very sensitive to changes in the molar mass of the polymers which is also often directly taken as an indicator for degradation [14.53]. While for an enzymatic attack at the surface, material properties only change if a significant loss of mass is observed (the specimen become thinner because of the surface erosion process; the inner part of the material is not affected by the degradation process) the situation is usually opposite for abiotic degradation processes. They

Fig. 14.10a,b Scanning electron micrographs of poly(β -hydroxybutyrate) films before (a) and after (b) incubation in an anaerobic sewage sludge. Amorphous material is degraded preferentially and spherulites of crystalline regions become visible

often take place throughout the entire material (e.g., hydrolysis of polyester or oxidation of polyethylene) and the mechanical properties of the plastics already change significantly before a loss of mass due to solubilization of degradation intermediates is observed (Fig. 14.4).

Accordingly, this kind of measurement is often used for materials where abiotic processes are responsible for the first degradation step, e.g., for the chemical hydrolysis of poly(lactic acid) or oxidation of modified polyethylenes [14.54, 55].

Weight Loss Measurements/Determination of Residual Polymer. Measuring the mass loss of test specimen (films, test bars or whole items) is often applied, especially in field- and simulation tests. However, again no direct proof of biodegradation is possible from these data. Problems can arise with proper cleaning of the specimen or when the material strongly disintegrates. In the latter case the samples can be placed in small nets to facilitate recovery, a method which is for instance applied in the full-scale composting procedure of ISO 16929. A sieving analysis of the matrix surrounding the plastic samples allows for a better and more reproducible quantitative determination of the disintegration process.

The degradation of finely distributed polymer samples (e.g. powder) can be determined by an adequate separation or extraction technique (polymer separated from biomass or polymer extracted from soil or com-

post). This procedure always has to be carefully adapted and verified for each specific system. Together with a structural analysis of the residual material and low-molecular intermediates a detailed insight into the degradation process can be gained [14.56].

Determination of CO_2 Production and O_2 Consumption. Under aerobic conditions microbes use oxygen to oxidize carbon and form carbon dioxide as one major metabolic end-product. The determination of the oxygen consumption (respirometric test) [14.45, 57] or of the carbon dioxide formation (so-called “Sturm-test”) are good indicators for polymer degradation and the most often used methods to monitor biodegradation processes in laboratory tests. In laboratory tests using synthetic mineral media, the polymer represents the major source of carbon in the system, and only a low background respiration has to be faced. Accordingly, the accuracy of the tests is usually good. Such kinds of tests already have been used to evaluate the degradability of low-molecular-weight chemicals in water (e.g., in OECD guidelines) and now have been modified for biodegradable plastics to take into consideration the special characteristics of usually hydrophobic, non-water-soluble materials. Also, more sophisticated experimental methods for the determination of CO_2 have been introduced to the standards. Beside the conventional entrapping of CO_2 in $\text{Ba}(\text{OH})_2$ -solution in combination with manual titration, the detection of O_2

and CO₂ concentrations in the air stream for aeration with infrared detectors and paramagnetic O₂-detectors are often used for such experiments.

However, besides of the advantage of an automated and continuous measurement, this kind of measurements harbor also some disadvantages. The exact air flow must be known and the signals of the detectors must be stable for weeks and month. If slow degradation processes have to be monitored, the CO₂-concentration or the drop in the O₂-concentration is very low, increasing the possibility of systematic errors during such long-lasting experiments. Here, entrapping CO₂ in a basic solution (approx. pH 11.5) with continuous titration or detection of the dissolved inorganic carbon [14.58] are useful alternatives. Other attempts to solve the problems with CO₂ detection use noncontinuously aerated, closed systems. Sampling techniques of the gas in combination with an infrared gas-analyzer [14.59] or a titration system [14.60] have been reported in the literature. An additional closed system with a discontinuous titration method has been described by *Solaro* et al. [14.61]. Tests using small closed bottles as degradation reactors and analyzing the CO₂ in the head space [14.62] or by the decrease in dissolved oxygen (so-called “closed bottle test”) [14.63] are simple and quite insensitive to leakage etc., but may cause problems due to the merely low amounts of material and inoculum which can be used.

The method of CO₂-determination to monitor polymer degradation was also adapted to tests in solid matrices such as compost [14.37]. Such methods are now standardized under the name “controlled composting test” (ASTM D 5338-98e1, ISO 14855, JIS K 6953). Actually the “controlled composting test” does not simulate a composting process, since in this test mature compost is used instead of fresh biowaste as a matrix. Biowaste contains large amounts of easily degradable carbon and, hence, would cause a high background CO₂-development, too high for an accurate measurement. Thus, already converted biowaste (= mature compost) is used instead of fresh biomaterials.

Monitoring polymer degradation in soil via carbon dioxide detection turned out to be more complicated than in compost. The usually significantly slower degradation rates causing on the one side very long test durations (up to two years) and a quite low CO₂ evolution compared to the background CO₂ formation in soil. Recent test developments in this area have been published by *Solaro* et al. [14.61]. Despite of the problems mentioned above, standardized methods for testing plastics degradation in soil are currently under development (ISO/PRF 17556).

In order to avoid problems with a high background CO₂ formation from the natural matrices of compost or soil, an inert, carbon-free and porous matrix has been used instead of soil or compost. The inert matrix is then wetted with a synthetic medium and inoculated with a mixed microbial population. This method turned out to be practical for simulating compost conditions (degradation at approx. 60 °C) [14.64, 65] but could not be optimized sufficiently for soil conditions up to now.

Measurement of Biogas. Analogous to the formation of CO₂ in the presence of oxygen by aerobic organisms, anaerobic microorganisms produce predominantly a mixture of carbon dioxide and methane (called “biogas”) as the major end-product of their metabolic reactions. The amount and the composition of the biogas can be theoretically calculated from the material composition with the so-called *Buswell* equation [14.66]. The biogas production is mainly used for monitoring biodegradation of plastics under anaerobic conditions [14.67–70] and also standards dealing with the anaerobic biodegradation of plastics are based on such measurements (ISO/DIS 15985, ASTM D 5210, ASTM D 5511). The biogas volume can easily be determined by a manometer method or a simple replacement of water. Additionally, the biogas composition can be analyzed, e.g., by sampling the produced gas and analysis by gas chromatography [14.71].

As discussed for the carbon dioxide evolution, the basic problem is biogas formation from the inoculum. Especially for slow degradation processes this problem affects the accuracy of the testing method. Attempts to reduce the background biogas evolution were made by *Abou-Zeid* [14.67] diluting the anaerobic sludges with a synthetic mineral medium.

¹⁴C-labeling. Applying biodegradable polymers which are radio-labelled with ¹⁴C can avoid many of the problems mentioned above. Already very low concentrations of ¹⁴CO₂ can be detected even if carbon dioxide from other carbon sources (e.g., biowaste) is produced simultaneously. Thus, radio-labelling is used especially when slowly degradable materials are investigated in a matrix containing other carbon sources than the plastics [14.72, 73]. However, in many cases there is a problem with producing the ¹⁴C-labelled materials and carrying out work with radioactive substances from the experimental point of view.

Clear-Zone Formation. The so-called “Clear-Zone test” is a very simple semi-quantitative method. In this test

the polymer is dispersed as very fine particles in a synthetic medium agar, resulting in a opaque appearance of this agar. When inoculated with microorganisms able to degrade the polymer the formation of a clear halo around the colony (Fig. 14.11) indicates that the organisms are at least able to depolymerize the polymer, which is the first step of biodegradation. The test is often used for screening of organisms which can degrade a certain polymer [14.67,74] but also semiquantitative results can be obtained by analyzing the growth of the clear zones' diameters [14.75].

Other Methods. Some other analytical methods for monitoring biodegradation processes, especially in degradation experiments with depolymerizing enzymes have been described in the literature:

- Analysis of the amount of dissolved organic carbon (DOC) in the medium around the plastics [14.76].
- Monitoring the decrease in optical density of small polymer particles dispersed in water [14.77].
- Analysis of decrease in particle size of small polymer particles using light-scattering [14.48].
- Determination of the free acids formed in enzymatic polyester cleavage applying a pH-stat-titration [14.29,46,49].

Standards for Biodegradable Plastics

At the beginning of the nineties demands were stated namely by the industry to establish suitable and reliable standardized testing procedures to evaluate the biodegradability of plastics. Most of the new standards developed were based on existing tests for the biodegradation of low-molecular-weight chemicals. An overview of standard test methods for biodegradable plastics is given in Table 14.5.

First standards, mainly focused on water- and landfill environments, were published by the ASTM. A test system to evaluate the compostability of plastics was first developed by the German DIN (DIN V 54900). This standard did not only specify testing procedures, but defined also limit values for the evaluation. Other international standards from ISO, CEN and ASTM generally followed the testing strategy given by DIN V 54900, which has meanwhile been substituted by the according European standard (EN 13432).

Currently, the development of standards is focussed on degradation in soil, since there is a great interest for applications of biodegradable plastics in agriculture, e.g., as non-recoverable mulching films or as matrices

Fig. 14.11 Clear-zone-test: Fine dispersed polymer (β -hydroxybutyrate) in an microbiological agar plate results in a turbid occurrence of the agar. Microorganisms growing on the agar form clear halos ("zones") if they are able to depolymerize the polymer

for controlled release of nutrients or pesticides etc. Compared to degradation in a compost environment, tests to evaluate degradation in a soil environment proved to be much more complex (e.g., due to different soils or wide variations in external conditions).

In the following, standardization agencies are listed which are involved in the development of standards for biodegradable plastics:

International:	ISO TC61/C5/WG22 "Biodegradability"
Europe:	CEN TC 261/SC4/WG2 "Biodegradability and organic recovery of packaging and packaging waste"
	CEN TC249/WG9 "Characterization of degradability"
National:	
France:	AFNOR
Germany:	DIN FNK 103.3 "Bioabbaubare Kunststoffe" (This group has been liquidated in 2002)
Italy:	UNI
Japan:	MITI/JIS
USA:	ASTM D20.96 "Environmentally degradable plastics"

A number of reviews dealing with standard testing methods for biodegradable plastics have been published during the last years [14.35,78–80]. For some particular

ASTM D 5512-96	Standard practice for exposing plastics to a simulated compost environment using an externally heated reactor.
ASTM D 6002-96	Guide to access the compostability of environmentally degradable plastics.
ASTM D 6400-99e1	Standard specification for compostable plastics.
UNI 10785-1999	Compostilata del materiali plastici – Requisiti e metodi di prova
Polyethylene degradation and photodegradation	
ASTM D 3826-98	Standard practice for determining end point in degradable polyethylene and polypropylene using a tensile test.
ASTM D 5071-99	Standard practice for operating xenon arc-type exposure apparatus with water and exposure of photo degradable plastics.
ASTM D 5208-01	Standard practice for operating fluorescent ultraviolet and condensation apparatus for exposure of photo degradable plastics.
ASTM D 5272-99	Standard practice for outdoor exposure testing of photo degradable plastics.
ASTM D 5510-94(2001)	Standard practice for heat ageing of oxidatively degradable plastics
Other tests	
ASTM D 5951-96(2002)	Standard practice for preparing residual solids obtained after biodegradability methods for toxicity and compost quality testing.
ASTM D 6003-96	Standard test method for determining weight loss from plastic materials exposed to simulated municipal solid waste (MSW) aerobic compost environment.

environments standards for biodegradable plastics will be discussed more in detail in the following:

Compostability of Plastics. The treatment of biodegradable plastics in composting processes is discussed as an alternative to plastics recycling or incineration. A number of standards for the evaluation of the compostability of plastics have been published, which all are, in major respects, congruent (ASTM D 6002-96/ASTM D 6400 99e1, EN 13432 2000); an international norm (ISO CD 15986) is currently under development. Generally, demands for compostability exceed those for biodegradability; compostability usually comprises four demands [14.81]:

- The organic fraction of the material must be completely biodegradable;
- The material must disintegrate sufficiently during the composting process;
- The composting process should not negatively be affected by the addition of the plastics;
- The compost quality should not be negatively influenced and no toxic effects should occur.

Taking account of this spectrum of criteria and the principle problems in testing biodegradability in complex (natural) environments discussed above, all test schemes follow for a successive, multi-step evaluation strategy:

1. Chemical characterization of the test material
These data serve for the identification of the ma-

terial, provide important data for the following tests (e.g., carbon content, composition, content on inorganic components etc.) and especially give information on toxic substances such as heavy metals.

2. Evaluation of biodegradability

The biodegradability is evaluated by laboratory testing methods monitoring the metabolization of the material by CO₂ formation or O₂ consumption. Two test methods use synthetic aqueous media (ISO 14851, ISO 14852) and allow to establish a carbon balance (besides carbon dioxide, newly built biomass is regarded as “degraded” carbon). The preferred testing method, however, is the so-called controlled composting test [14.37,40,41,82,83] with mature compost at a temperature of around 60 °C as matrix. The relevance of aquatic tests in a test scheme pertaining to a compost environment has been discussed critically [14.84]. However, disadvantages of the controlled composting test are the relatively high background CO₂ formation, which can be affected by the presence of plastics (“priming effect”) and difficulties in determining a carbon balance with sufficient accuracy. To overcome these problems, the biodegradation is calculated relative to the CO₂-release of a degradable reference substance (e.g. cellulose) or an inert solid matrix inoculated with an eluate from compost is used instead of mature compost [14.64,65].

In the test schemes, also limit values are given for the evaluation [14.85]. The maximum test duration is

usually 6 month (1 year for radio-labelled materials in ASTM D6400) and the degrees of degradation requested are 60% and 90% relative to the reference. The value of 60% CO₂ formation originates from the OECD guidelines which were developed for low-molecular, chemically homogeneous materials. The figure takes into account that a part of the carbon is converted to biomass. Plastics, however, are complex in their composition (blends, copolymers, additives) and, thus, the limit value of 90% had been set to ensure a complete degradability of the entire material (a 10% error range was assumed for the degradation tests). In aqueous media this limit usually can only be achieved including the biomass formed (carbon balance). In mature compost less new biomass is formed and CO₂ levels of more than 90% are observed for many polymers.

3. Characterization of disintegration in compost
Since in real biowaste respirometric measurements are not possible with a sufficient accuracy, in a real compost environment only disintegration of the materials is evaluated. Disintegration testing can be performed in laboratory tests using controlled reactors of some hundred liters content [14.86] or tests in a real composting plant. The degree of disintegration is determined by sieving the compost and analyzing polymer fragments larger than 2 mm (in all standards a maximum fraction of 10% is allowed).

4. Compost quality/toxicity
The quality of the final compost should not negatively be affected when plastics are composted. Tests to evaluate this requirement are defined by established national testing methods ensuring compost quality. Criteria for compost quality are, for instance, maturity, visual impurities, density, pH, content of nutrients, salts, heavy metals etc. Additionally, ecotoxicity tests focused on plant growth are part of the compost quality characterization (e.g., plant tests according to OECD guidelines (OECD 208). Additional toxicity tests (e.g., tests with earthworm, luminicent bacteria, *Daphnia magna*, fish) were discussed during the development of the standards [14.40, 56, 87, 88], but due to the limited experiences with these tests in combination with compost, these tests were not generally included in the test schemes for compostability (ASTM includes earth worm test according to OECD guideline OECD 207).

Anaerobic Biodegradability. Beside “normal” composting, the treatment of biowaste by anaerobic digestion

(“anaerobic composting”) is becoming more and more widespread. It has been demonstrated that the anaerobic biodegradation behavior of plastics can differ significantly from that under aerobic conditions [14.67, 68]. Thus, separate tests must become established in order to also include these conditions for biodegradation of plastics. Some standard methods for monitoring the anaerobic degradation via biogas formation do already exist (ASTM D 5511-94, ISO/DIS 14853 1999, ISO/DIS 15985 1999), based on testing protocols designed for low-molecular substances [14.89]. However, the evaluation schemes for biodegradable plastics do not mandatorily demand the proof of anaerobic degradability up to now (in EN 13432 anaerobic tests are mentioned, but are optional).

Biodegradation in Soil Environment. After focusing on degradation in landfills and then on composting processes at the first stage of standardization efforts, currently the characterization of the evaluation of plastics biodegradation in soils has become important since there is now a growing interest in applications of biodegradable plastics in agriculture (e.g., as mulching films or as matrix for controlled release of fertilizers and pesticides).

Compared to the evaluation of the compostability, standardization of testing methods focused on soil degradation face some serious problems.

- Composting is a technical process where parameters such as pH, temperature, humidity and biowaste composition are kept in certain limits to guarantee an optimal composting process. In soil, the kind of environment and the environmental conditions can vary significantly and usually can not be controlled in nature. Standards have to take these variations into account somehow.
- The higher temperatures and activity of the microorganisms involved, causes biodegradation of plastics during composting to usually be faster than in a natural soil environment.
It is much more difficult to monitor the slow degradation processes of some plastics in soil with a sufficient accuracy. Slow degradation sometimes causes extremely long test periods (>1 y).

Currently the CEN working group CEN TC249/WG9 “Characterization of degradability” is developing an evaluation scheme for soil degradation of plastics. The structure of this scheme very likely will be generally similar to that for composting including the different

aspects mentioned above. However, due to the variability in conditions and the differences in applications the test scheme will be more complex than the standards for compostability.

First standards describing the experimental conditions for testing biodegradation of plastics in soil have been established (ISO/PRF 17556-2002). A method for CO₂ detection in a closed system with minimized amount of soil was proposed by *Solaro et al.* [14.61]; *Albertsson et al.* [14.72] published a work based on ¹⁴C-labelled samples. Additionally to possible low carbon dioxide evolution rates, the determination of a carbon balance in soil is problematic and effects of the polymer added on the background CO₂ evolution have been observed [14.90] (“priming effect”). As proposed for the controlled composting test, the use of an inert matrix such as vermiculite is investigated, too.

Problems arise also for the evaluation of the disintegration behavior in soil. The influence of the soil characteristics and the environmental conditions on plastics degradation has been examined in some publications [14.91–95]. To solve this problem, degradation tests in a whole set of different selected soils or a test with a soil mixture are being discussed.

14.3.3 Paper and Textiles

Susceptibility of Paper and Textiles to Biodeterioration

Paper and textiles have been produced and used by humans for millennia. Until relatively recently the composition of both have been dominated by natural materials whether cellulose and plant fibers in the case of paper – or fibers derived from either plants or animals in the case of textiles. In the last 100 years, natural fibers have been mixed with man-made materials created either from polyolefins such as nylon or modified natural materials such as viscose and rayon and in some instances been completely replaced by them. In more recent times, synthetic materials have been used either to add new properties to paper or in some cases even replace paper in its traditional applications (e.g., tear- and water-resistant notepaper). In many cases, man-made fibers have either replaced traditional natural fibers in modern textiles or added properties which could not previously be obtained (e.g. a high degrees of elasticity). Despite this, natural fibers play an important role in both paper based and textile products.

Although it has been recognized that paper and textiles derived from natural materials can be damaged by the action of biological systems, i.e., rats and mice,

insects or microorganisms, for almost as long as they have been used, it was only in the 1940s that the study of the biodeterioration of these materials really became a scientific discipline in its own right [14.96]. Various armed conflicts in tropical regions of the Far East resulted in premature failure of items of military clothing (e.g. boots) and equipment (tents and tarpaulins) and attempts were made to predict the performance of materials under such conditions and identify treatments to prevent failure. A variety of standard tests began to emerge [14.97], mainly as part of military specifications, and many of these approaches are still used to this day. Despite the emergence of many man-made materials, the biodeterioration of textiles and paper remains a problem with microorganisms causing discoloration of/odor in finished goods and loss of functionality (e.g., destruction of plasticizers and loss of elasticity following microbial metabolism of critical components of the composition [14.98]). Similarly, microbial action in textile and paper manufacturing processes causes losses in productivity (e.g., microbial slimes resulting in defects in paper and rupturing in the manufacture) as well as function (e.g., blockage of applicators of spin finishes/weaving ancillaries by microbial growth/detached microbial biofilms resulting in either yarn being produced without antistatic agents/lubricants or areas of localized damage due to overheating on the loom).

Microbial attack of finished paper and textiles is most usually associated with fungi although a wide range of microorganisms cause problems in the manufacturing environment [14.99]. Growth occurs on the finished goods when the material is exposed to either high humidity or free water during use and storage. The resultant growth causes either marking/discoloration (Fig. 14.12) or, eventually, physical damage (Fig. 14.13). Such discoloration/spoilage might range from the small blemishes or foxing on historic documents [14.100] to the severe staining/musty odors associated with mildew on tents that have been stored without being dried properly first [14.97]. Growth of microorganisms is usually prevented by ensuring that insufficient moisture is present. In document archives, the humidity is strictly controlled to either prevent growth or to prevent further growth on material that already has some microbial damage. Not only does this ensure that the documents remain stable but also that growth of fungi and the production of fungal spores do not have a negative impact on the health of people who work in the archives [14.101]. Similarly, textiles that have heritage value are also conserved in controlled environments. Growth on other more utilitarian goods (e.g., tents and tarpaulins) can

Fig. 14.12 Staining due to mould growth on a cotton based textile

be prevented by ensuring that they are dry prior to storage and that they are stored in an environment which limits the availability of moisture. Where exposure to moisture is expected during service or where less than

Fig. 14.13 Microbial deterioration of a water damaged book

ideal storage conditions prevail, goods can be treated to prevent growth/spoilage [14.102].

The tests used to determine both the susceptibility of materials to microbial biodeterioration and to determine the efficacy of treatments intended to prevent it range from simple agar plate bioassays through cabinet-based

Table 14.6 Methods used to examine the resistance of textiles to biodeterioration

Reference	Title	Description	Major principle
prEN 14119	Testing of textiles – Evaluation of the action of microfungi.	The test is designed to determine the susceptibility of textiles to fungal growth. Assessment is by visual rating and measurement of tensile strength.	Agar plate test.
AATCC 30-1998	Antifungal activity, Assessment on textile materials: mildew and rot resistance of textile materials.	The two purposes of the test are to determine the susceptibility of textiles to microfungi and to evaluate the efficacy of fungicides on textiles.	Agar plate test.
DIN 53931	Testing of textiles; determination of resistance of textiles to mildew; growth test.	The test determines the efficacy of treatments for prevention of fungal growth on/in textiles. It also allows the performance testing of a treatment after UV irradiation, leaching etc.	Agar plate test.
MIL-STD-810F	Environmental Engineering considerations and laboratory tests; Method 508.5 FUNGUS.	The purpose of the method is to assess the extent to which a material will support fungal growth and how performance of that material is affected by such growth.	Humid chamber test (90 to 99% humidity).
BS 6085 :1992	Determination of the resistance of textiles to microbial deterioration.	The purpose of the method is to assess the extent to which a material will support fungal/bacterial growth and how performance of the material is affected by such growth. Visual Assessment and measurement of tensile strength.	a) Soil burial test, b) Agar plate test, c) Humid chamber test.
EN ISO 11721-1	Textiles – Determination of resistance of cellulose-containing textiles to micro-organisms – Soil burial test – Part 1: Assessment of rot retarding finishing.	The test is designed to determine the susceptibility of cellulose containing textiles against deterioration by soil micro-organisms. Preserved and unpreserved textiles are compared. Visual Assessment and measurement of tensile strength.	Soil burial test.
prEN ISO 11721-2	Textiles – Determination of resistance of cellulose-containing textiles to micro-organisms – Soil burial test – Part 2: Identification of long-term resistance of a rot retardant finish.	The test identifies the long-term resistance of a rot-retardant finish against the attack of soil inhabiting micro-organisms. It allows to make a distinction between regular long-term resistance and increased long-term resistance. Visual Assessment and measurement of tensile strength.	Soil burial test.

Table 14.7 Methods used to examine the resistance of textiles to biodeterioration

Reference	Title	Description	Major principle
BS 2011 : Part 2.1J (IEC 68-2-10)	Basic environmental testing procedures.	Mould growth test to show the susceptibility of a material towards colonization by fungi.	Humid chamber test (90 to 99% humidity).
AS 1157.2 – 1999	Australian standard – Methods of testing materials for resistance to fungal growth. Part 2: Resistance of textiles to fungal growth. Section 1 – Resistance to surface mould growth.	Test specimens are inoculated with a suspension of spores of <i>Aspergillus niger</i> and then incubated on the surface of a mineral salts based agar for 14 days and then assessed for growth. Both leached and unleached specimens are examined. Glass rings are employed to hold the specimens in intimate contact with agar when necessary. Specimens are examined for the presence of surface mould growth.	Agar plate test.
AS 1157.4 – 1999	Australian standard – Methods of testing materials for resistance to fungal growth. Part 2: Resistance of textiles to fungal growth. Section 2 – Resistance to cellulolytic fungi.	Test specimens are inoculated with a suspension of spores of <i>Chaetomium globosum</i> and then incubated on the surface of a mineral salts based agar for 14 days and then assessed for growth. Both leached and unleached specimens are examined and exposed samples are subjected to a tensile strength test. Glass rings are employed to hold the specimens in intimate contact with agar when necessary.	Agar plate test.
AS 1157.3 – 1999	Australian standard – Methods of testing materials for resistance to fungal growth. Part 2: Resistance of cordage and yarns to fungal growth.	Test specimens are inoculated with a suspension of spores of <i>Chaetomium globosum</i> and then incubated on the surface of a mineral salts based agar for 14 days and then assessed for growth. Both leached and unleached specimens are examined and exposed samples are subjected to a tensile strength test.	Agar plate test (other vessels containing media are employed for large specimens).

tests intended at simulating conditions of exposure in a more realistic manner to field exposure/soil burial trials. A range of such tests is given in Tables 14.6–14.9. The choice of test will depend upon the type of information required and the speed with which that data is needed as well as the importance of the accuracy of any predictions that are being made from it. Combined with some form of simulation of durability (e.g., leaching in water), simple plate assays can be used to screen a range of treatments to select one or two that are likely to function in service. However, such assays should be treated with caution as they do not always provide a realistic simulation of the inherent susceptibility of a material to spoilage (especially where the supporting media contain a source of nutrients) and can underpredict the protective capacity of treatments. For this reason, cabinet-based simulations (e.g. BS2011 Part 2J) and field trials should always be considered when more critical end uses are involved.

It can be seen from Tables 14.6 and 14.7 that there is a relatively large number of tests developed to examine the resistance of textiles to fungal growth. The majority of these tests are agar plate based but some use cabinets. In the case of the agar plate methods they range from simple single species tests performed with samples being placed on a complete nutrient medium

and then inoculated to multi-species tests performed on minimal media. While the former can be used to examine the dose response of a number of treatments used to prevent growth, the latter is more suited to gaining information about the inherent susceptibility of a material to microbial spoilage. The cabinet-based tests all take a similar format in which materials are inoculated with the spores of a range of fungi known to grow on textiles and are then incubated under conditions which stimulate fungal growth. Various soiling agents can be employed to increase the degree of severity of the simulation and the incubation period can be extended to simulate the durability required. In all cases growth similar to that experienced/expected under conditions of actual use should be demonstrated on an appropriate control material (in the case of BS2011 Part 2J a paper control is specified, however, the relevance of this to the material under test should be considered and an additional, relevant control included wherever possible). A similar range of fungal tests exists for paper (Table 14.8) but relatively few tests exist to simulate spoilage/biodeterioration by bacteria (BS 6085: 1992). In most instances, biodeterioration by bacteria is encompassed by soil burial trials but there are circumstances where this might be considered as too severe and work is required to develop suitable protocols in this area. In

Table 14.8 Methods used to examine the resistance of paper to biodeterioration

Reference	Title	Description	Major principle
DIN EN 1104	Paper and board intended to come into contact with foodstuffs. Determination of transfer of antimicrobial constituents.	A minimum of 20 replicates sub-samples (each 10–15 mm in diameter) taken from 10 samples of a batch of paper are placed in intimate contact with nutrient agar plates inoculated with either <i>Bacillus subtilis</i> or <i>Aspergillus niger</i> and incubated at 30 °C for 7 d and at 25 °C for 8–10 d respectively.	Zone Diffusion Assay.
ASTM D 2020-92	Standard test methods for mildew (fungus) resistance of paper and paperboard – direct inoculation.	Replicate samples (3) are inoculated with a suspension of fungal spores and then incubated on the surface of a minimal mineral salts medium to determine if they support fungal growth.	Biodeterioration Test.
ASTM D 2020-92	Standard test methods for mildew (fungus) resistance of paper and paperboard – Soil Burial.	Replicate samples (5) are buried in soil for 14 d and then examined for the deterioration compared with unburied samples for both physical deterioration and loss of tensile strength.	Biodeterioration/ Biodegradation Test.
AS 1157.7 – 1999	Australian standard – methods of testing materials for resistance to fungal growth. Part 6: Resistance of papers and paper products to fungal growth.	Test specimens are placed on the surface of a mineral salts based agar and then both the specimen and the agar are inoculated with a suspension of spores of a range of fungi. They are then incubated for 14 d and then assessed for growth. Growth on the specimen is assessed.	Agar plate test.
AS 1157.5 – 1999	Australian standard – methods of testing materials for resistance to fungal growth. Part 5: Resistance of timber to fungal growth.	Test specimens are placed on the surface of a mineral salts based agar and then both the specimen and the agar are inoculated with a suspension of spores of a range of fungi. They are then incubated for 14 d and then assessed for growth. Growth on the specimen is assessed.	Agar plate test.
AS 1157.6 – 1999	Australian standard – Methods of testing materials for resistance to fungal growth. Part 6: Resistance of leather and wet ‘blue’ hides to fungal growth.	Test specimens are placed on the surface of a mineral salts based agar and then both the specimen and the agar are inoculated with a suspension of spores of a range of fungi. They are then incubated for 14 d and then assessed for growth. Both leached and unleached specimens are examined Growth on specimens is assessed. Sucrose containing media is employed where true controls cannot be obtained.	Agar plate test.

other applications, e.g. geotextiles, soil burial is probably the only sensible manner to attempt to simulate their performance in practice.

A number of tests have also been developed for materials/processes used in the manufacture of paper and textiles. For example, ASTM E1839-96 (2002) describes a standard test method for efficacy of slimicides used in the paper industry and E875-00 (2005) describes a standard test method for determining the efficacy of fungal control agents used as preservatives for aqueous-based products employed in the paper industry. Work is also in progress on methods to determine the per-

formance of spin finishes and textile ancillaries by the Functional Fluids Group of the International Biodeterioration Research Group (IBRG). A number of specialized tests have also emerged in recent years to address problems that have resulted from the development of new materials. Non-woven ‘textiles’ have been developed to produce moist hygienic wipes for clinical and personal care (e.g., infant sanitary wipes). These products are supplied in multi-packs and contain pre-moistened wipes. However, in some instances these have proven susceptible to fungal growth in storage and in use and methods have been developed to both simulate the problem and

help predict the performance of preservatives intended to prevent growth (Table 14.10).

Antimicrobial Textiles and Paper

Recently a number of both textile- and paper-based goods have been produced which include antimicrobial properties which are not intended merely to prevent deterioration in service but to provide an antimicrobial function in use [14.103]. These articles include items of clothing fortified with microbicides to prevent odors

from being formed from human perspiration or prevent cross-infection in clinical environments.

It can be seen from Tables 14.11–14.13 that there are two major forms of test for microbiological effects of treated textiles which are not related to the prevention of biodeterioration. In the first, typified by AATCC 147, samples of textiles are placed onto agar plates which have been inoculated with bacteria and then incubated. The intention is that intimate contact between the textile and the bacteria/growth medium will

Table 14.11 Methods used to examine the antimicrobial activity of textiles (fabric, yarn or pile/wadding)

Reference	Title	Description	Major principle
ASTM E2149-01	Standard test method for determining the antimicrobial activity of immobilized antimicrobial agents under dynamic contact conditions.	Dynamic shake flask test. Test material is suspended in a buffer solution containing a known number of cells of <i>klebsiella pneumoniae</i> and agitated. Efficacy is determined by comparing the size of the population both before and after a specified contact time.	Relies on either diffusion of antimicrobial mater from treated material into the cell suspension. Some activity may be due to interaction between the population and the surface of the material in suspension.
AATCC 147-1998	Antibacterial activity assessment of textile materials: Parallel streak method.	Agar plates are inoculated with 5 parallel streaks (60 mm long) of either <i>Staphylococcus aureus</i> or <i>K pneumoniae</i> . A textile sample is then placed over the streaks and in intimate contact with the surface of the agar and incubated. Activity is assessed based on either the mean zone of inhibition over the 5 streaks or the absence of growth behind the test specimen.	Zone diffusion assay.
AATCC 100-2004	Antibacterial finishes on textile materials	Replicate samples of fabric are inoculated with individual bacterial species (eg <i>Staph aureus</i> and <i>K pneumoniae</i>) suspended in a nutrient medium. The samples are incubated under humid conditions at 37 °C for a specified contact time. Activity is assessed by comparing the size of the initial population with that present following incubation. A neutraliser is employed during cell recovery.	Cell suspension intimate contact test.
XP G 39-010	Propriétés des étoffes – Étoffes et surfaces polymériques à propriétés antibactériennes	Four replicate samples of test material are placed in contact with an agar plate that has been inoculated with a specified volume of a known cell suspension of either <i>Staph aureus</i> and <i>K pneumoniae</i> using a 200 g weight for 1 min. The samples are then removed. Duplicate samples are analysed for the number of viable bacteria both before and after incubation under humid conditions at 37 °C for 24 h. A neutraliser is employed during cell recovery.	Cell suspension intimate contact test.

Table 14.12 Methods used to examine the antimicrobial activity of textiles (fabric, yarn or pile/wadding)

Reference	Title	Description	Major principle
JIS L 1902: 1998	Testing method for anti-bacterial activity of textiles. Qualitative Test	Three replicate samples of fabric, yarn or pile/wadding are placed in intimate contact with the surface of agar plates that have been inoculated with a cell suspension of either <i>Staph aureus</i> or <i>K pneumoniae</i> and incubated at 37 °C for 24–48 h. The presence of and size of any zone of inhibition around the samples is then recorded.	Zone diffusion assay.
JIS L 1902: 1998	Testing method for anti-bacterial activity of textiles. Quantitative Test	Replicate samples of fabric (6 of the control and 3 of the treated) are inoculated with individual bacterial species (eg. <i>Staph aureus</i> and <i>K pneumoniae</i>) suspended in a heavily diluted nutrient medium. The samples are incubated under humid conditions at 37 °C for a specified contact time. Activity is assessed by comparing the size of the initial population in the control with that present following incubation. No neutraliser is employed during cell recovery.	Cell suspension intimate contact test.
prEN ISO 20645	Textile fabrics – Determination of the antibacterial activity – Agar plate test (ISO/FDIS 20645:2004)	Four replicate samples of fabric (25 ± 5 mm) are placed in intimated contact with a solid nutrient medium in a petri dish. The samples are then overlaid with molten solid nutrient media which has been inoculated with a cell suspension of either <i>Staph aureus</i> , <i>Escherichia coli</i> or <i>K pneumoniae</i> . The plates are then incubated for between 18 and 24 h and the plates are then assessed for growth based on either the presence of a zone of inhibition of > 1 mm or the absence/strength of the growth in the media overlaying the test specimen.	Zone diffusion assay.

result in the inhibition of growth either immediately adjacent to the textile or in an area around the textile, in case any antimicrobial agents that have been employed become dissolved in the growth medium. These methods are generally acknowledged as being nonquantitative although they can be employed as assays of certain antimicrobial products in the same manner that such techniques are used for certain antibiotics [14.104]. As with some of the biodeterioration tests described

above, this could be useful as a screening tool and for investigating the effect of wash cycles etc. These methods are widely employed in the textile industry as they provide a highly graphic representation of antimicrobial activity although this can lead to misunderstandings of either the scale of effect seen (bigger zones of inhibition looking better) and the implications that mobility of active ingredient could have on service life. Although these techniques are considered to be unsuitable for ‘quantifying’ the effect of the antimicrobial effects of treated textiles there are some disciplines in which they may provide data which is more relevant to the effect claimed than that delivered by a fully quantitative technique (e.g., predicting the effect/durability of bandages intended for use of suppurating wounds).

From Tables 14.11–14.13 it can be seen that there are at least four techniques which provide quantitative data on the effect of treated textiles on bacteria. These are typified by the method described in AATCC 100-2004 in which samples are inoculated with suspensions of bacteria and then incubated for a specified time before being examined for the size of the population present (Fig. 14.14). The methods differ in the form of the suspension medium, number of replicates examined, test species and, to a certain extent, conditions for incubation. Methods AATCC-100 and JIS L 1902 appear to be the most commonly employed. The Swiss Standard

Reference	Title	Description	Major principle
ISO/CD 20743	Textiles – Determination of antibacterial activity of antibacterial finished products: Absorption method.	Replicate (6) samples of textile are inoculated with a standardised broth culture of either <i>staph aureus</i> or <i>K pneumoniae</i> in individual tubes and then incubated at 37 °C for 18–24 h in closed containers. Samples are analysed for the presence of viable bacteria both before and after incubation by either total viable count or the determination of total ATP. Samples are sterilised prior to testing and a neutraliser is employed during recovery. The test is validated by growth of 1 order of magnitude during the incubation period.	Cell suspension intimate contact test.
ISO/CD 20743	Textiles – Determination of antibacterial activity of antibacterial finished products: Transfer method.	Replicate (6) samples of test material are placed in contact with an agar plate that has been inoculated with a specified volume of a known cell suspension of either <i>staph aureus</i> and <i>K pneumoniae</i> using a 200 g weight for 1 min. The samples are then removed. Replicate (3) samples are analysed for the either the number of viable bacteria or the total ATM content both before and after incubation under humid conditions at 37 °C for 24 hours. Samples are sterilised prior to testing and a neutraliser is employed during cell recovery. The test is validated by either growth of 1 order of magnitude during the incubation period or by a measure of the variability of the data obtained.	Cell suspension intimate contact test.
ISO/CD 20743	Textiles – Determination of antibacterial activity of antibacterial finished products: Printing method.	Replicate (6) samples of test material are either <i>staph aureus</i> and <i>K pneumoniae</i> by ‘printing’ cells collected on a membrane filter onto their surface in a standardised manner. The samples are then incubated under humid conditions for 18–24 h at 20 °C for a specified contact time(s). Replicate (3) samples are analysed for the either the number of viable bacteria or the total ATM content both before and after incubation. Samples are sterilised prior to testing and a neutraliser is employed during cell recovery. The test is validated by either determining the survival of the inoculum on the control material.	‘Dry’ inoculum intimate contact test.

Table 14.14 Methods used to examine the antimicrobial activity of textiles (fabric, yarn or pile/wadding)

Reference	Title	Description	Major principle
SN 195920	Examination of the antibacterial effect of impregnated textiles by the agar diffusion method.	Four replicate samples of fabric (25 ± 5 mm) are placed in intimated contact with a solid nutrient medium in a petri dish. The samples are then overlaid with molten solid nutrient media which has been inoculated with a cell suspension of either <i>staph aureus</i> or <i>E coli</i> . The plates are then incubated for between 18 and 24 h and the plates are then assessed as described in prEN ISO 20645 above.	Zone diffusion assay.
SN195924	Textile fabrics – Determination of the antibacterial activity: Germ count method.	Fifteen replicate samples (each replicate is comprised of sufficient specimens of 25 ± 5 mm to absorb 1 ml of test inoculum) are inoculated with cells of either <i>E coli</i> or <i>staph aureus</i> suspended in a liquid nutrient medium and incubated in sealed bottles for up to 24 h at 27 °C. After 0, 6 and 24 h, 5 replicate samples are analysed for the size of the viable population present. A neutraliser is employed. An increase of 2 orders of magnitude of the population exposed to a control sample is required to validate the test. The method defines a textile as antibacterial if no more than a specified minimum level of growth is observed after 24 h in 4 of the 5 replicate groups of samples.	Cell suspension intimate contact test.
SN195921	Textile fabrics – Determination of antimycotic activity: Agar diffusion plate test.		Zone diffusion assay.

SN195924 was based on AATCC 100 but was apparently modified to improve reproducibility and repeatability [14.105]. These methods show a clear potential as being suitable to determine both inherent bactericidal and bacteriostatic properties of textiles. Although pri-

marily developed for examining effects against bacteria, they can be extended to the investigation of the impact on yeasts, fungal spores and mycelial fragments. The impact on other species of bacteria can also be investigated. It is possible to envisage the method being extended to

Table 14.15 Methods used to examine the antimicrobial activity of carpets

Reference	Title	Description	Major principle
AATCC 174-1998	Antimicrobial Activity Assessment of Carpets Qualitative Antibacterial Activity	Petri dishes with nutrient media are inoculated with a single, diagonal streak (approx. 7.5 cm) of either <i>staph aureus</i> or <i>K pneumoniae</i> . An unsterilized test specimen (25 mm × 50 mm) is placed in intimate contact and transversely across the inoculum on the agar surface. The plates are then inoculated at 37 °C for 18–24 h. The front and back of the carpet are tested separately. After incubation, the plates are inspected for the presence of growth both below the specimens and for any zone of inhibition caused by the specimen is recorded. The test can also be used to test the effect of cleaning regimes. An untreated control is optional.	Qualitative assessment of rate of kill and zone diffusion test.
AATCC 174-1998	Antimicrobial Activity Assessment of Carpets Quantitative Antibacterial Activity	Unsterilized specimens of carpet are pre-wetted with either sterile water or a wetting agent before being inoculated with individual suspensions of either <i>staph aureus</i> or <i>K pneumoniae</i> in either a low or a high nutrient solution. The samples are then incubated in a tightly closed jar at 37 °C for a specified contact time. Cells are recovered in 100 ml of a neutraliser after 0 and 6–24 h of incubation. Activity is assessed by comparing the size of the initial population in the control (if used) with that present following incubation. A control is optional. When not employed, viable counts following incubation of the treated specimens alone are considered. The test can also be used to test the effect of cleaning regimes.	Cell suspension intimate contact test.

the examination of viral particles, algae and protozoa. In addition, such protocols can be combined with studies on ageing (e.g., the impact of washing cycles) to begin to satisfy at least some of the aspects associated with service life.

It can also be seen from Tables 14.11–14.13 that no fully quantitative methods exist for the examination of treated textiles on fungi. All of the protocols described are zone diffusion assays of one form or another. As with antibacterial properties, these may be sufficient to substantiate certain claims (e.g., that certain fungi significant to infections on the human skin cannot germinate and grow on the textile) and methods designed for the measurement of the potential for/prevention of biodegradation could be employed dependent on the claim being made (e.g., prEN 14119 – Table 14.11) as well.

In addition to the truly microbiological methods described above, at least three methods exist which describe the performance of woven textiles [14.106] and non-woven textiles [14.107, 108] to penetration by bacteria under wet and dry conditions. Further information is required to determine whether these have any use in evaluating treated textiles.

Although no specific standards exist for the examination of antimicrobial effects on paper and board, in many cases the tests intended for textiles can be employed. One method (DIN EN 1104) uses a zone diffusion assay to look for the presence of antimicrobial

agents in paper destined for food contact applications, the intention here being to prevent the transfer of any antimicrobial agents used in both the production of and to prevent the biodeterioration of the paper/board being transferred to food.

Selection of Test Method

For assessing potential biodeterioration and the efficacy of treatments intended to prevent it, the choice of methodology is relatively straightforward and is driven either by a specification to be matched (e.g., a military specification) or by the need to simulate an effect observed in service. In some cases, microorganisms that have caused failure in the field can be isolated and utilized in laboratory tests although care should be taken to use sufficient species/strains to measure an adequate spectrum of activity. Selecting a method to simulate a non-biodeterioration-related effect is, however, more problematic. Although many of the methods described above and in the tables below can be used to give a measure of an antimicrobial effect, it is important to ensure that this effect and the method used to measure it, is relevant to the application. For example, it may be sufficient to merely slow bacterial growth in a application intended to reduce the generation of odorous compounds from human perspiration. In this instance a test such as that described in AATCC 100 may be modified using species known to biotransform compounds in human

sweat to odor-forming molecules. The presence of moisture in the system could be considered as a reasonable model of certain items of sports clothing (e.g. socks) and the temperature used/contact time employed could be altered if necessary to bring the test closer to reality. However, in many other applications such tests provide a poor simulation of the end use. For example, a method that uses a cell suspension to saturate a sample which is then incubated at 37 °C for 24 hours cannot be considered as a suitable simulation of textiles used for soft furnishings and the uniforms of medical staff. In normal use these materials would be dry or at worst occasionally splashed with water/fluids containing microorganisms. Not only do the test conditions not simulate the normal environment of the textile in use, but they may artificially predict an effect where none would result in practice. Many antimicrobial agents require free water to facilitate their transfer from a material in which they are contained to a microbial cell that comes in contact with the material. Similarly, all microbial cells require free water to grow and many also require it to survive for any length of time. If either no or insufficient free water is present in an application then it is unlikely that an antimicrobial agent would migrate from a material to a cell or that the cell would be in a suitable metabolic state to interact with the active ingredient. In some instances, the inclusion of an ac-

tive ingredient might be to add potential activity which would provide function if suitable conditions were to arise (in a similar manner to the use of a fungicide in a textile intended to prevent mold growth should conditions suitable for growth occur – i.e., keeping the item dry would have the same function in most cases). In this instance care needs to be taken to understand what the effect one is trying to simulate is. If for example, it is to prevent cross infection from one patient to another by contact with the uniform of medical staff, the speed of action will be a critical factor. Not only will the level of moisture need to be selected to simulate the conditions (e.g., moisture from hand contact, a splash with a body fluid such as sputum) but the contact time will need to reflect the interval in which cross contamination might occur (potentially very short intervals in a busy clinical unit). In some circumstances, a significant level of moisture may simply never be present (e.g., during the settlement of airborne bacteria onto curtains). Methods are being developed which attempt to simulate such conditions (e.g., the printing method stage of ISO/CD 20743) although care must be taken to ensure no artifacts are introduced in the recovery phase of such techniques. Considerable work is still required before many of the claims made for treated textiles/paper can be substantiated and their true benefit be assessed in a robust manner.

14.4 Biological Testing of Inorganic Materials

Ageing applies more or less to all materials. This natural decay process is ruled by physical and chemical interactions with the environment and can be considerably accelerated and in some special cases slowed down by the interaction with organisms and especially microorganisms. The microbes involved are wide-ranging in speciation and at the same time often very specialized in their nutritional and environmental adaptations. Adhesion to surfaces and resistance to stressed conditions are of importance as well as special biochemical pathways to furnish energy, electrons, water and mineral matter to the microbes living on and in inorganic materials. In order to understand detrimental functions and reaction chains, new methods of study and differentiation of physical, chemical and biologically induced or accelerated processes had to be developed. Quantitative data on mere physical and chemical attack in comparison to biologically induced and catalyzed biotransformations and biotransfer

processes had to be compared in laboratory and field experiments. Methods of curing, protection, sterilization, biocide treatments had to be especially conceived and tested. Studies on the speed of physical/chemical deterioration as compared to biodeterioration were undertaken. In conclusion it can be stated that all inorganic materials exposed to surface conditions are more rapidly transferred and cycled biologically than under conditions of a sterile environment and atmosphere. Although water plays an eminent role in all biotransfer processes, it is shown that biologically induced accelerations of decay and ageing of materials takes place in practically all objects of industry, daily use, and of the cultural heritage. Examples of sub-aquatic and subaerial biofilms on inorganic surfaces and microbial networks (biodictyon) inside porous or damaged materials are given as well as the techniques to study them and eventually prevent their damaging potential.

14.4.1 Inorganic Materials Subject to Biological Attack

Generally, the decomposition of inorganic materials is related to empirical observations and even to subjective impressions. The physical, chemical and biological processes are usually not well understood. Thus everybody expects that granite, for example (or any stone) is more durable than tissue (or any other organic material). Some tombstones, however, decay so fast that the son may survive the inscriptions made to commemorate his own parents. Thus in an exclusively physical environment, it is evident that the decomposition of rock and the dissolution of rock-forming minerals proceeds much faster than the physical decay of a protein or carbohydrate. We can state that practically all materials used in the production of objects, buildings and machines will ultimately decay. Biologically induced or accelerated decay processes are, however, often underestimated. Acceleration rates of up to 10 000 times have been found in comparative laboratory experiments and field observations. The physical and chemical environment and conditioning of all objects of commercial and cultural value will determine (1) the longevity of any object and (2) the chances of biological attack and biological catalysis of the natural physical decomposition processes. One simple example is the aggressiveness of water on a marble statue. Distilled pure water has an extremely low dissolution capacity as only a minimal amount of protons are available. Marble in the vicinity of a bakery or a restaurant, however, absorbs volatile organic compounds, which – humidity given – will be transformed to carbonic acid by ubiquitous microbes. The aggressive action of water is modified through various biological processes. Therefore, a durability scale of materials will largely depend on the environmental and biological conditions. However, we can now say more specifically which inorganic materials are more susceptible to biological attack and biodeterioration as compared to others. In the following pages we will, after a short introduction on materials, focus mainly on the organisms and biological phenomena and processes involved in the deterioration of objects made of inorganic materials. We will introduce some modern terminology, describe methods of study and ways for protection of the inorganic materials from biological hazards.

Mineral Materials

Most buildings, sculptures and objects of use are produced from rock types found and procured locally. Since the Egyptian, Greek, Hellenistic and Roman times, how-

ever, international trading of beautiful and often most durable rock types is documented and the multiple use and transfer of materials such as Pentelic and Carrara marble, Egyptian porphyry and granite stones and objects is well documented, with famous examples of porphyry columns transferred from Egypt to Rome and from Rome to Provence etc. or Egyptian obelisks being transferred to modern cities such as Paris and London. Vitruvius in his time made a survey on their durability and thus, with the exclusion of cases where cheap materials were used, the more impervious rocks were traditionally used in production of objects if the future owner was ready to pay enough money.

Calcareous Materials. Calcium carbonate is a mostly biologically deposited mineral. It is produced by skeletal macroorganisms or from the byproduct of bacterial-, fungal- and algal metabolic activities. The so-called structure-less carbonate rocks and carbonate cements of sandstones are usually biologically catalyzed deposits. Marble is a pressure-temperature metamorphosis of limestone. Traditionally, travertines and carbonate tuffs (fresh-water deposits of calcium carbonate produced by carbon dioxide uptake through algae and/or by equilibration of water highly enriched with carbon dioxide) are regarded as high quality materials because it is very easy to cut and treat them in a wet state, while they harden when drying. Many colored marbles (carbonate breccia) are of Alpine Triassic origin. The yellow to brown color of many limestone-derived marbles comes from small amounts of iron oxide admixed. These are especially susceptible to the formation of brown or red films and crusts often called “scialbatura” or oxalate films. Since Roman times, calcium carbonate has also been used as a compound in the production of mortar, stucco and mural paintings. Because the physical and biological mechanisms of decay are practically the same, we shall include carbonate-cemented sandstones in the list of calcareous materials.

Siliceous Materials. Siliceous materials can be largely classified into four groups. The magmatic intrusive class embraces granites and diorites and the very stable porphyries. The magmatic extrusive class embraces a large variety, including basalt, andesite, volcanic tuffs and natural glass (e.g. obsidian). The metamorphic class comprises a large variety of quartzites, gneisses and schists. The sedimentary or exogenic cycle derived class includes siliceous or clay-cemented sandstones and breccia but also sinters and opal, a biologically influenced arid weathering product. The ancient Egyptian

architects probably found the most stable rock in the red porphyry of Upper Egypt. Columns and stones made of porphyry were used a great deal in many places. All dried, baked or sintered siliceous products such as adobe, terracotta, bricks, glassed bricks and glasses as well as enamel are included in this group. Interestingly, within this group are the so-called stabilized melts such as glass, brick and glazed brick or clinker.

Mixed Mineral Materials (Mainly Carbonate and Silicate). Astonishingly, mixtures of heated carbonates with quartz and other siliceous materials like the heated siliceous mineral compounds of (Portland) cement turned out to be extremely corrosion resistant. Opus cementicium of the Roman engineers is a well-studied example of producing almost miraculous results of stability of materials used in building and engineering. A mixture of sand and ground mollusc shells turned out to be one of the most corrosion-resistant materials of antique technology.

Metallic Materials

Pure metals and many alloys are widely distributed in buildings and objects of art. None of them are really eternally stable. The reinforcing of wood, stone and concrete by metal in buildings, the roofing by lead and copper, metallic sculptures such as the famous Marc Aurel Quadriga, the bronzes of Riace and the mysterious “never” rusting iron column in India are examples of out-door exposure of metal structures. Many metal sculptures designed for indoor exposure have, however, been subject to long periods of burial in soil or water. Patina, films, crusts and other surface changes of metallic products are partially regarded as an integral part of the artistic value of metallic objects. In some cases, artists give a finish to their products that initiates the formation of patina or can be regarded as patina from the beginning. The formation of a hydrogen layer, oxides, sulfates, carbonates on the surface of metallic objects may also contribute to their stability and longevity. All these compounds, on the other hand, contribute to the decay and loss of the original material in many cases. However, also biofilm formation may contribute to preservation although microbial attack on metallic materials is more frequent and protective action less than with mineral surfaces.

Gold, Silver, Copper, Bronze, Brass, Tin. These metals and alloys are mentioned first because they were first coming in use in a growing technological civilization. This is explained by the fact that the temperatures and

techniques of processing were first invented or found and did not face humankind with serious problems.

Iron and Steel. In order to recover metallic iron from a melt necessitates higher temperatures. Steel, in contrast to alloys such as bronze and brass needs exact supplements of carbon and other compounds such as chromium, nickel and later vanadium. Stainless steels aside more accidental findings as damascene iron are used only since the 20th Century at a larger scale and sophistication of production. The main aim was to yield highly corrosion-resistant materials. Also these, however, may undergo microbial attack by biopitting processes and other decay mechanisms.

Aluminum, Magnesium, Titanium, Platinum. These last metals have received attention as technical materials only since the onset of the 20th Century. They are very important construction materials of extremely high resistance to corrosion in cases of importance as extremely light weight materials in the construction of airplanes, for example. Most organic or plastic replacements pose higher corrosion and decay risks than the metallic compound.

14.4.2 The Mechanisms of Biological Attack on Inorganic Materials

All inorganic materials undergo transformation and destruction, decay, disintegration and solution, even sublimation or evaporation. In many if not all cases, biological and especially microbial interaction cause acceleration of such phenomena. Thus, the natural stability of a chosen material needs to be always regarded with respect to physical, chemical and especially biological processes interfering with the standard stability data. The environment of the final “resting place” of the technical product is of great importance in aesthetical and in a physical–chemical–biological viewpoint.

Krumbein and coworkers [14.109–111] have tried to define and explain the terms frequently in use in this field. Weathering with its meteorological connotation is a somewhat awkward term not directly implying the important biological interactions in the process of rock and material decay. It should be avoided in material sciences when biological processes are involved. Erosion and abrasion involve the physical attack of solids, liquids or gases on solids with the effect of particles detached and transported. Corrosion implies a chemical transfer with surface changes as a consequence. It is used in context with industrial materials and especially with metals

and alloys, to a lesser extent with stone and building materials. Degradation is a term for the combination of weathering, wearing down and erosion; it is also frequently used for the biological breakdown of organic or inorganic compounds, which serve as energy, electron or nutrient source for the organism. Also the formation of new mineral lattices and chemical compounds (rust) may be involved. Abrasion has a strong connotation with mechanical forces and material decay in moving parts of machines and other technical equipment. Deterioration and biodeterioration are terms widely used in material sciences. In the following sections we treat mainly biological actions on materials that have a deteriorative effect in terms of cultural heritage conservation efforts. The physical and chemical transfer actions will be described briefly in order to demonstrate the multitude of possible actions occurring in the ageing and decay of objects of art and technology.

14.4.3 Organisms Acting on Inorganic Materials

The durability of inorganic materials is affected by many biological activities and interactions. Biodeterioration has to be regarded as some kind of irreversible loss of information of objects of art made of mineral materials following the attack by living organisms. In this context we have to consider damages caused by man, animals, plants and microorganisms. The destructive activity of man by war, vandalism and neglect is probably the greatest of all biological effects.

Macroorganisms

All macroorganisms acting on materials are eukaryotic. Among macro organisms, roots or the climbing and adhering parts of leaves and stems of plants create a big problem to conservators because they cause partly evident aesthetic damage, partly an alteration of the stone due to (a) a mechanical action of roots, and fixing parts, (b) chemical action through ionic exchange between roots and alkali or earth alkali cations of the stone constituents, (c) vegetation shadowing slows down water evaporation [14.112].

Birds, and in particular pigeons, provoke a remarkable aesthetic and chemical damage by deposition of guano; guano, moreover can be a good growth medium for chemoorganotrophic microorganisms which, in turn, will determine a corrosive action on stone by release of acid metabolites.

There is a multitude of animals that live on and in mineral mixtures (rocks, mortar, mural paintings etc.).

They construct their dwellings, seek hide and food within that environment and hereby contribute to the material change and decay as well. The most important among them are spiders, flies, mosquitoes, stone wasps, ants, mites and beetles in common terms. Insects and arthropods are the groups most frequently involved with rock dwelling and rock decay.

Mosses, lichens and algae are macroscopically evident because they cover the material surfaces with visible films of growth. Consequently, first of all an aesthetic alteration is noticed. In addition, they have a corrosive effect on the substrate by release of acid metabolites, some of which are chelating agents that determine a solubilizing and disintegrative action on the constituents. Surficial microbial mats and films and lichen colonies by their exudates (mainly sugars) act as traps of dust and particles, which in turn supply aggressive compounds and nutrients for all kinds of organisms. Lichens provoke physical as well as chemical damage: acid metabolites solubilize and disintegrate the substrate. One of the most prominent effects of lichen is the formation of pits or crater-shaped holes (Figs. 14.15, 14.16), which are produced in some cases (epilithic lichen) by the algal symbiont, in other cases (mainly endolithic lichen) by the fruiting bodies of the fungal symbiont [14.110, 111]. It is of utmost importance to note that some lichens can act protective, while others on the same rock can act destructive. Therefore cleaning action has to be considered carefully. Many algae form inaeesthetic growth films, slime, which upon their degradation yields biocorrosive actions and can actively perforate the rock.

Microorganisms

It is well known that microorganisms are involved in rock and mineral decay in the geophysiological cycle of elements [14.113, 114].

A correlation between stone decay and the presence of microorganisms presents some difficulties because a great number and variety of species of microorganisms is involved. In fact, many autotrophic and heterotrophic bacteria, algae and fungi are found but a biodeteriorating role has been demonstrated only for some of them. In many cases microorganisms are directly associated to a deteriorating activity on stone materials, in others it is possible that products excreted from the cells under stress or upon lysis serve as nutrients for other heterotrophic decaying microorganisms or act directly on the material without a direct correlation to the organisms. According to terminology, among the rock- and material-damaging microorganisms we can notice that

microorganisms are defined as organisms barely or not visible with the naked eye. Microorganisms can belong to the animals, the plants, the fungi, the algae and protozoa (protocists) and to the prokaryotes (bacteria sensu lato).

Phototrophic Microorganisms

Lichens and cyanobacteria as the predominant rock dwellers are usually present in association with green and red algae and diatoms. The dominance of one or other of these groups varies both locally and regionally. Cyanobacteria (blue-green algae) and green or red algae growing on surfaces within such buildings as churches or grottoes are well adapted to survive at very low light levels. Communities' color varies with the color and growth form of the dominant forms. Cyanobacteria are predominant in the tropics and arid areas and there is no doubt that this is due in part to high temperatures and/or extremely high or low high air humidity as well as high or low irradiation. Cyanobacteria can endure strong illumination because their accessory pigments protect them and prevent chlorophyll oxidation in intense light [14.115].

Cyanobacteria and algae can form biofilms and crusts on rock and concrete surfaces that are deep or bright green in humid conditions and deep black, when dry. The black coatings of many rock surfaces can be explained this way. Upon extraction in polar solvents often a typical adsorption between 300 nm and 320 nm is observed besides the classical adsorption peaks in the 400 nm and 600 nm ranges. Apart from the evident aesthetic damage on stone monuments there are many evidences of significant physical and chemical deterioration of the surface by excretion of chelating organic acids and sugar-derived carbonic acids, which initiate the perforating activities of cyanobacteria, some of which are called endolithic, when they exhibit strong perforating activity. The algae have already been mentioned under the section of macroorganisms. Many of these eukaryotic phototrophs are, however, microorganisms and can also act perforating especially in connection with fungi or as symbionts of lichens. Some observations have also been made of the occurrence of anoxygenic phototrophic bacteria in decaying rocks and rock crusts.

Chemolithotrophic Bacteria

Sulfur Compound Oxidizers. Among the chemolithotrophic group, firstly the role of sulfur, sulfide and thiosulfate oxidizing bacteria has been clarified [14.116–119].

Fig. 14.15 A tear under the eye of the marble portrait of the poet Keats at the Cemetery near the Cestius Pyramid, Rome is visibly incised by black fungi and related microorganisms

High numbers of strictly autotrophic *Thiobacillus* sp. have been found not only under surfaces of highly deteriorate stones which presented a pulverizing aspect, but also on deeper layers (10 cm) where there was no stone decay yet [14.120]. Some anaerobic species, like *Desulfovibrio desulfuricans*, are not strictly autotrophic and can sometimes utilize organic compounds as electron donors. They can find sulfate from air pollutants or from soil and produce hydrogen sulfide by the reaction:

This product is a highly corrosive acid and its salts provoke on open air stone surface the formation of black and/or grey films and crusts often described as patina. Sulfate-reducing bacteria increase the decay activity of sulfur and sulfide or thiosulfate-oxidizing bacteria causing a deeper biodeteriorating action. In fact, on soil *Desulfovibrio desulfuricans* reduces sulfates to sulfites,

Fig. 14.16 Macropitting by lichens in the Namib desert

thiosulfates and sulfur. By capillarity these compounds can reach the superficial layers of stones where sulfur-oxidizing bacteria will oxidize them to sulfuric acid. This strong acid reacts with Calcium carbonate to form calcium sulfate (gypsum), which is more soluble in water than calcium carbonate (calcite, aragonite, dolomite).

Nitrifying Bacteria. The nitrifying bacteria are commonly found on deteriorated surfaces of rock materials [14.114, 116, 119–124].

Dissolved and particulate ammonia is deposited on rock surfaces with rain and wind from various sources among which agricultural sources (fertilizer, manure) are the most dramatically influential. But also bird excrements and other ammonia and nitrite sources are oxidized microbially by chemolithotrophic and, in part also by heterotrophic ammonia oxidizers and nitrite oxidizers to nitrous and nitric acid.

This transformation is divided into two steps:

1. Oxidation of Ammonium by *Nitrosomonas*, *Nitrosococcus*, *Nitrosovibrio*, *Nitrosospora*:

2. Oxidation of Nitrite by *Nitrobacter*, *Nitrococcus*, *Nitrospira*:

Both of the resulting acids attack calcium carbonate and other minerals. The CO_2 produced is utilized to form organic compounds while calcium cations form nitrates and nitrites, the latter being more soluble than the original mineral phases. Capillary zones can accumulate these products and hydrated and nonhydrated forms of such salts can create considerable damage by volume changes of the mineral phases. The characteristic symptom of the activity of nitrifying bacteria is a change of stone properties. The rock becomes porous, exfoliation occurs and fine powder may fall off, which sometimes is yellow from freshly formed iron oxides. Some evidence of organotrophic bacteria exerting nitrification has also been collected (E. Bock, private communication).

Iron- and Manganese-Oxidizing Microorganisms

The most common iron-oxidizing microorganisms which are not living exclusively in lakes and flowing water like *Gallionella* or *Siderococci* belong to the groups of fungi, chemoorganotrophic bacteria (*Arthrobacter*) or to the autotrophic group like *Thiobacillus ferrooxidans*, *Ferrobacillus ferrooxidans*, *F. sulfoxidans*. The

type *Metallogenium symbioticum* has often been reported also in connection to weathering. *Krumbein* and *Jens* [14.115] have isolated numerous Fe- and Mn-precipitating microorganisms from rock varnishes and some of the isolates were closely resembling to *Metallogenium symbioticum*. *Krumbein* and *Schellnhuber* (personal communication) suggest that the organism does not really exist. The structures are fractal physical biogenic phenomena associated with fungal metabolism and iron and manganese oxide deposition outside the cell walls of the fungi. Iron-oxidizing bacteria attack directly iron rocks as well as any structure made of iron associated with stone monuments. Iron oxidation is usually rapid and is sensitive to pH and oxygen concentration. Ferrous iron is oxidized to ferric iron, which reacts with oxygen to form iron oxide (rust). This latter determines characteristic chromatic alterations on stones. These, however, are often over-emphasized as compared to organic pigments causing the same chromatic alterations [14.125].

Chemoorganotrophic Microorganisms

In recent years a constantly growing number of contributions was made about the impact of chemoorganotrophic microbiota also on the deterioration and biotransfer of materials of inorganic composition with no direct source of organic substrate. *Paine* et al. [14.126] were about the first authors to attract attention to the effects of chemoorganotrophic bacteria in rock deterioration. *Krumbein* [14.127] showed convincingly that the organic pollution within large cities might increase the abundance of chemoorganotrophic bacteria and especially fungi in rocks transferred from rural environments by a factor of 10^4 within one year. This group of microorganisms requires organic compounds as energy and carbon sources. Stone (as an inorganic material) can support chemoorganotrophic processes for several reasons. Four different types of sources of organic materials are usually present in variable concentrations on rock and mineral surfaces (mural paintings especially). These are:

1. Consolidating and improving products applied to the surface like wax, casein, natural resins, albumin, consolidants, hydrophobic agents.
2. Dust and other atmospheric particles (aerosols) and organic vapors. The latter consist mainly of hydrocarbons from aircraft and car fuels or power plants but also of agricultural applications like manure and harvesting dusts or just pollen and other compounds excreted into the air by plants and animals. In industrial areas and cities manifold organic sources stem

from industry and craft such as food factories, bakeries etc. Recently it has been calculated, e.g., that the total amount of fossil fuels in terms of organic carbon could derive from the annual production of pollen and etheric oils and volatile etheric substances (smell of flowers) that are carried into the sea.

3. Not less important is the coexistence of photo- and chemolithotrophic microorganisms with chemoorganotrophic ones in biofilms, biological patina and microbial mats encrusting the upper parts of rocks or the whole paint and mortar layer of frescoes. In this context the chemoorganotrophic bacteria and fungi can survive and reproduce themselves easily because they have all nutrients from autotrophic organisms.
4. Sedimentary rocks usually contain between 0.2% and up to 2% organic matter retained in the rock. These compounds serve as source of energy and carbon for many microorganisms.

Chemoorganotrophic Bacteria. Extremely high numbers of these bacteria have been reported on stones [14.116, 118, 127–131]. Eckhardt [14.114] has estimated that the rate of deposition of chemoorganotrophic bacteria from the air onto stone surface is about 10^6 cells/(cm²·d). Krumbein (personal comm. [14.132]), and Warscheid [14.133], however, have reported that airborne bacteria are usually of different genera and species than those settling and dwelling permanently on rocks. Bacteria migrate into porous materials with the flow of groundwater and rain water washings and can reach depths of 160 m in porous rocks. Present-day information confirms, that microorganisms will invariably be detected and active at depths within the Earth's crust, which exhibit temperatures below 110 °C!

Paine et al. [14.126] found *Bacillus* and *Pseudomonas* strains on decaying stones that are also distributed in soil. Detailed investigations of Warscheid [14.133], however, demonstrated that the rock flora considerably differs from the soil flora composition. Vuorinen et al. [14.134] demonstrate a slow decay of Finnish granite due to cultures of *Pseudomonas aeruginosa*. Lewis et al. [14.135] isolated from decaying sandstone *Flavobacterium*, *Bacillus* and *Pseudomonas* strains that showed a severe decay activity in test cultures. Warscheid [14.133] isolated high numbers of gram-positive chemoorganotrophic bacteria from both, carbonaceous and quartzitic sandstones. Most of them were able to grow under oligotrophic conditions. They demonstrated that coryneform bacteria are among the main decomposers of rocks [14.133].

Fig. 14.17 At the surface of marble tiny black colonies and satellite colonies of black yeast are visible to the naked eye. The connecting and nourishing mycelium can only be made visible by PAS-staining for polysaccharides

The chemoorganotrophic bacteria (and the fungi) will be especially detrimental and persistent on rock surfaces and within the rock pores when they produce adhesion-promoting extracellular polymeric substances such as slimes, fibrils and other means of attachment such as hydrophobic compounds. Fungi especially may form penetration pegs and hyphae, while at the surface black-stained small and resistant microcolonies occur. The true dimension of the attack is usually made visible only by staining (Fig. 14.17) or complicated thin section techniques (Fig. 14.18). Water availability and water activity in addition largely modifies the aggressiveness of chemoorganotrophic microorganisms versus mineral substrates. Mineral-bound water, surface films of nanometer-range on minerals and between the layers of hydrated clays as well as bacterially stored water have to be more considered

Fig. 14.18 Thin sections of marble can show as well the extent of drilling through grains and fungal penetration along grain boundaries

in environments which are under permanent stress of desiccation.

Chemoorganotrophic bacteria further determine their deteriorating action by metabolic products (acidic, alkaline and gaseous) [14.127, 131]. Another mechanism is the production of highly stable pigments. These in turn react with mineral elements causing an aesthetic deterioration and biogenic decay [14.125, 136].

Actinomycetes. These bacteria are thus called, because they similar to fungi form hyphae-like vegetative growth forms and produce spores similar to fungal spores. For this and other reasons their decay mechanism could be the same as of fungi (hyphae penetration and acids release). Among these microorganisms, the genus *Streptomyces* is most frequently occurring in biodeteriorated stone. Penetration of the substrate by their hyphae is increased by their ability to excrete a wide range of enzymes [14.137]. They can form a whitish veil or a granulose patina on mural paintings [14.125]. They also produce water-soluble and insoluble dark pigments. Recently it was documented, however, that they rarely if ever produce noteworthy amounts of organic acids and chelates in a rock-decay environment. They may have less detrimental activities. Their presence in high numbers, however, indicates a very intense population of fungi and other microorganisms. They can perfectly well resist dryness and therefore can be regarded as excellent indicators of a progressed infection of rocks and mural paintings by other microorganisms. Early stages of rock infections usually do not exhibit high numbers of this group of actinomycetes [14.138]. On the other hand the new edition of Bergey's Manual of Systematic Bacteriology suggests placing the Actinobacteria, among which some coryneform bacteria, as already formerly the nocardioform bacteria into the group of actinomycetes or Actinomycetales. The coryneform and nocardioform bacteria, however, have been identified as frequently occurring on rock materials and producing acids from organic pollutants on building stones thus contributing considerably to biocorrosion and biodeterioration [14.133].

Fungi. Fungi are very commonly found on stone surfaces [14.117, 139]. Their deteriorating effect is due to mechanical and chemical action. The first one is related to hyphae penetration of materials that has deep-reaching deteriorating effects such as swelling and deflation as physical effects, channelling water into and keeping it in considerable depths and constant microvibrations through micromotility; the second

one is due to production of acid metabolites (oxalic, acetic, citric and other carbonic acids). The latter have a chelating and solubilizing effect on many minerals [14.114, 117, 127, 140].

14.4.4 Biogenic Impact on Rocks

The phenomenological study from geological, chemical and biological groups together with many microbiological analyses of deteriorating rocks in a great number of monuments revealed various forms of deterioration such as pulverization, alveolarization, desquamation, exfoliation, efflorescences, black biofilms, films (patina), crusts and pitting [14.141–143]. Of these, pulverization and black crusts dominate sandstone and quartzitic sandstone while corrosion by biopitting and biofilms was observed more frequently on limestone and marbles. The mutual relationships and effects of biology and rock destruction phenomena as well as different corrosion levels depending on both the coating of lichens and biofilms or microbial mats and crusts were studied in many places. Environmental conditions including pollution and the mutual influence on rock biota have as well been studied. Therefore, now a selection of some characteristic examples can be described and brought in a biological context.

Pulverization

Both sandstone and quartzitic sandstone are mostly characterized by profound pulverization of the rock. This deterioration is evidenced by a reduction in cohesion and adhesion between structural components, with an increase in porosity and a reduction of the original mechanical strength leading to a spontaneous or weather or shock induced detachment of the rock material in powder form. Pulverization as a sandy surface phenomenon is also observed on limestones and marbles. In these rocks it is, however, usually by far less conspicuous than biopitting. Sometimes, this sanding changes into the formation of alveolar erosion, a deterioration of highly porous rock materials resulting in the formation of big and deep cavities. In its advanced state, it may lead to the tafonis characteristic for many desert environments [14.119, 144, 145].

In all these cases less algae, lichens and other conspicuous microorganisms are visible and involved in the biotransfer process. Chemoorganotrophic bacteria, ammonia- and nitrite-oxidizing bacteria (especially in tafonis) and masses of cocci (or coryneform bacteria) and rod-shaped bacteria forming slimes are often ob-

served in such places and can be correlated with this type of (bio-) corrosion.

Exfoliation, Chipping and Desquamation

Exfoliation and desquamation occur in most sandstone types and granites and gneisses analyzed, but may also be observed on limestones and marbles. These corruptions are marked by a lifting, followed by the detachment, of one or more large thinner (exfoliation), small thinner (chipping), or large thicker (desquamation) rock layers.

Throughout the lichenological study of monuments, the level of this type of (bio-) corrosion is positively correlated to the lichen covering, based on observations that these structures appear more intensive, the lower the degree of lichen covering, of which particularly the lichen *Lecanora conizaeoides* as well as, e.g., *Acarospora fuscata*, *Candelariella vitellina*, *Lecanora polytropa*, *Lecidea fuscoatra*, and *Physcia orbicularis* were observed on siliceous rocks exhibiting chipping and exfoliation. Often, a significant algal layer occurs besides the lichens mentioned.

Desquamation after crust formation is often observed when an endolithic algal mat is forming under high light conditions or surficial extreme desiccation. Also when dense endolithic layers of iron-mobilizing fungi do transform parts of the cement into new and fresh reddish iron incrustations, large desquamations may occur as it was especially frequently observed in the case of Schlaitdorfer sandstone at the “Kölner Dom” (Cologne cathedral). The same phenomena have also been observed in desert environments.

Patinas and Varnishes; Crusts and Incrustations

More or less dark-colored films, rock varnishes or patinas (often called scialbatura in the Italian and art history literature) as well as thinner or thicker yellow, reddish, brown and black epilithic and endolithic crusts are very typical for many biologically attacked and degrading rocks and tombstones. We are treating these phenomena preliminary in one section because the many different phenotypes have not yet been associated with appropriate chemical, physical and biogenic chemical and physical transfers of the original rock and mineral material.

In pollution-stressed environments sandstones can be covered by a black crust, a product of the transformation of the surface of the material including dust and soot. Its chemical and mineralogical nature and physical characteristics are partly or completely different from those of the substrate material from which it may be-

come separated sometimes by exfoliation in other cases even by pulverization underneath the black film or crust. The crust is composed of different hydrocarbons and alcohols as a result of air pollution agents and biogenic residues, especially EPS (extracellular polymeric compounds). The latter serve like flypaper as a trap and agglutinant for foundry or other ashes and dust particles when wet [14.127]. In the dry state they appear to have extremely high viscosity and serve as a migration and diffusion barrier to chemical compounds before completely rewetted. Even in the wet and swollen stage the EPS drastically reduce the diffusivity of gases and solutes into and out of the rock [14.119, 127, 133]. Gypsum as a biocorrosion product is frequently observed in these black crusts particularly in carbonate cemented sandstones, limestone and marble, but even in pure siliceous sandstones and granites. Natural basaltic rocks have also been analyzed and underneath crustose lichens biotransformation products of earth alkali containing feldspars have lead to white gypsum layers between the black basalts and the lichen crusts. The normal approach is, that acid rain especially near industrial centers and in big cities promotes transformation of limestone into gypsum crusts. This, however, is not true. Like in the case of the highly discussed damage to forests by acid rain, acid rain does not really damage building stones. In both cases other reasons are predominant: In the case of mineral transformations this is witnessed and evidenced by gypsum formation in remote desert regions, where no acid rain is documented. The view of microbiologists today is that microbial transformations of sulfur are the most active agent of transformation of calcium carbonate into calcium sulfate.

It is almost premature to analyze the biological impact on the various types of films, crusts, and patinas. Therefore, a few focal points shall be given to initiate discussion and further studies.

- (a) **Patinas and Varnishes (Scialbatura).** Yellow, red, brown, and black varnishes and surface films on many rock types are usually the product of repeated colonization by thin epilithic crustose lichens and/or fungal films on and beneath the surface of relatively dense rock materials such as the extremely low porosity marbles and quartzitic sandstone or silicified rock. A typical product of the biotransfer of mineral matter within these films (patina, scialbatura, rock varnish) is (1) the indicative high enrichment of manganese(IV) versus iron(III) with respect to rock derived and dust derived manganese/iron ratios (2) the often observed

ring-type distribution of such films, (3) the presence of calcium oxalates (weddelite and whewellite as well as iron and manganese oxalates such as humboldtine). A recent survey on biogenic pigmentations was given by *Krumbein* [14.125].

- (b) **Crusts and Incrustations.** Crusts and incrustations are often brought about by the same biotransferring microbiota namely biofilms and microbial mats of algae, cyanobacteria, fungi, lichenized fungi, and often also endolithic lichens with characteristic fruiting bodies. Epilithic biofilms and microbial mats on hard substrates will form **crusts** and crustose outwards-directed growth zones. Epi-endolithic biofilms and microbial mats will form more or less deep incrustations underneath the original and transferred rock surface. In these cases the degree of light penetration, humidity regimes and other biotic factors as well as the porosity of the usually more porous rocks will regulate the thickness of the incrustation and also the question whether the physical decay phenomena will lead to exfoliation, desquamation or other effects. *Krumbein* [14.144] has given a schematic presentation of the biofilm-derived entrapping and outgrowing crusts, which will lead to an addition above the original rock surface under desquamation or exfoliation of the outwards growing crusts together with some of the rock material underneath in cases.

Incrustations and the fate of the rock material in the case of incrustation by biofilms, slimes and microbial mats forming an endolithic dense network have been first described by *Krumbein* [14.144] and schematically elaborated in a morphological and geophysiological sense by *Krumbein* [14.146]. They occur especially in Mediterranean and arid zones. In some cases also endolithic lichens have been observed to form incrustations. The physical rock development after a hardening and solidifying period is often very thick desquamation of surface parallel layers of the whole building stone or natural rock surface to a depth of up to 1 cm. After desquamation a new crust may develop in turn.

Concretioning and other types of hardening of the original rock substrate may often occur during the biotransfer process especially in crusts and incrustations. Usually ultimately the rock in question will, however, suffer more serious damage than in the case of less hardened rocks.

Colorations

A phenomenon of rock alteration (physical, chemical and biogenic physical and chemical change) as well as

deterioration (worsening of the original rock material also in an aesthetical sense), closely related in most cases, however not in all, with patina, rock varnish, crust and incrustation is a general color change or coloration occurring with building stones and monuments. This is especially unwanted in the case of marble statues and sculptures in general. The surficial films and crusts may have yellow to black colors in special but also all other colors of the rainbow due to the following mostly biological or biologically catalyzed effects and products:

- (a) **Pigmented salts of iron and manganese.** Iron and manganese are the two most frequently occurring metals in rocks. Many of their hydroxides, oxides, sulfates, phosphates and oxalates are initiated by chemical reactions with the atmospheric environment and polluting agents but also very considerably by oxido-reduction reactions catalyzed by microbiota. The solution, complexation and precipitation of, e.g., calcium, iron and manganese leads to multicolored light-yellow to black staining on rock surfaces and within rock incrustations which may largely contribute to pigmentation and pigmentation changes in rocks [14.115].
- (b) **Organogenic pigmentations.** Many organogenic pigments do occur in nature and thus also in microbially influenced rocks. Naturally the mineral content of rocks and the different substratum does influence the coloring considerably. The dark-green to pitch shining black pigmentation of rocks is usually due to chlorophylls of cyanobacteria and algae growing on rock surfaces. When dry, all chlorophylls appear deep and shining black or lead-grey depending on substrate, concentration of chlorophyll per surface area and degree of wetness. Only in very rare completely wet conditions (growth period, not to be confused with the annual seasonality of, e.g., plankton blooms) the crusts will appear olive, bright, or dark green. Often one observes also brownish, grey and even black pigmentations of the biogenic crusts and biofilms when actinomycetes and some melanin-producing fungi are predominant. Protective pigments of the carotene type and other pigments may be produced and embedded into the EPS of algae and cyanobacteria as a shield against UV-light and further modify the pigmentation and coloration of rock films and crusts. Yellow to deep-brown and black stains may occur in very rare cases in which microbial nitric acid production leads to yellow to brown xanthoprotein reactions; perhaps even the caramelization effect of sugars

and other organic compounds may be produced by especially (biogenic?) sulfuric acid attack. This “caramelization” or “coalification” through concentrated acids has, however, never been proved on rocks. The Maillard reaction, however, which is so well known in the cooking environment (brown sauces) may play an important role also in the natural rock decay environment [14.125]. Lastly, the possibility exists that – upon the death of any microorganism – enzymes are excreted from the protected cell interior, which may react and form melanin in the environment of decaying cell masses. These processes, however, need enormous amounts of cells and proteins. It is thus probably rarely observed in comparison to other above-mentioned active staining processes, among which the tremendous potential of the black yeast-like fungi needs to be mentioned. *Gorbushina* et al. [14.147] gave an excellent insight into this exceptionally modern topic. The topic is modern in as much as it explains color changes in a new and logical way. The essence of this line of research is, that organic pigments attached or adsorbed to rock and soil particles may explain the color of soils and rocks in a much simpler way than any inorganic chemical pathway involving iron and manganese transformations.

Some of the aesthetically most detrimental and yet not fully understood colorations of marble, alabaster and other white rock sculptures and ornamental elements of buildings are pink, orange, cadmium and even carmine to violet red stains in many marble sculptures and mosaics. These stains have also been observed in some marbles of the Acropolis, Athens.

(c) **Colored dust trapping and binding.** Certainly dust particles entrapped and agglutinated mainly by the EPS of biofilms and rock-covering microbial mats in their active growth stages or after rewetting will be other major factors of coloration and pigmentation (flypaper effect). In the northern hemisphere it is usually the black of coal soot and flight ashes. In special cases flight ashes will also produce red colors, when originating from iron foundries and cokeries of lignite (brown or low-vitrinized coal). In other regions red stains are derived from hematite desert dust, which is carried through the stratosphere to far away regions. This was observed many times by Ehrenberg in the 19th Century.

(d) **Special heavy metal stains.** Special colorations (e.g., of surface films and crusts on metal containing monuments) may be derived from the (bio-) solubilization oxido-reduction and redeposition of the salts and minerals of copper, manganese, cobalt, silver, sulfur, and other elements. The most typical colors occurring on cemeteries are black and grey through lead letters, green and blue through copper alloys, red through iron and other specific stains usually biologically mediated [14.115].

Efflorescences and “Salt Nests and Carpets”

Incrustations usually are produced by a large amount of different microorganisms and their metabolic products as well as by the water supply and modification of the pore space by biological and chemical activities. In the process of this some salts are produced and remain stable for considerable time that are quite soluble alkali and earth alkali salts and double salts with often astonishing capacities of volume changes with temperature and humidity regimes. Up to 300% volume changes have been reported for such salts [14.127]. These salts frequently are the product of the rock-inhabiting microflora [14.127]. Often, the black surface crust is thus accompanied by efflorescences of salts. These crystalline formations of soluble salts on the surface of the object are whitish in color and incoherent. They may, however, be colored by the admixture of traces of reduced and oxidized iron as already suggested in [14.119, 127, 148]. Besides the typical crystals of gypsum, chlorides and nitrates and double sulfates have been analyzed by X-ray diffraction and EDX-studies. Oxalates (whewellite, weddellite and some rarer minerals such as the iron oxalate humboldtine, the magnesium oxalate glushinskite and the yet unnamed oxalates of manganese and copper or oxammite, ammonium oxalate) have been identified as microbial mineral transformation products in crusts and efflorescences [14.146, 149]. Depending on both, the rock material and the environmental conditions, the specific composition of these salts cannot be generalized. The efflorescences may be induced below the crust, which becomes then more and more separated from the substrate material. Many of the soluble salts may come and go with the waterfronts passing through the rock. It has been suggested that the mineralization is independent from the biological activities. This is, however not true. In and underneath lichenic crusts and in and underneath biofilms halophilic and highly halotolerant bacteria were found. In their vicinity new minerals have

been shown to occur, such as the phosphates apatite, struvite, dahllite, lazulite, wavellite, and even turquois or novaculite. Sometimes, the biogenic mineral formations only ephemerally play a destructive role and are later only identified by empty places of a specific mineral form near bacterial aggregates. The cleaving and fissuring effect and the strongest efflorescences are usually limited to the lower part of the tombstones, as a result of interactions with rising water from the subsoil that also contributes nutrients and rare energy sources such as hydrogen sulfide, methane and other compounds. Special salts like jarosite have been shown in many other places to be biogenic efflorescences and recently we have found much more salt efflorescence in highly saline mural paintings. In order to complete or almost complete the list of biologically influenced efflorescence minerals the sulfates, nitrates and even chlorides shall be mentioned that are a consequence of mainly chemolithoautotrophic bacteria but also of some chemoorganotrophs as is the case with oxalates and phosphates. Highly detrimental and often observed together with bacteria are the mixed (double-) salts of sodium, potassium, calcium and magnesium as glauberite, astrakanite, mirabilite, but also nitronatrite and nitrokalite. In special cases aluminum and silica salts and even new clay mineral formations have been reported but not yet solidly evidenced [14.114].

Biopitting

The term pitting as a synonym for smaller or larger crater-shaped cavities forming in many decaying rocks is derived from “coal and iron pit mining” of the primitive technological societies. The definition according to geological nomenclature is: “small indentation or depression left on a rock surface as a result of some corrosive or eroding process such as etching or differential solution”. We have identified and defined biopitting as the sole source of these crater-shaped cavities in many places, publications leading back to the book of Moses (Leviticus). Krumbein [14.144]; Krumbein and Jens [14.115], Gehrmann et al. [14.110, 111] and other scientists have now fully elaborated the micro-, meso- and macropitting as being caused mainly by endolithic and epilithic lichens. Danin et al. have substantially developed some of the work on biopitting [14.150]. On limestone and marbles biopitting, chipping, cracking and fissuring are frequently seen of which the biocorrosion by biopitting dominates. In all cases of studied biopitting the latter was correlated positively with epilithic or endolithic lichen species. This phenomenon of biocorrosive crater erosion was

first introduced into literature by Krumbein [14.144]. Gehrmann et al. [14.110, 111] have classified these characteristic holes and cavities into three size groups namely (1) micro-, (2) meso- and (3) macro-pitting of the rock surface. Of these, both, micropits and mesopits were identified, upon maceration, as produced by the activities of the calcicole lichen *Caloplaca flavescens*. The specific pitting pattern indicated by the penetration of bundles of hyphae (Mesopits) as well as by individual hyphae (micropits) is clearly to be seen on the rock surface. When the pits fuse they may cause kinds of alveolarization but of a significantly different morphology [14.144]. In view of the general importance of this biogenic process the present classification is given here:

- 1) **Micropitting.** In this case etching figures are observed which correspond very much to the pencil etching described by mineralogists. They are caused by individual cells and trichomes or mycelia of fungi and are only visible by scanning electron microscopy. The diameter of these micropits is between 0.5 and 20 μm . The depths can reach several micrometers and even hundreds of micrometers in special cases.
- 2) **Mesopitting.** In this case we are dealing with the etching figures of the fruiting bodies of endolithic lichens, in some cases also with the “nap-shaped” grooves of cyanobacteria and/or algae underneath a crustose lichen film. They form little pockets which, upon further biocorrosion or chemical weathering have the shapes of half-ellipsoids or lens type cavities. Also fungal hyphae can be associated with this pitting type. The diameter of the craters is usually between 20–800 μm .
- 3) **Macropitting.** These are the typical pits and scars clearly visible on many statues and marble monuments all around the Mediterranean but also on a smaller scale in Potsdam and northern areas. A schematic model of pit formation has already been published [14.146]. In this case we are dealing with the not yet sufficiently analyzed “fusion” of several pits in which fractal physical patterns may also play an important role. Some of the macropits are also derived from deeply incising epilithic lichens of ill-defined taxonomy. The macropits usually range in diameter from 1 mm to maximally 2 cm and depths between 1 and 5 mm.

The processes of mesopitting and macropitting produce characteristic depressions, which are ovoid or circular at the rock surface, the diameter of which is usually at least double the size of the depth. The process of bio-

pitting is well separated from the well-known, but very badly understood process of alveolization of many limestones and sandstones. Water potential and availability as well as microchemical gradients play an important role in these interesting formations observed also in many Greek temples (Akrokorinth). Alveoli usually reach sizes of 1 to several cm in diameter and are almost always deeper than their diameter.

Pitting or better biopitting thus is an exclusively biological process related to endolithic and epilithic lichens in almost all cases with a few exceptions of lichenized fungi without a defined lichen thallus and fructification.

Swelling

Another deterioration phenomenon, formerly assumed as abiogenic was called “swelling”. Swelling leads to a gradual physical relaxation of the mineral context within the complex aggregate called a rock or a building stone. It has to be kept in mind that physically, chemically and mineralogically a rock is not something in which particles or minerals are glued together by a sort of glue or cement. On the contrary: rocks are aggregates of smaller or larger individual mineral or rock particles of which some, because they are younger or smaller are conventionally called “cementing minerals” that by physical and chemical history are intimately mixed and entangled into a more or less solid, more or less hard, more or less age and decay resistant, more or less porous aggregate. The contacts between the smaller or larger particles follow all the same physical rules of electrostatic, van der Waal or other adhesion and “stickiness” promoting forces including very thin-layered water molecule, organic molecule and gas molecule films. The best example of such a noncemented aggregate perhaps is marble with its relatively uniform calcium carbonate crystals, its micro- and macroporosity and its sudden structural disintegration. It has to be kept in mind, however, that all other rock types, albeit more complex are nothing else but densely packed particles. The weakening of the adhesive forces can be brought about by mechanical causes (less load after quarrying, earthquakes, vibrations, even storm shock waves), chemical causes (gases, liquids, redox-processes) and especially by biogenic forces and products as described before. Swelling (namely of EPS) is a very typical biogenic physical rock transfer action that contributes largely to pulverization, chipping, exfoliation and even to pitting.

A lichen crust that is often bending out before it breaks away from the surface always has some rock particles adhering. Such patterns of biogenic initial stages of desquamation is connected

with epilithic crustose lichens, especially *Acarospora fuscata*, *Candelariella vitellina*, *Lecanora grumosa*, *Lecanora polytrapa*, *Lecanora rupicola*, *Lecanora sulfurea* and *Lecidea fuscoatra*. Removing the lichen crust, an advanced state of incoherence of the rock surface layers is recognizable, characterized by an increase in porosity and an apparent decline in the original mechanical strength. Moreover, longitudinal sections of such lichen-encrusted sandstones reveals an extensive compact network of hyphae penetration up to 3 mm inside the rock. Often and even in the absence of lichen hyphae a very dense, slimy layer of EPS is observed in contact with the mineral grains and the uppermost layers of an endolithic or epilithic rock film or microbial mat. These slimes or EPS, among which a high percentage of polysaccharides and their acids have a phenomenal capacity of swelling with water. Many bacterial EPS (often also designated as alginates) and lower and higher eukaryote water retention systems as, e.g., *Laminaria* spp. and *Sphagnum* spp. may swell with sufficient water supply to 1600% of the dry weight and can reach more than ten-fold volumina easily. These swelling and contraction stresses are some of the most dramatic biogenic physical transfers in the disintegration of aggregates such as rock, plaster, mural paintings and other materials. EPS, cellular and hyphae swelling and water retention and transport capacities are usually more damaging even as the volume changes in the alkali and earth alkali salts mentioned in the section on internal and external efflorescences.

14.4.5 Biogenic Impact on Metals, Glass, Pigments

Interaction of Microorganisms with Metals

Microbial degradation of metals is associated with a wide range of biochemical processes, including acid metabolite production and galvanic coupling. Chemolitho- and chemoorganotrophic microorganisms exert an active corrosive action on metals by production of inorganic and organic acids. *Cladosporium resinae* causes corrosion of aluminum alloys by the secretion of citric, isocitric, *cis*-aconitic, and α -oxoglutaric acids, resulting in pitting and selective removal of zinc, magnesium and aluminum, leaving copper and iron aggregates behind. This suggests that microbial acid corrosion plays an important role in pitting corrosion [14.151].

In recent years some bronze monuments have been exhibiting serious corrosion damage in the form of “patina”. It starts as a reddish-brown oxide skin to a black coating, which intermingles with green patina under-

neath. In this phenomenon also bacteria are involved. In fact, organic matter reacts with mineral particles (from metals in the bronze and/or deposited by the environment) and the consequence is corrosion processes. The loss of material beneath a patina surface is “just” some microns each 100 years or so, but it is these microns that represent a large part of a bronze’s artistic qualities.

Bacterial extracellular polymeric substances (EPS) are a crucial factor to microbial corrosion. They strongly bind the metals, with a wide range of variations that influence its adhesion to metal surfaces and result in preferential oxidation of particular metal species [14.152]. The primary mechanism of bacterial corrosion of metal surfaces involves the creation, within an adherent biofilm, of local physicochemical “corrosion cells”. The practical consequence of this perception is that bacteria must be in sustained contact with a metal surface, in well-organized microbial communities before the corrosion process is initiated. Bacterial corrosion seems to occur only within the biofilm! [14.153]. It often shows the same biopitting characteristics as on marble and glass, i.e., small crater-shaped holes and pits going several hundred micrometers deep through patina and material.

Interaction of Microorganisms with Glass

Biocorrosion of glass was observed on optical glass corroded in tropical climates and on church windows and other some objects [14.146, 154, 155]. Even if some authors [14.156] suggest that biodeterioration is a minor and negligible process, others had demonstrated the important role played by lichens [14.157, 158] by fungi and other microorganisms [14.159, 160]. *Krumbein* et al. stated that microbial growth can occur on clean glass in the presence of sufficient humidity. In addition of the supply of hydrating forces, bacteria and fungi act as physical and chemical agents. They can also metabolize, leach, accumulate and redeposit elements like K, Ca, Mg, Fe, Mn, Ag, P. On dirty glass, water supply and pollutants deposited on it act as growth-supporting substrate. As a result of the establishment of microbial communities often pits are formed and/or other etching figures that can be clearly related to microbial activities.

Interaction of Microorganisms with Pigments

Mineral, plant and animal pigments can be more or less susceptible to light (especially plant pigments), but the most important factor of their susceptibility to degradation is the addition of organic substances like albumen,

casein, wax, arabic gum, etc., which are an optimal growth substrate for microorganisms. Some of them provoke chromatic alterations by release of acid or alkaline products (e.g., turning to blue of malachite green). Many fungi and bacteria can cause pigment alterations and addition of detrimental and disturbing fluorescent pigments that are added to the pigments in wall paintings and thus altering the total appearance of the mural painting.

14.4.6 Control and Prevention of Biodeterioration

The main effort in the study of biodeterioration of works of art and the interaction of macro- and microorganisms with the materials of which the objects exist is to understand the deteriorating activity and as a consequence to develop specific and specialized methods for controlling the growth of organisms responsible for and hereby preventing the biodeterioration of these valuable materials for as long as possible.

The choice of methods is related to (1) the nature of the material (stone, wood, paintings, paper, glass, etc.), (2) its location (archeological area, museum, church, library, etc.), (3) the extension and form of treated surfaces (little objects, statues, buildings, walls), (4) the processes physical/chemical and organisms involved (macro- or microorganisms). In fact, no method exists that is an overall remedy for all materials, objects and organisms. Impregnations with consolidants and water-repellent substances have been frequently proposed and used and the interactions of these compounds with microbiota were discussed [14.127, 161, 162]. The substances that have been tested and used range from silanes and siloxanes over acrylic resins and polyurethanes to epoxy materials, vinyl polymers, inorganic materials to natural oils, waxes and other substances. Very dangerous and perilous substances seem to be fluorosilicon compounds and several hydroxides that have been frequently used as well as water glass in the past centuries and in the early decades of this century.

In the context of this mainly microbiological review, however, biological methods of treatment and the microbial interaction with chemical consolidants is far more of interest. In the control of biodeteriogenic organisms growing on and in buildings or monuments, as well as other objects of art, the first step should be to eliminate the most determining factors favoring or accelerating biodeterioration: light, temperature, relative humidity (RH), nutritive factors, dust, dirt, etc. This is easier in indoor environments

while it is not always possible in outdoor environments, where however, the use of particular devices like environmental recovery and protective measures can keep these parameters in a range of acceptability. Prevention of biodeterioration of indoor objects is largely determined by the conditions of the environment where the object is kept (exhibition or storage). Low RH, conditioning systems and periodic cleaning can control growth of microorganisms. *Valentin et al.* [14.163] found that the combination of low RH and low oxygen levels significantly decreases microbial activity on solid support. Previously *Curri* (pers. comm.) suggested keeping valuable sculptures made of marble under an inert atmosphere of nitrogen. Nitrogen, however, may not prevent totally microbial growth in humid conditions. Thus the prevention of humidity must be added. These latter methods, however, are noninvasive, safe and relatively inexpensive and could be an important alternative in the field of conservation of art materials in museums.

As stated by the relevant Italian Committee (Normal B doc. 33/88) presently mechanical, physical, biological and chemical treatment methods are in use. These techniques have been published by *Pochon and Tardieux* [14.164] and are mostly still in use. Molecular techniques are amply described in *Saiz-Jimenez* [14.162]. Detail microscopy can be applied following classical direct and replica techniques. Recently we have applied also atomic force microscopy (AFM) which enables quantitative approaches to the volume of material loss by, e.g., biopitting.

The choice of methods should be taken with care because such methods affect frequently not only the organism causing deterioration but also the work of art itself or the stabilizing and consolidant additives.

- **Mechanical methods** consist in the manual removal of biological structures. This is actually what Hooke did with his valuable book infected by the imperfect fungus revealed for the first time to the eye of a microscopist. These methods, however, have not a great efficiency because they do not totally eliminate the organisms present. They have a useful function, however, in the first step of cleaning operations when it is useful to reduce the biomass and then to continue with other treatments.
- **Physical methods** have a narrow range of applications and have been used to control the growth of algae and cyanobacteria in indoor plaster and walls (MUVU) [14.165] and as deterrent for pigeons (low electricity impulses). Gamma irradiation

is used to sterilize library materials and was tested at Sans Soucis in the last Century.

- **Biological methods** utilize either specific nutritive requirements of organisms or biological antagonisms of different species to eliminate undesirable growth [14.166]. Lal Gauri and co-workers have proposed a biotechnological treatment of sulfated marble (black crust) using a broth containing a mixed culture of an oxidizing bacterial biofilm producer and an anaerobic bacterium *Desulfovibrio desulfuricans* that transforms gypsum into calcite. These methods are subject to criticism of their control and incomplete removal after treatment.
- **Chemical methods** are the most frequently employed. They consist in the application or fumigation in the environment by chemical compounds with biocidal activity. The choice of biocides to be used during conservation and restoration of works of art is not easy. It involves factors like:
 - specific efficiency towards the biodeteriorative agents
 - toxicity towards the person applying the technique
 - damage potential towards the work of art
 - relative ease of application and availability.
 Before applying this kind of products, e.g., on stone in objects of art they must firstly fulfil some prerequisites:
 - a) efficacy – it is influenced by: (1) dose expressed as amount of product/surface unit; (2) action spectrum (range of sensibility of microorganisms involved); (3) persistence of the active principle,
 - b) toxicological characteristics and pollution potential – it should be considered from the view of operators care and environmental risks,
 - c) noxious interference with the substrate,
 - d) outdoor environments (archeological area, buildings, statues of different material).

Mineral Materials

The microbial attack and thus the necessity of treatment of rock and mineral material is usually restricted to outdoor objects, since indoor objects rarely exhibit serious microbial decay phenomena. We have, however, several times been asked to analyze serious fungal infections of statues which are stored in humid conditions in magazines and store rooms and have persistent fungal infections. Detailed recommendations on use and application of biocides on stones are described in the Document Normal 33/88 (CNR-ICR, 1988). It is

stressed, as a partly general criterion, that biocides in order to avoid the interference with substrate must have no coloration, no chemical or physical reactivity capable to modify the characteristics of stone. Biocides, also, must be washed (pulled off) after their time of action. In this way risks of interference between residues of the applied products and stones are reduced to a minimum. Also the danger of damage to the personnel and visitors is reduced this way. Some indication on modern approaches to polyphasic biocidal treatments can be

viewed on the Website of BIOGEMA under EU projects (<http://www.biogema.de>).

Tests with biocides on different kinds of stones and other mineral materials (*Groß* and *Krumbein*, personal communication) have put in evidence, that the efficiency of a biocide of a given concentration in direct contact with the material to be treated can largely vary with lithotypes (e.g., effectless when applied to limestone, while considerable effect is stated when applied to the same flora on sandstone).

14.5 Coatings and Coating Materials

14.5.1 Susceptibility of Coated Surfaces to Fungal and Algal Growth

It is widely recognized that surface coatings can be susceptible to contamination and spoilage by microbial growth during service [14.167]. Examples of growth of fungi and algae on exterior facades are common (Fig. 14.19) and strategies to limit their growth are widely accepted in the industry. In general, these strategies rely on the inclusion of an antimicrobial agent [14.168] into the formulation and its presence inhibits the growth of microorganisms when the coating is used in areas where microbial growth is known to occur. In exterior conditions, growth is often an aesthetic problem although as it progresses, physical damage to the coating can occur. However, in interior situations, growth of certain fungi on surfaces has been implicated in human respiratory disorders [14.169]. In these circumstances limiting fungal growth on coatings has an impact on human health. Coatings for submerged sur-

faces such as the hulls of ships also suffer from problems associated with the growth of microorganisms (principally algae) along with colonization by species of molluscs and crustaceans.

While behavior under normal conditions of use will always be regarded as the definitive test for performance, a number of laboratory tests have been developed to provide a more reproducible and rapid means of gathering data. These tests can be combined with weathering studies ranging from simple leaching in water, through the use of weathering cabinets, to the prior exposure of coated surfaces under field conditions as is employed in studies on the efficacy of treatments on timber against blue-stain in service (Sect. 14.2).

Aside from field exposure, there are two major approaches that are employed to examine the susceptibility of surface coatings to fungal and algal growth. In the first, an artificial substrate (such as a glass fiber or paper filter) is coated and then placed onto a semi-solid microbiological growth medium in a petri dish. The coating and, in some cases, the medium is then inoculated with either single strains of test species or a combination of such strains (Fig. 14.20). This provides a highly accelerated mechanism of testing although it can be argued that the presence of a growth medium, which may diffuse into the coating, can result in the growth of species that are not true biodeteriogens of the coatings system under test. This is especially true when testing for activity against fungi and in some instances a non-nutrient medium (or at least one lacking a source of carbon) is employed such that it simply provides a source of moisture and, occasionally, certain essential trace elements. Of course when testing algae a source of light is essential and this is usually defined in the method and in some cases reproduces a normal diurnal cycle. The major test protocols employed for surface coatings are

Fig. 14.19 Growth of algae on a painted facade

Fig. 14.20 Growth of fungi on a coated filter paper (prEN15457)

given in Tables 14.16–14.18 below, although in some instances, where particular specifications are being defined (such as powder-coated materials for military applications) methods such as ISO 846 and BS2011 Part 2J are employed. Until relatively recently many workers have based their tests on the conditions described in ASTM D5590-94. However, especially within the EU, the guidelines provided by VdL have formed the basis of so-called ‘filter paper tests’ for many laboratories and companies. These guidelines have also formed the basis for two provisional EN norms intended for use in providing data on the suitability of biocidal products to protect paint films in support of requirements of the Biocidal Products Directive [14.170]. While these ‘filter paper tests’ can provide data on compatibility of biocidal products with coating formulations and may even be correlated with performance under field conditions in some circumstances, many coating companies and test institutes regard them as useful screening tests and prefer cabinet-based simulation tests. Probably the most widely employed cabinet-based tests are BS3900 Part G6 (in Europe), ASTM D3273-00 (in the USA) for fungi and the IBRG algal test (Table 14.18). In all cases the same basic principle is applied where a combination of either fungal spores or algal cells are applied to the surface of replicate test panels. These panels are then incubated under conditions that are suitable for the growth of the species under test. After the specified interval, the panels are inspected for growth and rated and, probably most importantly, their appearance is recorded photo-

Fig. 14.21 Fungal and algal growth on panels from a cabinet test (BS3900 Part G 6 and IBRG Algal Test)

graphically (Fig. 14.21). As discussed earlier, coatings can be subjected to a number of ageing processes prior to inoculation/incubation to simulate a service cycle (e.g., paint might be aged in the can prior to application, be subjected to exposure with water spray and UV light in an exposure cabinet, be soiled or abraded). Multiple inoculation events can also be employed and soiling agents applied. Such approaches have been applied to a wide range of coating applications from traditional exterior and interior coatings to powder-coated panels used in air-conditioning systems. One of the great strengths of cabinet-based tests is the ability to use a substrate appropriate to the coating under test (wood, plaster, concrete, steel etc.) and study interactions between the substrate and the coating. Modifications can even be used to explore the impact of environmental factors such as temperature and relative humidity on colonization and growth.

As discussed earlier, outdoor exposure trials are often considered to be the definitive means of testing coated surfaces (and indeed almost the only method employed for marine and freshwater anti-fouling products) however, care needs to be taken to ensure useful data is obtained. The amount of growth that is obtained on test panels differs greatly from location to location. Panel orientation (vertical, horizontal, north facing, south facing etc.), height above ground level and even the time of year in which the trial is initiated can have a highly significant impact on the outcome. This has been examined extensively in [14.171] and many companies employ multiple sites and long-term exposure periods to ensure they gain a thorough understanding of the potential performance of their systems (often in support of products developed using laboratory-based methods and already on the market).

Table 14.16 Methods used to examine the resistance of surface coatings to fungal and algal growth

Reference	Title	Description	Major principle
BS3900 Part G6	Assessment of resistance to fungal growth.	Replicate test panels coated with the test coating are inoculate with a suspension of spores of fungi known to grow on the surface of paints and related materials. The samples are then incubated under conditions suitable to support fungal growth (23 ± 2 °C and high humidity/surface condensation). In the published standard, condensation on the test panels is achieved by increasing the temperature in a water bath below the samples for short periods of time. Revisions are in progress which may obviate this step. The method is validated by the need for fungal growth/germination of spores to be observed on a standard coatings known to be susceptible to fungal growth after incubation for 2 weeks. After incubation growth is rated in accordance with a scale related to the percent cover with fungal growth (following visual and microscopical examination). A natural and artificial soiling agent are described in the method which can be employed when appropriate.	Growth cabinet based test.
ASTM D3273-00	Standard test method for resistance to growth of mold on the surface of interior coatings in an environmental chamber.	Replicate test panels coated with the test coating are inoculate with a suspension of spores of fungi known to grow on the surface of paints and related materials. The samples are then incubated under conditions suitable to support fungal growth.	Growth cabinet based test.
ASTM WK4201	Standard test method for resistance to mold growth on building products in an environmental chamber.	Replicate test panels coated with the test coating are inoculate with a suspension of spores of fungi known to grow on the surface of paints and related materials. The samples are then incubated under conditions suitable to support fungal growth.	Growth cabinet based test.
ASTM D5590-2000(2005)	Standard test method for determining the resistance of paint films and related coatings to fungal defacement by accelerated four-week agar plate assay.		Agar plate test.

Susceptibility of Coating Systems to Microbiological Growth in Their Wet-State

Many coatings systems are either entirely or at least substantially water-based and, without some form of protection, are susceptible to spoilage through microbial contamination of the product in its wet state [14.172]. Continued regulatory pressure is also resulting in the reduction/elimination of co-solvents that contribute to the overall concentration of volatile organic carbon (VOC). This is leading to an increase in the degree of susceptibility of many products including those which have formerly been protected by the antimicrobial properties of co-solvents present in the formulation (e.g., 2-butoxy ethanol in waterborne paints for automotive applications [14.173]). In-can preservation systems are now used in many coating formulations to prevent spoilage due to microbiological growth such as the development of foul odors, discoloration, loss of structure and the generation of gasses that might distort/damage the final packaging. The protection provided includes the interval during manufacture as well as storage both within the plant and prior to sale. The protection should

be sufficient to provide a shelf-life suitable for the product and may be extended to allow storage of part-used containers by the end user.

By far the most common approach to assessing both the susceptibility of a coating formulation to microbiological spoilage and the potential efficacy of a preservation system is a microbiological challenge test. A relatively limited number of standard test protocols have been developed over the last few decades (e.g. ASTM D 2574 - 86) and some operators have tried to employ methods based on those described in the various pharmacopoeias for cosmetics and pharmaceutical products although these have been found to be far from satisfactory. The International Biodeterioration Research Group (IBRG) has been developing a test protocol for testing the in-can preservation of paints and varnishes. Although still under development it is the most common method employed by workers in the field although in many cases some modification is made to the method described [14.174]. The method uses a combination of microorganisms which have been demonstrated to grow in water-based paints to challenge a paint formulation

Table 14.17 Methods used to examine the resistance of surface coatings to fungal and algal growth (cont.)

Reference	Title	Description	Major principle
SS345 Appendix B	Formal title missing at present.	The bottom of glass petri dishes are coated with paint. After drying a culture of algae in a suitable growth liquid medium is placed into the dish and incubated under conditions suitable for algal growth.	Liquid immersion test.
prEN15457	Paints and varnishes – Laboratory method for testing the efficacy of film preservatives in a coating against fungi.	Coatings are applied to glass fiber discs and then placed in intimate contact with the surface of nutrient agar plates. The coatings and surrounding media are then inoculated with a mixed suspension of spores of 4 fungal species selected from a list of 10. The plates are then incubated at 24 °C for X d and then assessed for growth using a rating scale. The test is intended to support claims that a biocide can have an effect in a surface coating in support of its listing in the relevant use category within the EU BPD. It is not intended to assess the performance of surface coatings.	Zone diffusion assay/agar plate test.
AS 1157.10 - 1999	Australian standard – Methods of testing materials for resistance to fungal growth. Part 10: Resistance of dried or cured adhesives to fungal growth.	Test materials coated onto glass microscope slides are inoculated with a suspension of spores of a range of fungal species and then incubated on the surface of a mineral salts based agar for 14 d and then assessed for growth.	Agar plate test.
prEN 15458	Paints and varnishes – Laboratory method for testing the efficacy of film preservatives in a coating against algae.	Coatings are applied to glass fiber discs and then placed in intimate contact with the surface of nutrient agar plates. The coatings and surrounding media are then inoculated with a mixed suspension of 3 algal species selected from a list of 5. The plates are then incubated at 23 °C under illumination (16 h day length, 1000 Lux) for X d and then assessed for growth using a rating scale. The test is intended to support claims that a biocide can have an effect in a surface coating in support of its listing in the relevant use category within the EU BPD. It is not intended to assess the performance of surface coatings.	Zone diffusion assay/agar plate test.

on a number of occasions. Pre-incubation of samples at elevated temperatures prior to inoculation can be used to explore the interaction of biocidal products with the formulation as well as the loss of highly volatile materials and the decay of other reactive components. It has been argued that only two repeat inoculations are required to simulate the interaction of the microorganisms with a paint formulation [14.175], however, most workers in the field recommend that a minimum of three repeat inoculations (usually at weekly intervals) be applied [14.174]. However, care must be taken not to continue re-inoculation until growth is achieved in the formulation. While this could be used to bioassay the concentration of preservative within a system, it provides less information about the interaction of a preservative system and the paint formulation than a carefully structured trial including phases of ageing and relatively short campaigns of microbiological challenge. As with the number of inoculations, both the cell density and the volume of inoculum should be kept within a sensible

range both to prevent the test from becoming a disinfection test and the formulation being diluted unnecessarily. Typical total bioburden applied is often in the region of 10^7 colony forming units/g with an inoculum volume of between 100–500 µl per challenge.

After inoculation, the paint is examined for the presence of viable microorganisms. The paint is examined at least just prior to the next inoculation although in some cases analysis at intervals between the two inoculations (e.g. 1 and 3 days) can provide useful information. Many works utilize some form of semi quantitative technique to estimate the size of any population surviving after challenge using the argument that any significant growth/survival represents a failure of the in-can preservation system. The use of a fully quantitative technique (with appropriate neutralization of preservative) can be useful in some circumstances. Techniques such as impedimetry and the measurement of metabolic markers like adenosine triphosphate (ATP) have been employed with success, however, care must be taken to ensure

Table 14.18 Methods used to examine the resistance of surface coatings to fungal and algal growth (cont.)

VdL RL06	Guideline to evaluate the resistance of coating materials against mould growth.	Coatings are applied to paper discs and then placed in intimate contact with the surface of nutrient agar plates. The coatings and surrounding media are then inoculated with a mixed suspension of spores of <i>A niger</i> and <i>Penicillium funiculosum</i> . The plates are then incubated at 28 °C for 3 weeks and assessed for growth using a rating scale after 1, 2 and 3 weeks. Coatings for exterior use and 'wet' applications are leached in water prior to testing.	Zone diffusion assay/agar plate test.
VdL RL07	Guideline to evaluate the resistance of coating materials against mould growth.	Coatings are applied to paper discs and then placed in intimate contact with the surface of nutrient agar plates. The coatings and surrounding media are then inoculated with a mixed suspension of <i>Scenedesmus vacuolaris</i> and <i>Stichococcus bacillaris</i> . The plates are then incubated at 23 °C for 3 weeks under illumination (16 h day length, 1000 L) and assessed for growth using a rating scale after 1, 2 and 3 weeks. Coatings for exterior use and 'wet' applications are leached in water prior to testing.	Zone diffusion assay/agar plate test.
IBRG Algal Test	Method to determine the resistance of surface coatings to algal growth.	Replicate test panels coated with the test coating are inoculated with a suspension of cells of algae known to grow on the surface of paints and related materials. The samples are then incubated under conditions suitable to support algal growth (18 ± 2 °C and high humidity/surface condensation/illumination – 1 Klux, 16 h photoperiod) for up to 12 weeks. After incubation, growth is rated in accordance with a scale related to the percent cover with fungal growth (following visual and microscopical examination).	Growth cabinet based test.

no adverse interaction between the formulation and the system results in misleading data.

While it is important that challenge studies on coating formulations use a relatively wide range of microorganisms (principally bacteria, but certain yeast and filamentous fungi can be relevant to certain formulations), a significant fraction of these should have been derived from spoiled formulations at some time in the past. They should obviously be maintained in such a manner that they do not lose the ability to grow in paint matrices and some form of passaging may be required to ensure this (Sect. 14.6). Ideally, at least part of the challenge microorganisms should be shown to actually be capable of growing in the unprotected formulation under examination. Although they can be relevant to the spoilage of paint, care should be taken when considering the use of endospore-forming bacteria (and the spores of some species of fungi) as the survival of spores within the system can prove difficult to interpret. In many cases, studies with these species should be performed at least alongside the main challenge studies. In many variants of the basic challenge method, the cell suspensions used to create the challenge consortia are prepared from organisms grown on solid nutrient media. However, it can be argued that organisms grown in carefully standardized liquid culture (e.g., in shake flasks) are more suitable as they better mimic the manner in which contamination is introduced in practice (i.e., through the contact of paint

with contaminated wash water in a production environment and via water contained in brushes and rollers used to apply the product). The use of contaminated paint has been used as a mechanism to inoculate test products but this can be difficult to standardize, may be highly selective toward certain components of a consortium and may stimulate the formation of capsules and exopolysaccharide in the challenge species and lead to the prediction of the need for excessive concentrations of preservative.

The principle of the challenge test can be a useful tool in the prediction of both the susceptibility of a coating formulation to microbiological contamination and spoilage and the efficacy of systems designed to preserve it. Careful use of appropriate ageing, incubation conditions (temperature etc.) and challenge consortia can be used to match a method to a wide range of system types from emulsion paints to industrial electrocoat systems. In-can protection of water-based tinters have been studied with success using the principles described above, however, the simulation of growth of fungi on the surface of such systems has yet to be successfully simulated in the laboratory and is the subject of concerted international research at the time of publication [14.176].

Hygienic Coatings

Although antimicrobial activity has been a component of certain coating systems for many decades, in the last few years this activity has been extended to provide a wider

spectrum of activity and coatings are now being produced which are intended to provide hygienic benefits to the surfaces coated with them [14.177, 178]. In part, these developments have been fuelled by a raised public interest in hygiene resulting from high profile food poisoning outbreaks and the current high rate of hospital acquired infections.

The control of microbial activity associated with the spoilage of coated surfaces as described above, usually depends on the use of antimicrobial agents to prevent growth in association with the material to be protected [14.168]. In traditional applications, the addition of the antimicrobial agent is intended to protect the coating either during manufacture, in storage or in service. For example, a coating system intended for use on the outside walls of a building might be formulated with the addition of a fungicide and algicide to defend it from attack by microfungi and algae and so protect the film from aesthetic defacement and surface deterioration in service. In this instance the use of antimicrobial agents in the coating is intended to prevent microbiological deterioration of the surface. However, in recent years a new form of interaction between surface coatings and microbial populations has emerged along with a plethora of other materials modified to elicit similar effects [14.179]. In part, these new materials can be viewed as demonstrating either an extension of the degree of protection provided to them by the inclusion of an antimicrobial agent or as the transfer of the properties of external treatments into the material itself. The inclusion of the antimicrobial agent is now not simply intended to protect the material from deterioration but to exert a biological effect either to the immediate surrounding of that material or to items that come into contact with it. These effects may range from the prevention of growth of undesirable microbial populations on a material to which they pose no physical, chemical or biological threat, (e.g., the proliferation for bacterial species such as *Listeria monocytogenes* on surfaces in a cook/chill production unit) to the immediate destruction of individual microbial cells as they come into close association with its surface (possibly without even coming into direct physical contact). In all cases the effect is external to the material and is not merely present to protect either the material or the article/surface itself. In this context, we are now dealing with treated articles [14.180]. Coatings which impart such properties on the surfaces to which they are applied can be considered to be transforming technologies. They transform objects/surfaces into treated articles. For example, a door handle coated with a powder coating which claims

to have antimicrobial properties has transformed that door handle into a treated article and the testing technology needs to be able to provide data that is consistent with the claim made.

As mentioned above, there are several methods in use around the world which are employed to examine the effect of microorganisms on coated surfaces and measure the performance of additives used to protect them from microbial spoilage (mainly fungi and algae). A number of examples are given in Tables 14.16–14.18. However, there are no formal tests which are intended to measure the ‘hygienic’ effects of antimicrobial coatings although in some cases (e.g., inhibition of fungal growth), certain tests described in Tables 14.16–14.18 could be employed for that purpose. A number of test methods do exist for other treated articles (e.g., nonporous polymeric materials see Tables 14.19 and 14.20) and some of these may again prove appropriate for coated surfaces. These methods predominantly examine the effects of such articles against bacteria but, again, these could be modified to suit other types of microorganism (e.g., yeasts and fungal spores). Although no standard methods yet exist for the determination of virucidal activity on surfaces, a test based on JIS Z 2801: 2000 has been described.

Many bacterial test assays rely on the production of growth on nutrient media to visualize their effect. Zone diffusion assays are commonly employed to investigate antibacterial agents such as antibiotics [14.181]. Their use for examining antibacterial coatings could be confusing, however, as in some systems it would be difficult to separate the residual effect of the in-can preservative from true antibacterial activity (Fig. 14.22, [14.169]). These methods also do not generate the truly quantitative data which will be required for the support of claims for treated articles.

Antibacterial activity of hygienic surfaces tends to fall into two distinct categories:

1. Surfaces which are bactericidal (i.e., a material which results in a significant reduction in bacterial numbers following a specific contact time).
2. Surfaces which are bacteriostatic (i.e., a material on which a small bacterial population did not exhibit significant growth during exposure).

A number of test protocols have been described (e.g. [14.177]) which are based on the Japanese Industrial Standard JIS Z 2801: 2000 [14.182] (Fig. 14.23). In these methods, a bacterial cell suspension is held in intimate contact with a coated surface using a sterile cover (e.g., either a membrane filter, flexible polypropylene film or a glass microscope cover slip) under humid

Table 14.19 Methods used to examine the antimicrobial activity of non-porous surfaces

Reference	Title	Description
JIS Z 2801: 2000	Antimicrobial products – Test for antibacterial activity and efficacy.	The surface of replicate sample (3 for each treatment and 6 for the blank reference material – usually 50 mm×50 mm) are inoculated with a suspension of either <i>E coli</i> or <i>Staph aureus</i> in a highly diluted nutrient broth. The cell suspension is then held in intimate contact with the surface by the use of a sterile polyethylene film (usually 40 mm×40 mm) for 24 h at 35 °C under humid conditions. The size of the population on the treated surface is then compared with the size on the control surface both prior to and after incubation. A neutraliser for certain biocide types is employed. Antibacterial activity is certified if the difference between the log ₁₀ of the population on the treated sample and that on the control surface is > 2.
ISO / NP 22196	Plastics – Measurement of antibacterial activity on plastics surfaces.	This is the current New Work Proposal at ISO created from JIS Z 2801 by the SIAA of Japan. Modification and validation is in progress in collaboration with the IBRG. Some changes are expected.
XP G 39-010	Propriétés des étoffes – Étoffes et surfaces polymériques à propriétés antibactériennes	Four replicate samples of test material are placed in contact with an agar plate that has been inoculated with a specified volume of a known cell suspension of either <i>Staph aureus</i> and <i>K pneumoniae</i> using a 200 g weight for 1 min. The samples are then removed. Duplicate samples are analysed for the number of viable bacteria both before and after incubation under humid conditions at 37 °C for 24 h. A neutraliser is employed during cell recovery.

conditions. After a set contact time, the size of the residual bacterial population is compared with an appropriate control coating using standard microbiological enumeration techniques. ASTM 2180-01 has also been modified to examine such coated surfaces. These test protocols can examine both bactericidal and bacteriostatic performance.

When considering the generation of efficacy test data, it is important to note that the protocols described above rely on the presence of free water to function. It is critical therefore, to interpret the data generated with care as just because an effect is seen during testing it does not necessarily follow that activity would be seen in practice. For example, if the activity of a coating was

only exhibited when moisture was present (e.g., due to the presence of a water soluble active ingredient such as silver ions or triclosan), activity would be detected in the test. If however, the coating was used in dry conditions, it is unlikely that an effect of the same scale would be exhibited and some microbial cells might remain viable on the surface (although this would probably be for a limited period only for many species [14.183]). Clearly under some circumstances (e.g., medical applications) cross-infection could still occur [14.184] despite the presence of an antimicrobial agent intended to prevent it. In this context the relationship between the environment in which the coating will be employed and the conditions under which supporting data were generated

Table 14.20 Methods used to examine the antimicrobial activity of non-porous surfaces

Reference	Title	Description
ASTM E2180-01	Standard test method for determining the activity of incorporated antimicrobial agent(s) in polymeric or hydrophobic materials.	Replicate (3) samples of material are inoculated with cells of either <i>Staph aureus</i> or <i>K pneumoniae</i> suspended in molten semi-solid isotonic saline/agar. This attempts for form an ‘artificial biofilm’ which holds the suspension in intimate contact with the test surface of inherently hydrophobic materials. Samples are then incubated at a temperature similar to that intended for the final use for a specified period (usually 24h) under humid conditions. The size of the viable bacterial populations on the control and treated surfaces is then determined using total viable count. Any effect is recorded using percent reduction calculated from the geometric means of the data. A neutraliser may be employed and sonication is used to separate the ‘biofilm’ from the test surfaces and suspend the agar gel. Subsequent imprinting of the test surface onto solid nutrient media can be performed to look for the presence of adherent viable cells.
ASTM E2149-01	Standard test method for determining the antimicrobial activity of immobilized antimicrobial agents under dynamic contact conditions.	Dynamic shake flask test. Test material is suspended in a buffer solution containing a known number of cells of <i>Klebsiella pneumoniae</i> and agitated Efficacy is determined by comparing the size of the population before and after a specified contact time.

Fig. 14.22 Zone diffusion assay using liquid paint (*left*) and a coated filter paper (*right*). In both cases only an in-can preservative is present

become critical factors in providing evidence of efficacy in use.

Similarly, the rate of kill would be important in many circumstances. In the control of cross-infection in clinical situations, surfaces which come into frequent contact with medical staff and patients (e.g., door furniture, bed frames etc.) may need to be able to deactivate microbial cells very rapidly to provide a useful function. In this context, the contact time becomes a critical factor and tests in which a 24-h contact interval is employed may provide data which provides no useful information relating to efficacy in use. A slower rate of kill might be appropriate, however, to complement hygienic control on walls, flooring and difficult-to-access areas.

Although in many circumstances free water is not present, relatively few methods have been described which can simulate such conditions. Work has been published which examines the interaction of bacteria with polymeric coatings over time by spraying them onto

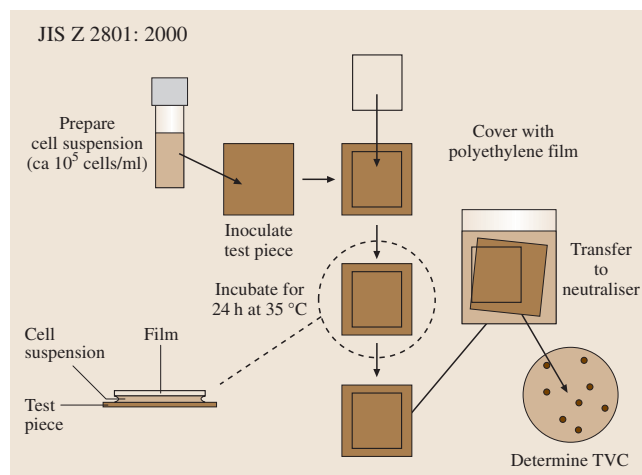

Fig. 14.23 Schematic representation of JIS Z 2801: 2000

surfaces both with and without the presence of soiling agents and holding them under differing environmental conditions. Direct vital staining and epifluorescent microscopy was employed to measure the effects [14.185]. Modifications to JIS Z 2801 have been described which expose the inoculum to a relatively low relative humidity (65%) and measure survival at a number of intervals thereby simulating the effect on bacteria contained in an aqueous deposit coming into contact with the coating and then drying out. A number of methods are also under development in which the inoculum is presented with minimal moisture, but more work is still required before the range of effects claimed for hygienic surfaces can be investigated in a scientifically sound manner.

14.6 Reference Organisms

Methods for the determination of materials performance often require the application of test organisms. For instance, DIN EN 113 describes a test method for determining the protective effectiveness against wood-destroying basidiomycetes using a set of basidiomycetes as test strains. ISO 16869 is a method for the assessment of the effectiveness of fungistatic compounds in plastic formulations where fungal test strains are applied as spore suspensions. ISO 14852 comprises the determination of the ultimate aerobic biodegradability of plastic materials in an aqueous medium. Sludge from a sewage plant is used to inoculate the test, so all or-

ganisms inhabiting the sludge can be referred to as test strains.

For comparability of test results, the use of identical test strains is an inevitable prerequisite. These strains should therefore be specified as reference organisms.

Attempts to verify the identity of prokaryotic or eukaryotic test strains in pure culture or in an environmental sample have traditionally been performed by plating dilutions onto certain standard growth media and by assessing certain physiological, morphological and/or chemotaxonomic traits after culturing.

As molecular methods are especially valuable for fast and reliable discrimination and identification of (micro-) organisms, this chapter gives emphasis to methods for genomic characterization of strains, species and microbial communities.

One of the more widely used culture-dependent methods of analyzing and characterizing microorganisms (bacteria and fungi) is the commercially available BIOLOG identification system. This system is also used extensively for the analysis of microbial communities in natural environments [14, 187]. The organism/microbial community of interest is inoculated into a specialized microtiter tray with 95 different carbon sources. Utilization of each substrate is detected by the reduction of a tetrazolium dye, which forms an irreversible, highly colored formazan when reduced. The microtiter trays are read with a conventional plate reader, and the results are compared with a computer database, allowing identification.

As pointed out by Hill et al. [14.170], there are a number of considerations in the use of this method for community analysis. Beside the crucial step of the requirement of a standardized inoculum of *vital* cells, it has to be kept in mind that the color formation in each well is not solely a function of the number of organisms present in the sample (as is often assumed). Some strains may use a certain substrate more efficiently than others, thereby appearing to dominate the sample. In addition, the substrates found in commercially available BIOLOG microtiter trays are not necessarily ecologically relevant. Therefore, the method still suffers from similar bias problems as encountered with culture plating methods and future work with ecologically meaningful substrates should render it more suitable for the characterization of microbial communities.

14.6.2 Genomic Characterization

A major area of research in microbial characterization has been the development of molecular methods for genotyping organisms. Genotypic methods can be highly specific and sensitive and are largely independent of the physiological or growth-state of the organism. Especially the development of the PCR and PCR-based techniques provides sensitive and specific tools to detect and characterize microorganisms in the absence of growth.

Polymerase Chain Reaction

The polymerase chain reaction (PCR) is a molecular method for amplifying DNA fragments. Using PCR and PCR-based techniques, rapid detection and identification of micro- and higher organisms in laboratory cultures as well as in environmental samples is possible.

The DNA fragment to be amplified is determined by the selection of appropriate primers. Primers are short, artificial DNA strands of approximately 20–30 nucleotides, that exactly match the beginning and end of the DNA fragment to be amplified. This means that the exact DNA sequence must already be known. Primers can be constructed in the lab or purchased from commercial suppliers.

There are three basic steps in PCR (Fig. 14.25). First, the target genetic material must be denatured – that is, the strands of its helix must be unwound and separated – by heating to 90–96 °C. The second step is hybridization or annealing, in which the primers bind to their complementary bases on the now single-stranded DNA. The third is DNA synthesis by a polymerase. Starting from the primer, the polymerase can read a template

Fig. 14.25 The three basic steps in PCR

strand and match it with complementary nucleotides very quickly. The result is two new helices in place of the first, each composed of one of the original strands plus its newly assembled complementary strand. A cyclic repetition of denaturation, primer annealing and DNA synthesis results in the exponential amplification of the desired DNA fragment.

The development of group-specific or species-specific primers enables sensitive detection and rapid identification of selected organisms in culture and environmental samples.

ARDRA – Amplified Ribosomal DNA Restriction Analysis

In the ARDRA technology PCR-amplified ribosomal RNA (rRNA) genes are digested with restriction enzymes (enzymes that cut double stranded DNA at enzyme-specific recognition sites) and the resulting fragments are separated electrophoretically. Comparison of patterns to those obtained from a database allows assignment of isolates to species, whereby the resolving power is depending on the restriction enzymes chosen.

This method, which can be used to screen large numbers of isolates rapidly, has gained widespread application in the detection and identification of fungi in laboratory cultures and natural substrates.

Fig. 14.26 Scheme for ARDRA of fungi (courtesy of S. Schwibbert)

Ribosomal DNA is the molecule under investigation, because it is particularly well suited to the development of taxon-specific primers due to interspersed regions of relatively conserved (18S rDNA-, 5.8S rDNA-, 28S rDNA-gene) and nonconserved (ITS I, ITS II) sequences and a large copy number per genome [14.171, 173, 174]. Universal primers, e.g., ITS1 and ITS 4 [14.188], or primer pairs specific for higher fungi (ITS1-F/ITS4-B) or basidiomycetes (ITS1/ITS4-B) [14.189], are used for the amplifi-

cation of rRNA genes and inserted ITS sequences. The PCR fragments are subjected to restriction digestion, and depending on the position of restriction sites, bands of different number and sizes appear after gel electrophoresis (Fig. 14.26). The majority of ARDRA profiles generated by any given enzyme are unique at the species level, but restriction digestion with *AluI*, *HpaII*, *HaeIII* and *TaqI* proved to be especially useful for the discrimination of decay fungi [14.174].

RAPD – Random Amplified Polymorphic DNA (Arbitrary-Primed PCR)

Random Amplified Polymorphic DNA (RAPD) or Arbitrarily Primed PCR (AP-PCR) is a method that creates genomic arrays of DNA fragments (fingerprints) from species of which too little sequence information is available in order to design specific primers. It is used to identify strain-specific variations in (chromosomal) DNA [14.190] Fig. 14.27.

Arbitrarily chosen primers are used to prime DNA synthesis from genomic sites which they fortuitously match or almost match, which results in the amplification of intervening DNA. Typically, PCR is performed under conditions of low stringency. The number and position of the primer binding sites will vary amongst different strains and consequently will lead to different strain-specific fingerprints. As a prerequisite, the primers must be within reasonable distance of each other, as the DNA polymerase must synthesize a product long enough so that it contains the site for annealing to the other primer. How soon the polymerase “falls off” the template depends on the purity and the constituents (GC-content) of the template itself.

BREND – Bacterial Restriction Endonuclease Nucleic Acid Digest Analysis and RFLP – Restriction Fragment Length Polymorphism

The BREND approach is mainly used for the characterization of prokaryotic, i.e., bacterial strains. Chromosomal DNA is digested with diverse restriction endonucleases and the DNA fragments are separated electrophoretically. Depending on the genome size and the enzymes used, the frequencies of restriction sites differ between strains, resulting in different fragment profiles. Usually, the profiles are highly complex and therefore difficult to analyze.

The number of detectable bands is reduced in the RFLP approach. Chromosomal DNA is submitted to a restriction digest and gel electrophoresis. Then, the DNA fragments are transferred and immobilized on a solid support such as a cellulose or nylon membrane.

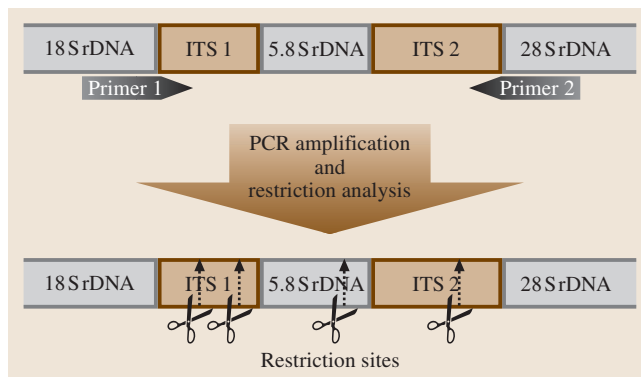

Fig. 14.27 RAPD patterns of eleven different strains of the wood degrading basidiomycete *Coniophora puteana* obtained with the same random primer. All strains were originally considered to be identical and used in the European Standard EN113. M: molecular size marker (2.0, 1.5, 1.2, 1.0, 0.9, 0.8, 0.7, 0.6, 0.5, 0.4, 0.3, 0.2, 0.1 kb) (after [14.190])

A target nucleotide sequence can be detected by a hybridization process, whereby a labelled DNA fragment (DNA probe) binds to the complementary target gene on the membrane. The presence or absence of the restriction endonuclease sites in two strains under investigation will cause differences in the length of the fragments that contain the targeted gene (Fig. 14.28). This technique, like the BRENDA approach, enables discrimination between strains [14.172].

Various systems for labelling and detection of nucleic acid probes are available nowadays. Radio-labelled probes are visualized using autoradiography, nonradioactive systems are based on the enzymatic, photochemical, or chemical incorporation of a reporter group (e.g., fluorescent dyes, marker enzymes coupled to chemiluminescence detection or to silver enhancement) which can be detected with high sensitivity by optical, luminescence, fluorescence, or metal-precipitating detection systems. For details about synthesis, labelling and detection of DNA probes (Hames and Higgings [14.191]).

As **rRNA** genes have some highly conserved regions (across species) which permits to use **rRNA** from one organism, e.g., *E. coli*, as a universal probe, these genes are regularly used as target genes. This so-called “ribotyping” which can be regarded as a special kind of **RFLP**, examines differences in the restriction pattern of **rRNA** genes between strains. Usually, the pattern is more complex than observed after **RFLP** targeting other genes, because **rRNA** genes are present in multiple copies per genome. The resolving power of ribotyping is dependent on the species studied and the restriction enzyme chosen.

Ribotyping has been facilitated by the availability of commercial, fully automated systems such as the Ribo-Printer[®] Microbial Characterization system (Qualicon Inc., Wilmington, DE). This molecular workstation performs the restriction digest (using *EcoRI* or other restriction enzymes) of the chromosomal DNA, separates the restriction fragments by gel electrophoresis, and simultaneously blots the DNA fragments to a membrane. DNA fragments are hybridized to a bacterial probe that is based on the conserved regions of the genes for the ribosomal *Dann* operon. Each fingerprint is stored in a database, so it can be accessed for future comparisons and identifications. The Ribo-Printer system is frequently used for quality control and authentication.

Gene probes addressing genes responsible for particular physiological activities (e.g., nitrification, nitrogen fixation, virulence associated genes etc.) are useful to

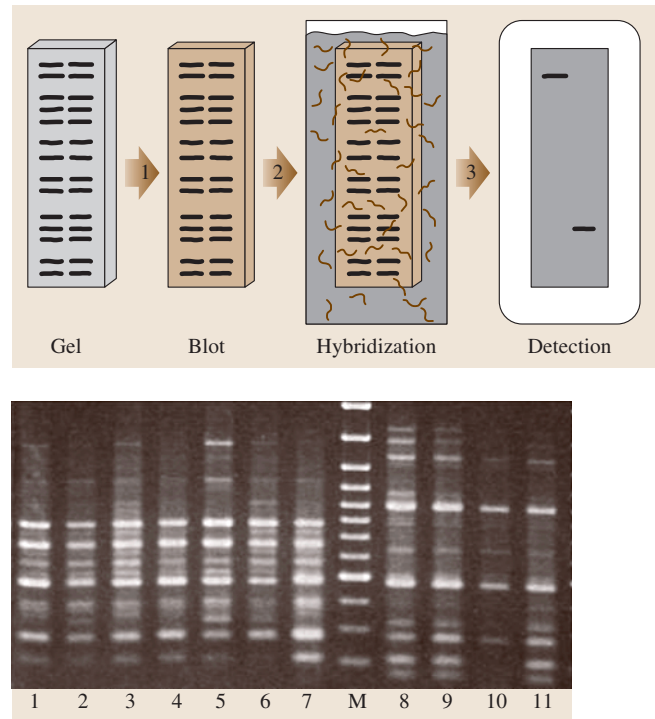

Fig. 14.28a–c Scheme for the **RFLP** approach. (a) Digested DNA of two strains under investigation is separated by gel electrophoresis, denatured and transferred (blotted) onto a nylon or cellulose membrane (b) The blotted DNA is incubated with a labelled DNA probe which binds to the complementary target gene on the membrane (c) After removal of unspecifically bound DNA probe, the targeted gene can be detected, e.g. by autoradiography (courtesy of S. Schwibbert)

characterize a subset of microorganisms or a microbial community, where the taxonomy or species composition of the community are of minor interest.

FISH – Fluorescence in situ Hybridization

Fluorescence in situ hybridization has been used primarily with prokaryotic communities. It allows the direct identification and quantification of specific or general taxonomic groups of microorganisms within their natural microhabitat. As whole cells are hybridized, artefacts arising from bias in DNA extraction, **PCR** amplification and cloning are avoided. **FISH** is a powerful tool that can be used not only for studying individuals within a population, but also has the potential to study population dynamics and tracking microorganisms released into the environment.

The composition of complex microbial communities is most often analyzed by **rRNA**-targeted nucleic acid probes: Whole cells are fixed, their 16S or 23S **rRNA** is hybridized under stringent conditions with fluorescently labelled taxon specific oligonucleotide probes. The labelled cells are viewed by fluorescence microscopy. Scanning confocal laser microscopy (**SCLM**) surpasses epifluorescence microscopy in sensitivity and allows to assess the distribution of several taxonomic groups simultaneously.

The large amount of **rRNA** in most cells and the availability of huge **rRNA** databases for comparative sequence analysis are the major advantages of **rRNA** targeted nucleic acid probes. With the ARB software package, **rRNA** oligonucleotide probes can be designed in a straightforward fashion [14.192]. Specific organisms or groups can be selected and parameters such as probe length, G+C content, and target region can be defined and the ARB probe design tool will then search for potential target sites against the background of the full sequence data set. As the ARB database is frequently updated, old probes should not be used without re-checking the database.

Microbial groups without a common diagnostic target site should be detected with more than one probe. For increased sensitivity, as for the detection and tracking of functional genes, the application of horseradish peroxidase-labelled oligonucleotide probes is advisable. Oligonucleotide probes labelled with a variety of fluorochromes can be purchased commercially.

DGGE –

Denaturing Gradient Gel Electrophoresis

Denaturing gradient gel electrophoresis is widely used in recent years for profiling microbial consortia. This

method is particularly useful when temporal and spatial dynamics of the population structure are analyzed. It allows the separation of DNA fragments of the same size but different nucleotide sequences by their denaturing profiles. For the characterization of microbial communities, ribosomal RNA genes are obtained directly from a bulk DNA sample by **PCR** and subjected to DGGE. The resulting banding pattern serves as a fingerprint of the microbial community.

During electrophoresis in an increasing gradient of denaturant (e.g. urea) or in an increasing temperature gradient (TGGE – temperature gradient gel electrophoresis), DNA molecules remain double-stranded until they reach the denaturant concentration or temperature that melts the molecules. Melting DNA branches and thus displays reduced mobility in the gel. As the melting behavior is mainly determined by the nucleotide sequence, theoretically any rDNA gene found in the mixed template DNA could be specifically amplified and resolved on a DGGE gel. Following DGGE electrophoresis, rDNA fragments can be sequenced and analyzed for similarity to other known sequences in public-domain databases. It has to be kept in mind that one band often does not represent only one species, so this approach is better suited for less complex communities.

This technique also might be limited by Dann extraction efficiency, which differs among microorganisms and type of environment (soil, mud, water). Amplification bias has also been shown to occur for templates that differ substantially in abundance, with preferential amplification of more abundant sequences [14.193]. For a detailed review of possible sources of amplification bias, see [14.194].

Material–Env

15. Material–Environment Interactions

There is no usage of materials without interaction with the environment. Material–environment interactions are relevant for all types of materials, be they of inorganic or organic in origin. Interactions with the environment can cause damage to materials but also might lead to an improvement of materials properties (e.g. oxidative passivation of aluminium or patina formation on copper surfaces). Interactions with the environment might also occur prior to the usage of materials, i. e. in the production phase. For example, before steel can be used for manufacturing of metal products, iron ore has to be extracted and processed.

The impact of the environment on the processes of the *materials cycle* (Fig. 3.7) will be discussed in Sect. 15.1.1 of this chapter. An important material–environment interaction, especially for inorganic materials, is corrosion, which has already been addressed in Chap. 12. Also the biological impact on organic and inorganic materials can be manifold and are presented in Chap. 14. Environmental mechanisms that impair the functioning of organic polymeric materials – such as weathering, ultraviolet (UV) radiation, moisture, temperature and high-pH environments – are the topics of Sect. 15.1.2. The influence of materials on the indoor climate and measurement methods to characterize emissions from materials are treated

in Sect. 15.2. Fire exhibits a drastic impact on materials; methods to characterize the flammability and fire behavior of materials are discussed in Sect. 15.3.

15.1 Materials and the Environment

15.1.1 Environmental Impact of Materials

The flow of materials has a significant global impact on the environment. Whereas at the beginning of the 20th century approximately 40% of the materials flow was attributed to renewable resources such as wood, fibres or agricultural products, this fraction dropped to only 8% by the end of the century [15.1]. The enormous increase in materials consumption within the United States is displayed in Fig. 15.1. The materials with the highest consumption rate are construction materials

(sand, gravel, stones, cement). Other categories selected for Fig. 15.1 are minerals (clay, bauxite, phosphate rock, salt), iron and steel, nonrenewable organics (coal, oil, gas products), wood and agricultural products (with 5 Mt in 2000 not visible in the diagram). Wood and products from agriculture and fishery are the only renewable resources from this point of view. All data are derived from the US Geological Survey [15.2]. The pattern of consumption is steadily increasing with some major historical events visible in the chart (world wars I and II, the depression in the 1930s, the oil crisis in the mid 1970s

Fig. 15.1 Consumption of selected materials in the United States from 1900 to 2000 [15.2]. See text for material categories

Fig. 15.2 The consumption of steel (circles) and copper (diamonds) per c.p.t. as a function of the gross domestic product per c.p.t.. Data source [15.3]

and later recessions). The figures suggest that the materials consumption per c.p.t. has increased by a factor of 6 from 2 t to 12 t per c.p.t. [15.1].

The environmental impact of materials usage is not easy to quantify. However, there are expressions which display the driving forces of this impact. *Graedel and Allenby* [15.4] describe the environmental impact as the product of population, gross domestic product (GDP) per person and environmental impact per unit of per c.p.t. GDP:

$$\text{Environmental impact} = \text{population} \times \frac{\text{GDP}}{\text{person}} \times \frac{\text{environmental impact}}{\text{unit of per c.p.t. GDP}} \quad (15.1)$$

Population, the first term in (15.1), is still increasing globally. However, the population in most industrialized countries is more or less stable. GDP per person is a criterion for prosperity and varies from country to country. The general trend is positive. The last term in the equation is strongly technology-related. From (15.1) it is obvious that the production of materials using more efficient technologies and less waste production might lead to a reduced environmental impact if the effect of the first two terms can be compensated for. The fact that materials consumption is a function of the GDP per c.p.t. is shown exemplarily for steel and copper in Fig. 15.2.

The technology-related term, environmental impact per unit of per c.p.t. GDP, is the reciprocal value of the efficiency. One possibility to quantify the efficiency of materials production is to estimate the specific energy

consumption (SEC), i.e. the consumption of energy per mass of material produced. The world's SEC for steel has dropped significantly by more than 50% from 2.6 GJ/t to 1.2 GJ/t over the last five decades [15.5]. However, the world production of steel is more than 400% of that in 1950 (1950: 190 Mt/a, 2000: 848 Mt/a [15.2]). Thus, the global energy consumption for steel production, i.e. the product of global production and SEC, increased from 500 to 920 PJ per year. The environmental impact is directly related to energy consumption (e.g. consumption of fossil fuels, emissions etc.). As a result the environmental impact of steel production has increased, although the figure representing the technology term reduced to less than 50% of the initial value.

Specific energy consumption for the production of a certain material is only one part of the total impact of materials production on the environment. The concept of total material requirement (TMR) is an attempt to quantify the environmental impact of materials. TMR is the sum of domestic and imported primary natural resources and their hidden flows [15.6]. Hidden flows are often not considered in environmental analyses because they are attributed with no cost. However, overburden from mining, earth-moving for construction and soil erosion are major sources of ecological damage. The concept of TMR is exemplarily shown in Fig. 15.3 for the production of steel. From mined minerals to the final products a series of process steps takes place (exploration, mine-site development, extraction, milling, washing, concentration, smelting, refining, fabrication), each step is connected to other input flows such as en-

Table 15.1 The **TMR** of some metals, minerals and fuels

Material	TMR (t/t material)	Global production (t)	TMR (Mt/y)	References
Hard coal	2	3 740 000 000	8826	[15.8]
Sand and gravel	0.65	8 000 000 000	5200	[15.8]
Phosphate	34	130 000 000	4420	[15.8]
Gold	1 800 000	2445	4401	[15.7]
Crude oil	1.22	3 485 000 000	4252	[15.8]
Copper	300	12 900 000	3870	[15.7]
Iron	5.1	571 000 000	2912	[15.7]
Silver	7500	160 000	1200	[15.7]
Uranium	11 000	45 807	504	[15.7]
Lead	95	2 980 000	283	[15.7]
Platinum	1 400 000	178	249	[15.7]
Aluminium	10	23 900 000	239	[15.7]

ergy or other resources. The run-of-mine coal and the mined iron ore are the hidden flows within this example. The hidden flows for metals related to metal-ore mining have been investigated by Halada et al. [15.7]. Table 15.1 lists the data for some metals, together with the data for some minerals and fuels.

The **TMR** in the United States in the 1990s was 80–100 t per c.p.t., in the European Union (EU-15) it was approximately 50 t per c.p.t. [15.9]. Although the **TMR** concept is widely accepted, there are no economic incentives to reduce **TMR**. However, attempts have been made to lower the environmental impact without reduction of economic wealth. Many companies evaluate the eco-efficiency of their products. Eco-efficiency is defined as the ratio of economic benefit per environmental and resource impact [15.10]

$$\text{Eco-efficiency} = \frac{\text{Benefits}}{\text{Costs}} = \frac{\text{Economic benefit of good or service}}{\text{Environmental and resource impacts}} \quad (15.2)$$

The objective is to maximize environmental and economic benefits and reduce both environmental and economic costs. That this approach is advantageous for the economy is supported by numerous examples from industry [15.11]. The concept of ecomaterials (ecomaterials = environmentally conscious materials) was developed in Japan and follows a similar direction [15.12]. Ecomaterials are defined as materials with green environmental profile, hazardous substance-free materials, recyclable materials and materials with high material efficiency. All four types of ecomaterials lead to a reduction in **TMR** and thus higher eco-efficiency.

Fig. 15.3 Global steel production and specific energy consumption (global average) for the production of steel over the last five decades (circles steel production (Mt/a), squares SEC (GJ/t steel))

Fig. 15.4 The concept of **TMR**. The brown boxes are regarded as the hidden flows and account for the estimates of **TMR**. The sizes of the boxes are not to scale

15.1.2 Environmental Impact on Polymeric Materials

Relevant Environmental Factors

In chemistry, a differentiation is usually made between inorganic and organic matter. This discrimination is not an arbitrary one but rather reflects the completely different nature of the two. While the corrosion of metals as the economically most important environmental impact on inorganic matter has already been dealt with in Chap. 12, this subsection will look exclusively at polymeric materials. The latter not only present the most important sector of organic material but also exhibit an abundant variety of reactions and in general complex reaction behavior.

For (technical) polymeric materials, some special environmental factors are of basic relevance. Bond energies of a few eV make them sensitive to UV radiation, which makes weathering resistance a basic topic for polymers. Other relevant environmental factors will be only shortly discussed here.

Ageing – all the irreversible physical and chemical processes that happen in a material during its service life – often limits the serviceable lifetime to only a few years or even months. Thermodynamically, ageing is an inevitable process, however its rate ranges widely as a result of the different kinetics of the single reaction steps involved. Ageing becomes noticeable through changes of different properties, varying from slight loss in appearance properties to total mechanical–technical failure. Ageing is mostly associated with a worsening of material properties, but sometimes it can also result in an improvement of properties, e.g. UV hardening.

Relevant environmental factors for the ageing of polymers are:

1. solar radiation (see *weathering exposure* in the following),
2. heat,
3. chemical environment,
4. mechanical stress,
5. ionizing radiation,
6. biological attack.

Heat. Because of their low bond energies technical polymers can only be used in a limited temperature range [15.13]. Polyvinylchloride (PVC) for instance is only suited for permanent use up to 70 °C, polycarbonate (PC) up to 115 °C.

Thermal properties in general are dealt with in Chap. 8.

Chemical Environment. Exposed to water some polymers, like polyamides (PA), polyester, polyurethane, can be hydrolyzed, the mechanism for which may depend on acidity. Other polymers show a high sensitivity to atmospheric pollution, e.g. polyamides and polyurethanes even at room temperature are attacked by SO₂ and NO₂.

Akahori [15.14] used exposure to neutral oxygen radicals, produced by a plasma generator, for accelerated ageing tests.

Mechanical Stress. In the case of mechanical exposure, free radicals can be formed by rupturing chemical bonds, which is used as the initiation step in stress chemiluminescence [15.15].

Ultrasonic degradation can be used to produce polymers with a definite molecular size [15.16] or to degrade polymeric waste products. Frequent freezing/thawing cycles may also lead to degradation of dissolved polymers.

Ionizing Radiation. The impact of high-energy radiation (γ -, X-ray) leads to degradation and/or crosslinking [15.17]. In the presence of oxygen, degradation predominates.

Biological Attack. Not counting the mainly mechanical attacks of rodents or termites, microorganisms – such as mildew, algae and bacteria, that colonize their surfaces – can damage polymeric materials. Damage mechanisms vary for different polymers [15.18]. The microorganisms may attack in a direct way by breaking chemical bonds, or can act indirectly, e.g. increasing the migration of stabilizers. Producing their own pigments they can also disturb the appearance of the surfaces by color change.

In contrast with protecting polymeric materials from biological attacks (biocides) the opposite strategy is followed in sensitizing polymers to biodegradation for recycling.

Chapter 14 deals with the biogenic impact on materials in general.

Often the combined action of these environmental factors, which occur as synergistic or antagonistic effects, has to be considered.

Weathering Exposure

Ageing of polymeric materials by the impact of weathering is mainly initiated by the action of solar radiation. However, other climatic quantities such as heat, moisture, wetting and ingredients of the atmosphere, influence the photochemical ageing and are answerable for the final ageing results. To date there are no satisfactory

answers to the questions of the accurate mechanisms of the photo-oxidation and photodegradation of pure polymers, not to mention technical polymeric materials.

General Principles of Photoinitiated Ageing. From a theoretical point of view, pure aliphatic polymers show no absorption in the spectrum of solar radiation. For example, the UV absorption bands of pure polyethylene, which contains only C–C and C–H bonds, are located at wavelengths below 200 nm. Only polymers with aromatic groups or conjugated double bonds absorb natural solar UV radiation. For this reason, many polymers should be capable of withstanding the action of solar radiation during outdoor exposure.

The spectral response of a property change of a polymer in the solid phase does not coincide with its absorption spectrum in the spectral range of solar radiation. Even in many aromatic-type polymers, the absorption of radiation, which is responsible for the initiation of ageing, takes place through chemical irregularities or impurities. These originate either during the polymerization process and the processing of the polymers or are residues of catalysts. These chromophores, which are capable of absorbing the UV portion of terrestrial solar radiation, are unavoidable in technical polymers. *Menzel and Schlüter* [15.19] for example describe an increase of absorption at wavelengths above 300 nm and a decrease of weathering resistance after multiple processing of PVC.

Photoinitiated ageing of polymeric materials can be caused:

1. directly via an excitation of a molecule in a non-binding state that leads to photolytic chain scission (dissociation);
2. indirectly via an excitation of a molecule in a bound singlet state S_x that can be deactivated by several reaction paths, e.g. an oxidative reaction of the excited polymer molecule with O_2 .

The multistage processes of photoageing can be illustrated by the rough scheme in Fig. 15.5, which shows the levels of the excited states of an organic molecule A. The levels S_1 and S_2 (singlet states) and T_1 and T_2 (triplet states) are the most important energy levels in photochemistry. The thin lines above these levels indicate the vibrational and rotational levels. The nearly vertical solid arrows indicate the absorption and emission of radiation, the dashed arrows show radiationless energy transfers. The main processes are described below.

Fig. 15.5 Scheme of the energy levels and transfers in an organic molecule, a: absorption, f: fluorescence, p: phosphorescence and photochemical degradation

1. Absorption of radiation is the initiating photophysical reaction. At room temperature the polymer molecule A is in the ground state S_0 . By the absorption of a photon, it is transferred from the ground state S_0 to the excited state S_1 (including vibrational and rotational levels) and, at a higher photon energy, also to the excited state S_2 . Under conditions of natural and artificial weathering, the absorption of radiation can be considered as largely independent of any external influences.
2. This is followed by deactivation of excited states. The electronically excited states are no longer in a thermal equilibrium and try to transfer the absorbed energy within a very short time. This deactivation takes place by several competing processes:
 - a) Intramolecular deactivation. This energy transfer takes place from the excited state S_1 by fluorescence, or after internal conversion, intersystem crossing and relaxation from higher vibrational energy levels from the excited state T_1 by phosphorescence. This type of deactivation does not change the polymer molecule. Therefore, the absorption of radiation is not a sufficient condition for an ageing process. Even if the absorbed energy is high enough to rupture a bond, the energy has to be accumulated in this bond.
 - b) Intermolecular deactivation. This also takes place from the excited states S_1 and T_1 by radiative and radiationless transitions to an acceptor. This energy transfer plays an important role in

photostabilization and even the photosensitization of polymers.

- c) Deactivation by chemical reactions. In a non-binding electronically excited state, the weakest of the bonds involved dissociates into two radicals. These reactive intermediate pieces can recombine or react with many other molecules to form stable final products.

For a comprehensive survey of the photochemistry of polymers see, e.g., *Calvert and Pitts* [15.20] or *Ranby and Rabek* [15.21].

This short and superficial representation of the complex reaction processes during photochemical ageing gives an idea of the numerous factors that can influence photoinitiated ageing at many stages. These influences on the ageing behavior of polymers can only be roughly predicted by means of theoretical considerations. Quantitative results on the influence of the different climatic quantities have to be determined by experiments.

To interpret the results from artificial weathering tests, it is necessary to have an idea of the influences of the different climatic quantities on photochemical ageing. This paper summarizes some results of investigations on the spectral response of polymers and on the influence of heat, moisture, the style of wetting, acid precipitation and biofilms on ageing results.

Spectral Response of Polymers. The spectral response of polymers is usually expressed in terms of their spectral sensitivity or activation spectrum, which unfortunately are not used consistently in literature. Data on the spectral response of polymers can be obtained in principle by two methods:

1. A direct method, where the effect of a wavelength of radiation is determined by irradiation with a small spectral band or line of radiation with known irradiance. This technique determines the spectral sensitivity (or wavelength sensitivity), see *Trubiroha* [15.22].
2. An indirect method, which ascribes the incremental property change measured behind a pair of filters to the incremental (UV) radiation of a radiation source transmitted by the shorter-wavelength filter of the pair. This technique, the so-called filter technique, is used to determine the activation spectrum of a polymer, described in full, e.g., by *Searle* [15.23].

Spectral Sensitivity (or Wavelength Sensitivity): Spectral sensitivity data can be obtained by:

Fig. 15.6 Spectral sensitivity of polyamides, change in molar mass M_v as a function of wavelength of irradiation

Fig. 15.7 Spectral sensitivity of polycarbonate at 10 °C and 50 °C. The graph shows the radiant exposure H_e , necessary to produce a 10% loss in internal transmittance as a function of the wavelength of irradiation

1. observing the changes of a polymer property as a function of an equal radiant exposure with nearly monochromatic radiation at different wavelengths,
2. observing the radiant exposure with nearly monochromatic radiation, necessary to produce a defined change of the polymer property, if the change of the property is not linearly dependent on the radiant exposure.

The spectral sensitivity of the decrease of molar mass of additive-free polyamide films with a thickness of about 40 μm is illustrated in Fig. 15.6. The changes were normalized for an equal radiant exposure of 1 MJ/m^2 at each wavelength in the spectral range 280–380 nm. The

figure shows the decrease of the molar mass M_v of the two polyamides PA 6 and PA 66 with wavelength of irradiation. The change of M_v was linearly dependent on the radiant exposure in the investigated range.

PA 6 was more sensitive than this PA 66. The sensitivity of molecular degradation increases strongly with decreasing wavelength. Molecular degradation of the PA 6 film was only sensitive to wavelengths shorter than 370 nm. The PA 66 film only degraded at wavelengths below 340 nm.

The spectral sensitivity of the yellowing of a PC film with a thickness of 0.7 mm specimen temperatures of 10 °C and 50 °C is shown in Fig. 15.7. Because the yellowing of PC is not linearly dependent on the radiant exposure the figure shows the radiant exposure H_e which is necessary to reduce the internal transmittance of the PC film at 360 nm by 10%. With increasing wavelength higher radiant exposures are required to produce this defined change of internal transmittance. With increasing temperature the curve shifts to longer wavelengths by about 10 nm, when the temperature rises from 10 °C to 50 °C, which means that the spectral sensitivity increases with increasing temperature.

Activation Spectrum: The activation spectrum is the polymer spectral response data measured using the filter technique and is specific to a defined type of radiation source and a fixed exposure time.

An example of the calculated activation spectrum (AS) of the PA 6 film with a thickness of 40 μm mentioned above to solar global radiation E_{glob} and the spectral sensitivity (SS) are given in Fig. 15.8. A simplified qualitative definition of an activation spectrum is the superimposition of the spectral sensitivity (SS) of a property change of a test specimen onto the spectral irradiance $E_{e\lambda}$ of a given radiation source. At short wavelengths the activation spectrum must be zero where the spectral irradiance of the radiation source is zero; at long wavelengths the activation spectrum must be zero where the spectral sensitivity is zero. Therefore, information on an activation spectrum needs to be accompanied by information on the spectral irradiance of the radiation source.

Many other unstabilized and stabilized polymers show no remarkable response to radiation of wavelengths above 400 nm [15.22, 23]. However, investigations of very light-sensitive papers by the National Institute for Standards and Technology (NIST) [15.24] and of TiO₂-pigmented polymers and paints by Kämpf and Papenroth [15.25] ascertained a slight response to wavelengths up to about 450 nm. Only very light-

Fig. 15.8 Polyamide 6 film: Spectral sensitivity (SS) and activation spectrum (AS) at solar global radiation E_{glob}

sensitive color pigments fade strongly on exposure to visible radiation.

These experimental determinations of the spectral response of polymers have to be considered as typical results that can be influenced for example by the temperature, the degree of crystallinity and the thickness of the specimen or the duration of exposure, not to mention additives and pigments, which can be photostabilizers or photosensitizers, see Trubiroha et al. [15.26].

Irradiance Level. Besides the wavelength, the irradiance level during exposure may also have an influence on the degradation behavior of transparent test specimens.

Figure 15.9a shows the decrease of radiant flux in a clear transparent film for three different values of the product μd (absorption coefficient \times thickness of a film/sheet) in relative units. If the photochemical ageing only depended on the absorbed energy, the ageing results (Fig. 15.9b) would run parallel to the curves of radiant flux in the film, calculated according to $E = E_0 10^{-\mu d}$.

Figure 15.9b illustrates schematically the changes of carbonyl concentration in a low-density polyethylene (PE-LD) sheet with a thickness of 3 mm as a function of depth at different partial pressures of oxygen, measured by Furneaux et al. [15.27]. In a pure oxygen atmosphere, the change of the carbonyl index [infrared (IR) absorption region of the oxidation products] runs parallel to the decrease of radiant flux. However, the radiation exposure in air shows a strong formation of carbonyl groups at the two surfaces of the sheet. In the specimen's core thickness of 1 mm only very low carbonyl concentrations could be found. The rate of photo-oxidation definitely

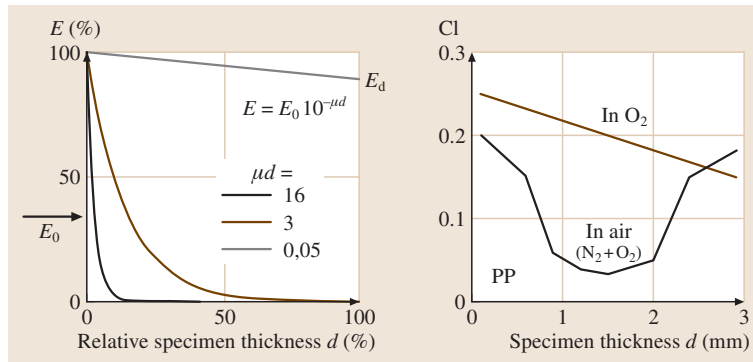

Fig. 15.9 (a) Radiant flux in a transparent sheet, (b) change of carbonyl index (CI) in a low-density polyethylene sheet with depth and partial pressure of oxygen

depends on oxygen diffusion, and thereby on the irradiance level, which implies an indirect dependence on the specimen temperature.

Photodegradation: Influence of Heat. Increased temperatures do not only increase diffusion rates but generally most chemical reactions. Figure 15.10 shows the loss of gloss of a white rutile-pigmented paint with a binder system consisting of linseed oil/alkyd as a function of the temperature of the specimen surface. It shows the decrease of the reflectometer value at 20 °C, 35 °C, and 50 °C, with time of weathering exposure. With increasing temperature, there is an increasing loss of gloss.

The strong dependence of many photodegradation reactions on the specimen temperature explains why it was not successful to establish a weathering station high in the Alps, although there is a higher level of UV radiation. The mean temperature was about 20 °C lower

than in weathering stations at sea level. Even *Boysen's* attempts to combine the natural weathering under daylight with artificial UV exposure during the night did not show the estimated acceleration due to the influence of temperature [15.28]. The low temperature of the specimen surfaces in the night with artificial irradiation changed the ageing processes.

It has to be mentioned here that the increase of surface temperature by irradiation can be different under natural and artificial irradiation, depending on the source of radiation and the color of the specimen. This temperature difference influences the acceleration factors for specimens with different colors.

Photodegradation: Influence of Moisture and Wetness. For unpigmented translucent PVC no dependence of the discolouration in the range of relative humidities between 10% RH and 90% RH could be found. However, the yellowing of white TiO₂-rutile-pigmented PVC used for window frames, which occurred as a weathering effect, showed a strong dependence on the relative humidity during irradiation [15.29].

Figure 15.11 shows the discolouration of eight specimens of PVC frames with different stabilizers and modifiers expressed in color differences ΔE corresponding to the grades of the grey scale after UV radiant exposure of about 190 MJ/m² at 50 °C. The discolouration in the moist climate was much lower than in the dry climate. This effect can be explained by the photoactivity of TiO₂ at high relative humidity, which destroys the polyene sequences in PVC.

The influence of relative humidities of 10% RH and 90% RH in the temperature range from 0–50 °C on the photodegradation of PA 6 is shown in Fig. 15.12. The figure shows the changes of molar mass M_v after UV radiant exposure of about 3.5 MJ/m². With increasing relative humidity and temperature, increasing degrada-

Fig. 15.10 Loss of 60° gloss of a paint with exposure duration t and specimen temperature

tion can be seen. In the temperature range 20–40 °C a stronger increase of the dependence, which probably correlates with the change of the glass-transition temperature, can be observed.

In contrast to Matsuda and Kurihara [15.30], who observed a strong influence of moisture content on changes of mechanical properties of PE-LD during weathering, we could not confirm this result in the 1970s with three different PE-LD samples. Investigations with different high-density polyethylene (PE-HD) films however, showed a distinct influence of moisture on the changes of mechanical properties, decrease of molecular mass and the formation of carbonyl groups [15.31]. After UV radiant exposure of 13 MJ/m² in a Global UV-Test device at 40 °C and relative humidities of 20%, 55% and 95%, the carbonyl index increased from 0.6 at 20% RH to 2.5 at 95% RH; the decrease of molar mass increased from 14% at 25% RH to 23% at 95% RH.

From these results, one cannot conclude that the photo-oxidation of PE-HD is dependent on moisture in contrast to PE-LD. The PE-LD was a pure polymer whilst PE-HD contained additives.

Other important parameters may be the type of wetting, e.g. dew or rain, and the duration of the wetness of the wet–dry cycles, which can cause mechanical stresses during the absorption or desorption of water.

Photodegradation: Influence of Atmospheric Acid Precipitation. Investigations on atmospheric precipitation show that rain with a pH of 2.4–5.5, fog with a pH of 2.2–4.0 and dew with a pH ≥ 2.0 are not rare phenomena, and not only observed in industrial regions. Acid atmospheric precipitation is formed when specific pollutants combine with water or dust particles in the atmosphere. By far the largest contribution to this problem arises from sulphur dioxide SO₂, a by-product of fossil-fuel combustion. In the atmosphere, SO₂ concentrations of up to 1 ppm are no rarity during the morning rush hours with the increased use of heating systems. When oxidized to sulphuric acid, H₂SO₄, it accounts for 62–79% of the acidity of rain. Most of the remaining acid is from nitrogen oxides NO_x, found mainly in automobile exhaust fumes, which are oxidized to nitric acid HNO₃ (15–32%). In addition to these two main species, hydrochloric acid HCl (2–16%), also produced by burning coal, is found in the atmosphere [15.32].

However, rain, dew, fog and dust with pH ≥ 2.0 are not the final forms of the acid precipitation which can act on surfaces of polymeric materials. Following the vapor-pressure curves it can be stated that the acid precipitation will concentrate up to about 70% sulphuric acid on hot

Fig. 15.11 Weathering-induced discolouration ΔE of white polyvinylchloride at low and high relative humidity

Fig. 15.12 Photodegradation of polyamide 6 with temperature and relative humidity after UV radiant exposure of about 3.5 MJ/m², where M_v is the molar mass

and inert surfaces by the evaporation of H₂O, HNO₃ and HCl. A summary of the influence of acid precipitation on different polymers has been published [15.33]. Hindered amine light stabilizers can be another weak point of technical polymeric materials [15.34].

Results generally show a synergetic effect of acid precipitations with UV radiation which accelerates the effect of artificial weathering tests, but there are also hints that the ageing processes of some polymers, e.g. unstabilized PE and PC, can also be slowed down by acid precipitations.

Photodegradation: Influence of Biofilms. Any surface of a material has a biofilm. This biomaterial or products of their metabolism may also have a syner-

gistic effect on the weathering behavior of polymeric materials, e.g. the mildew growth that causes pinholes in automotive coatings, especially in warm and humid climates like in South Florida. An attempt to produce the formation of these pinholes by means of standardized laboratory mildew tests that did not incorporate radiation failed [15.35].

Dragonflies that confuse a glossy clear coat with a water surface lay their eggs on this surface. Because of heating by solar radiation and the photochemical action of UV radiation, these eggs will be destroyed. *Stevani et al.* have demonstrated that the degradation products can hydrolyze acrylic/melamine resins that are in common use for clear coats [15.36].

Photodegradation: Influence of Antecedents of Test Specimens. *Menzel and Schlüter* [15.19], see above, described a decrease of weathering resistance after repeated processing of PVC. Similar results were obtained by *Chakraborty and Scott* for PE-LD [15.37].

This means that results from weathering, as well as being influenced by climatic quantities, may also be affected by the prior history of the exposed specimen (surface), for example by the quality of the specimen surface. Figure 15.13 demonstrates the influence of surface roughness on the discolouration of a white specimen of an extruded PVC window frame. By artificial irradiation in a dry climate, dark brown stripes develop over some areas, where the unexposed specimen showed a reduced gloss from processing.

Drying conditions of a coating may influence its ageing behaviour different loss of stabilizer. An increase of the degree of crystallinity of polyamide by annealing can increase its stability. Therefore, different prior history of test specimens are often the cause of varying weathering results.

Fig. 15.13 Effect of surface roughness on the discolouration of a white polyvinylchloride specimen. Surface areas that were originally glossy show a light color change, surface areas that were dull show a strong dark brown color

Natural Weathering. In practice, many polymeric materials are exposed to the whole variety of climatic conditions in the world. High levels of UV irradiance, annual UV radiant exposure, temperature, and humidity are extreme conditions for most polymeric materials. However, depending on the anticipated market of the polymer product, other exposure conditions may be important, e.g. maritime exposure to salt spray.

Corresponding to the variety of climates that are a result of latitude, altitude, and special geographical conditions, there are numerous natural-weathering sites across the world.

Benchmark climates for natural-weathering tests are the warm and humid, subtropical climate in Florida and the hot and dry, desert climate in Arizona, see *Wypych* [15.38].

At a given exposure site the real action of weather conditions can be varied by different exposure angles from the horizontal to vertical, by exposure under glass, by sun-tracking exposure or by Fresnel solar concentrators.

The following considerations have to be taken into account:

1. It is very difficult to really reproduce results from an outdoor exposure in weathering devices, because the outdoor exposure results vary for different locations, e.g. outdoor exposures at geographical locations such as Florida or Arizona, which accelerate the ageing of polymers compared to Europe, do not duplicate the ageing results of outdoor exposures in Europe. Even at one geographical location, the weather conditions of a season or a year, and therefore the ageing results, are not repeatable within a manageable time.
2. Any accelerated test, either artificial or outdoor, is only an approximation to the exposure stress in the field.

Artificial Weathering. To estimate the service life of products made from polymers or for the development of more-stable polymers, the conditions of outdoor exposure are simulated in accelerated artificial-weathering devices. These machines were introduced in 1918, but a long period of time was required for the development from the first purely artificial radiation sources equipped with a carbon arc to artificial weathering devices. In the course of time, these devices have become good simulators of the actinic portion of the solar radiation. This means that there may be a good simulation of the first photophysical reaction of photochemical ageing.

ing in these machines. The other climatic quantities of the weather can never be simulated perfectly due to time compression or acceleration; for this reason deviations can influence the ageing result and affect the correlation with results from outdoor exposures.

There are a number of different concepts for these weathering devices:

1. Devices equipped with xenon arc lamp(s). These machines show good simulation of the maximum of spectral irradiance in the UV and visible (VIS) range of terrestrial solar radiation at vertical incidence of direct solar radiation [15.39–41]. The main advantage of these devices is that even very light-sensitive materials, i.e. sensitive to VIS radiation, can be investigated. The main disadvantage is the high thermal charge to the specimen surfaces by VIS and IR radiation, which makes conditioning of the surfaces at low temperatures and high relative humidity during irradiation impossible.
2. Devices equipped with fluorescent UV lamps These machines show good simulation of the actinic portion of terrestrial solar radiation with fluorescent type 1 (340) UV lamps [15.39,40] and a combination of different types of fluorescent UV lamps [15.42]. The big advantage of these devices is their low energy consumption and a very low thermal charge to the specimen surfaces by VIS and IR radiation. Therefore, irradiated surfaces of specimens can be easily conditioned over wide temperature and relative humidity ranges. However, there are some limitations concerning lightfastness tests of specimens that are very sensitive to visible radiation.
3. Devices with carbon arc(s) These machines show a spectral distribution of irradiance that differs strongly from that of terrestrial solar radiation [15.41]. Additionally there is the same disadvantage as for xenon-arc machines: a high thermal charge to the specimen surfaces by VIS and IR radiation.

These machines are mainly used in the Asian market.

Weathering Standards. There are hundreds of national and international standards and company specifications that prescribe exposure conditions for artificial and outdoor weathering exposure tests considering usual and specific conditions, e.g. in the automotive industry or for roofing materials.

Most of these tests procedures are based on the following International Organization for Standardization (ISO) standards:

- For the natural exposure of plastics: ISO 877 Plastics – methods of exposure to direct weathering, to weathering using glass-filtered daylight, and to intensified weathering by daylight using Fresnel mirrors;
- for paints and varnishes: ISO 2810 Paints and varnishes – natural weathering of coatings – Exposure assessment.
- Artificial exposure procedures are described for plastics in: ISO 4892 Plastics – methods of exposure to laboratory light sources, parts:
 - a) General guidance,
 - b) Xenon-arc sources,
 - c) Fluorescent UV lamps,
 - d) Open-flame carbon-arc lamps,
- and for paints and varnishes in: ISO 11341 Paints and varnishes – artificial weathering of coatings and exposure of coatings to artificial radiation alone – exposure to filtered xenon-arc radiation (09.94); and ISO 11507 Paints and varnishes – exposure of coatings to artificial weathering – exposure to fluorescent UV and water.

Some failures of polymeric materials from outdoor exposure may not be able to be reproduced in artificial-weathering devices using standard weathering conditions. In these cases, it may be necessary to deviate from the standard conditions.

Determination of Property Changes. Before a property change due to environmental impact can be detected, it is of the outmost importance to characterize the material to be exposed as thoroughly as possible in the unexposed state. It has to be taken into account that the production process of the material might already have resulted in a heterogeneous material in regard to its properties on the surface compared to the bulk.

In most cases, an environmental impact on a material first affects its surface before it accumulates and spreads over the bulk of the material. This brings up two consequences for the determination of property changes: especially in the early stages of an environmental impact a heterogeneous distribution of property changes between the surface and bulk will result [15.43] and secondly, the first effects of weathering will be able to be detected by surface-emphasizing detection techniques.

Generally, weathering-induced degradation will start on a molecular level. For instance impurities in the material or external contamination with highly reactive secondary molecules can cause an increased reactivity in this region and act as the starting point of the degra-

gradation process, which can then spread like an infection until ultimately the whole bulk of the material is affected by the degradation process [15.43]. This means that detection techniques for weathering effects that are able to detect changes on a molecular level have the potential to detect the earliest stages of a degradation process.

Guidance for the determination of property changes of general interest is given for plastics by ISO 4582 (Plastics – determination of changes in color and variations in properties after exposure to daylight under glass, natural weathering or laboratory light sources) and for paints and varnishes by ISO 4628 (Paints and varnishes – evaluation of degradation of coatings; designation of quantity and size of defects, and of intensity of uniform changes in appearance), Parts 1–10.

A number of detailed techniques for the investigation of individual property changes are described in separate standards. Common testing procedures of effects of environmental impacts and – as far as they exist – their respective standards can be found in Table 15.2:

A review of the analytical techniques to look for the reasons for the observed changes can be found in Kämpf [15.44] and other references [15.45–49]. A number of these techniques are listed in the following.

Spot Analysis of Polymer Surfaces. The aforementioned spatial heterogeneous reaction of most interactions between polymeric materials and the environment implies the necessity for imaging microscopic techniques. These

Table 15.2 Common test procedures for property changes due to environmental impact on plastics, paints and varnishes

Property category	Individual property assessed	Standard
General	Mass Dimension	
Appearance	Gloss retention Light transmission Haze Blistering Cracking Flaking Chalking Corrosion around a scribe Filiform corrosion Cracking or crazing Delamination Warping Colorimetry, for instance yellowing Biofilm formation Migration of components from inside to surface	ISO 2813 ISO 13468-1 ISO 14782 ISO 4628-2 ISO 4628-4 ISO 4628-5 ISO 4628-6 (tape method) ISO 4628-7 (velvet method) ISO 4628-8 ISO 4628-10

Table 15.3 Analytical techniques that can be used for spot and surface analysis (see also Sect. 6.1, surface chemical analysis)

Acronym	Meaning	Principle/assessed Property	Resolution	References
EMA	Electron beam micro-analysis	Excitation by electrons, emission of X-ray photons for elements boron to uranium. Applications: detection of inorganic inhomogeneities in polymeric materials	Lateral: 0.1–3 μm (minimum 13 nm)	[15.50]
SEM + EDX	Scanning electron microscopy coupled to energy dispersive analysis	As above, but energy dispersive analysis instead of focusing wavelength dispersive analysis. For light elements slightly inferior spectral resolution and lower sensitivity than EMA	Lateral: 1 μm , Depth: \approx 1 μm	[15.51, 52]
TEM	Transmission electron microscopy	Scattered and unscattered electrons are detected after excitation with electrons. In crystalline regions electron diffraction occurs	Lateral: 0.2–10 μm	[15.53]
LAMMA	Laser microprobe mass analysis	Excitation by photons. Laser light is focussed through a light microscope onto the sample, which is caused to evaporate. Emitted ions are detected in time-of-flight mass spectrometer. Detection limit better than 10^{-18} – 10^{-20} g or concentrations in ppb range	Lateral: better than 1 μm Depth: > 0.1 μm	[15.54, 55]
ESCA (XPS)	Electron spectroscopy for chemical analysis (X-Ray photoelectron spectroscopy)	Photoionization of electrons on inner atomic shells by characteristic X-ray irradiation. Quantitative identification of atoms, determination of bonding state, oxidation states, depth profiling, identification of polymers. Detection of inorganic or polymeric impurities on polymer matrix. Crude depth profiling possible by angle-resolved XPS (control of analyzer collection angle)	Lateral: 1–1000 μm . Imaging: e.g. 0.1–10 mm Depth: 1–10 nm	[15.56, 57]
AES	Auger electron spectroscopy	Emission of secondary electrons after excitation with X-ray. In combination with ablation by sputtering allows depth profiling	Lateral: 0.1–3 μm Depth: 0.4–2.5 nm	[15.58]
(TOF-) SIMS	(Time-of-flight) secondary ion mass spectrometry	Surface is sputtered with positively charged ions. Emitted particles are neutral as well as secondary ions; the latter are detected by means of mass spectrometry. Trace detection of polymers, composition of copolymers and polymer blends, detection of additives or contamination on polymer surfaces, determination of molecular mass	Lateral: < 50 μm , (imaging SIMS: 200 nm), Depth: 1 nm	[15.59, 60]
XFA	X-ray fluorescence analysis	Excitation by photons, emission of photons. Applicable for trace detection of impurities at 10^{10} – 10^{13} atoms/ cm^2	Lateral: 1 μm	[15.61]
ATR-IR	Attenuated reflection infrared spectroscopy	Absorption spectroscopy with infrared radiation source. Sample is characterized using multiply attenuated reflection of IR between sample surface and totally reflecting crystal on top. Vibrational spectra allow qualitative and quantitative analysis of functional groups and render information on the constitution. Carbonyl bands can give measure for oxidative ageing	Lateral: \approx 3 mm	[15.62]
Micro-IR	Micro infrared spectrometry	Coupling of infrared spectrometer to microscope	Lateral: 1 μm	[15.63]
AFM	Atomic force microscopy	The force between the tip and the surface of the sample is monitored while scanning over it	Depth: 0.5 nm	[15.64]
LM	Light microscopy	Photons of visible light transmitted through, or reflected from, the sample material are depicted	Lateral: \approx 1 μm	[15.65]

Table 15.4 Analytical techniques allowing the investigation of bulk changes

Acronym	Meaning	Principle/assessed property	References
	Optical transmission spectroscopy (IR, VIS, UV)	Species are identified by the frequencies and structures of absorption, emission, or scattering features, and quantified by the intensities of these features. Enable trace analysis of organic additives such as heat and UV stabilizers, flame retardants, slip and deforming agents, solvent or monomeric or oligomeric residues, softeners	[15.66,67]
	Thermo-analytical techniques	Investigate a physical property of the sample as a function of a controlled temperature program. Increased analytical value by coupling to infrared or mass spectrometers, for instance TG-FTIR or TG-MS	[15.68]
AAS	Atomic absorption spectrometry	Atomized either by flame or electrothermally; AAS is characterized by selective resonance absorption of neutral atoms of the light of monochromatic light, proportional to its concentration	[15.69]
XFA	X-ray fluorescence analysis	Emission and detection of characteristic X-ray radiation of atoms after excitation by means of high-energy γ -ray Bremsstrahlung. Allows multi-element analysis. Semiquantitative analysis of inorganic components in polymers	[15.61]
ICP-MS	Inductively coupled plasma mass spectrometry	Ionization of a sample and separation of the ions in a mass spectrometer. Allows multi-element analysis. Remarkably lower detection limits (ppt range) than AAS. Only low concentration solutions usable	[15.70]
GPC	Gel permeation chromatography	The molar mass of polymers dissolvable in GPC solvents [most commonly tetrahydrofuran or chloroform] can be determined as retention time in chromatographic columns that work according to the size exclusion principle. Requires calibration of molar mass as function of retention time. Gives the complete molecular-weight distribution curve	[15.71]

allow a distinctive analysis of spots within the bulk as well as the surface to be done.

Polymer Bulk Detection Techniques. *Changes in the Composition (Polymer–Copolymer–Additives–Fillers).* The techniques listed under this topic also look at bulk properties but particularly allow conclusions to be drawn about the composition of a multicomponent system.

Limits of Lifetime Predictions. For lifetime predictions many industrial areas have already made the transition from strong dependence on long-term practical tests to strong reliance on short-term laboratory test results. In these cases the lifetime of the material mostly depends on the impact of only one or two, often relatively constant, exposure parameters, e.g. the temperature, that dominate the limitation of lifetime.

For polymeric materials exposed to natural weathering conditions lifetime predictions on the basis of laboratory tests are much more complex. The results of property changes of polymeric materials as a conse-

quence of accelerated artificial and long-term outdoor exposures may depend on:

1. The specific material under test (e.g. polymer type, formulation, dimensions, processing conditions, the age and the initial moisture content of the test specimen at the start of exposure),
2. The exposure conditions (e.g. mean and maxima of the UV irradiance, temperature, relative humidity and time of wetness, acidic or biological attack, the season when outdoor exposure is started and when it is terminated), and
3. The type of analytical determination and evaluation of the property changes (e.g. physical or chemical properties, surface- or bulk-influenced properties).

This means that lifetime prediction for polymeric materials needs a lot of information on the ageing behavior of the material under consideration, on the artificial and outdoor exposure conditions and on the determination of relevant material properties. These requirements mean that lifetime prediction remains an art rather than a science.

Table 15.5 Techniques particularly suited to determine changes in composition

Acronym	Meaning	Principle/assessed property	References
NMR	Nuclear magnetic resonance	Resonance interaction between the nuclear spins of, for instance, ^1H or ^{13}C atoms of the sample, which is placed in a homogenous external magnetic field, with high-frequency radio waves. Allows analysis of composition and structural changes, such as chain branching and stereochemical configuration. NMR is not sensitive enough for minor components	[15.72, 73]
IR	IR/Raman spectroscopy	Vibrational spectra allow qualitative and quantitative analysis of functional groups (kind and concentration) and render information on the constitution. Carbonyl bands can give measure for oxidative ageing	[15.74]
UV/VIS	UV/VIS micro-spectrophotometry	For depth profiling, typically microtome cross-section slices of the sample are investigated in transmission mode. Allows the detection of the formation or disappearance of chromophoric groups, such as degradation products of the polymer as well as additives	[15.75]
ESCA	Electron spectroscopy for chemical analysis	For the principles see Table 15.3. Applicable for depth profiling in combination with sputtering	Sect. 6.1.2
SIMS	Secondary-ion mass spectrometry	For principles see Table 15.3. Applicable for depth profiling in combination with sputtering	Sect. 6.1.3
Pyrolysis-MS	Pyrolysis mass spectrometry	A sample is pyrolyzed using heat, and the fractions are analyzed by a mass spectrometer to which the pyrolysis cell is coupled	[15.76]

For several decades, scientists had a fundamental knowledge of the weathering performance of the different types of polymeric material in use. Developments of new formulations or techniques mostly did not dramatically decrease or increase their performance. Because of a lack of confidence in results from artificial accelerated tests the different lifetimes of these new polymeric materials were, estimated by comparative artificial or/and short-time outdoor exposure tests.

During this period, the normally applied procedure of lifetime prediction was to simply compare the radiant exposures from artificial tests with the expected radiant exposures in the field of application. There was no consideration of the influence e.g. of different spectral distributions of irradiance, temperatures, relative humidities and cycles of wet and dry periods. And, even now, we have no confirmation that the reciprocity law is generally valid for the different irradiance levels applied in natural and laboratory exposure tests [15.77]. Only over the last two decades, the lack of confidence in results from artificial accelerated tests is decreasing and knowledge on the influence of different climatic quantities and other weather factors is continually growing.

Today the rapid progress of developing new polymeric materials with clearly changed formulations and additives that meet the demands of new processing technologies and environmental restrictions, e.g. the reduction of volatile organic compounds and waste disposal, does not allow sufficient durability testing by outdoor exposure. For the lifetime of their products the producing and processing industries have to rely on data determined by accelerated exposure tests and on lifetime predictions on the basis of these data.

Therefore, there is an increasing activity of research on different methods of lifetime prediction based on reliable laboratory tests.

Key factors in further research of lifetime prediction estimates for a given polymeric material are:

1. understanding actual in-service conditions and its variability,
2. understanding the influence of the variety of actions caused by outdoor exposure, and
3. confidence in results from laboratory tests at controlled exposure conditions.

15.2 Emissions from Materials

15.2.1 General

Emissions from materials influence the surrounding environment. Gaseous emissions – mainly volatile organic compounds (VOC) – into indoor air are of special interest due to the fact that they affect indoor air quality (IAQ). VOCs are of importance because they are strongly related to the so-called sick-building syndrome (SBS). Materials are not the only source of indoor air pollution. Other important sources are every type of combustion (e.g. fire places, gas cooking), especially smoking [environmental tobacco smoke (ETS)] and the use of household chemicals (sprays, solvents e.g.). Whereas these kinds of sources can be influenced by the user (to use or not to use it) materials emissions cannot be influenced by the user to the same extent. Often the user is simply not aware that materials might have emissions.

To reduce emissions from materials, first of all knowledge is needed about:

1. what is contained in the material,
2. what is emitted (quality),
3. how much is emitted (quantity),
4. duration of the emissions (time behavior, ageing).

In addition to these material parameters environmental parameters such as temperature, relative humidity, and air exchange rate influence the emissions or the resulting concentration in air.

To measure materials emissions, emission test chambers are used, which simulate environmental conditions such as those mentioned above. Air sampling and analysis is an essential part of emission testing.

15.2.2 Types of Emissions

Emissions from materials can be divided into classes of volatility and product classes depending on their field of application.

Classes of Volatility

According to [15.78,79] volatile organic compounds are divided into very volatile organic compounds (VVOCs), VOCs, semi-volatile organic compounds (SVOC) and particulate organic matter/organic compounds associated with particulate matter (POM) (Table 15.6) depending on their volatility.

An important sum parameter for VOCs is the so-called total volatile organic compounds (TVOC) value. According to ISO 16000-6, the TVOC is defined as sum of volatile organic compounds sampled on Tenax TA and eluting between and including *n*-hexane and *n*-hexadecane in a nonpolar gas-chromatography (GC) column.

Product Classes

Depending on the material and its intended field of use many chemicals are contained that might be released during the use of the material. Some examples of materials relevant to indoor use are listed here:

1. lacquer, paints, coatings,
2. wood, wood-based materials,
3. furniture,
4. construction products,
5. insulating materials,
6. sealants,
7. adhesives,
8. flooring materials,
9. wall papers,
10. electronic devices,
11. printed circuit boards.

Even in the simple case of e.g. a single polymer it can still contain remaining monomers or solvents and additives from the production that can generally be emitted. Additionally special types of polymers like e.g. polycondensated resins (e.g. urea-formaldehyde resins) can be hydrolyzed and release monomers. Furthermore materials can contain a wide spectrum of additives like, e.g.

Table 15.6 Classification of organic indoor pollutants according to their volatility

Description	Abbreviation	Boiling point range* (°C)
Very volatile (gaseous) organic compounds	VVOC	< 0 to 50–100
Volatile organic compounds	VOC	50–100 to 240–260
Semivolatile organic compounds	SVOC	240–260 to 380–400
Organic compounds associated with particulate matter or particulate organic matter	POM	> 380
* Polar compounds are at the higher end of the range		

1. plasticisers,
2. biocides (e.g. from production, pot preservatives, film preservatives),
3. flame retardants,
4. photoinitiators,
5. stabilizers.

15.2.3 Influences on the Emission Behavior

The emission behavior of materials is influenced by material and environmental parameters.

Material Parameters

The following material parameters are of importance for emission behavior

1. type of material,
2. ingredients,
3. structure,
4. composition,
5. surface,
6. age.

According to [15.80] the rate of emission of organic vapors from indoor materials is controlled by three fundamental processes: evaporative mass transfer from the surface of the material to the overlaying air, desorption of adsorbed compounds, and diffusion within the material.

Environmental Parameters

The following environmental parameters influence emission behavior

1. temperature (T),
2. relative humidity (RH),
3. air exchange rate (n),
4. area specific ventilation rate (q),
5. air velocity.

According to [15.80] temperature affects the vapor pressure, desorption rate, and the diffusion coefficients of the organic compounds. Thus, temperature affects both the mass transfer from the surface (whether by evaporation or desorption) and the diffusion mass transfer within the material. Increases in temperature cause increases in the emissions – as can be seen in Fig. 15.14 as an example – due to all three mass-transfer processes mentioned above.

The air exchange rate is another important parameter that affects the concentration of organic compounds in indoor air. The air exchange rate is defined as the flow

Fig. 15.14 Influence of temperature on the concentration (here the factor for the change of concentration) for a VOC and an SVOC emitted from a UV-curing acrylic lacquer applied to wood

Fig. 15.15 Influence of the air exchange rate on the concentration (here the factor for the change of concentration) for some VOCs emitted from different lacquers (polyurethane (PU) lacquer, UV-curing acrylic lacquer) both applied to wood

of outdoor air entering the indoor environment divided by the volume of the indoor space, usually expressed in units of h^{-1} . The higher the air exchange rate the greater the dilution, assuming that the outdoor air is cleaner, and the lower the concentration (see Fig. 15.15 for example).

Variation of the air exchange rate by a factor of 5 (Fig. 15.15: $F_{C1.5/0.3}$ ($n = 1.5 \text{ h}^{-1}/0.3 \text{ h}^{-1}$)) results in a change of concentration (F_C) of 5.6 to 6.4 with the exception of benzophenone. For benzophe-

none the concentration changes only by a factor 2.1, which is assumed to be due to adsorption effects of this SVOC.

15.2.4 Emission Test Chambers

Emission test chambers are necessary to provide defined environmental conditions for the evaluation of materials emissions. In addition to those mentioned above the following criteria have to be met:

- 1. clean air supply,
- 2. emission-free or low-emission chamber materials (stainless steel or glass, low-emission sealings),

- 3. sufficient mixing of the chamber air,
- 4. tightness of the chamber,
- 5. low adsorption on chamber walls,
- 6. easy cleaning of the chamber after tests.

In Europe and meanwhile international a distinction is made between emission test chambers (EN ISO 16000-9 [15.81]) and emission test cells (EN ISO 16000-10 [15.82]). Furthermore EN ISO 16000-11 [15.83] exists, describing sampling and storing of material samples and the preparation of test specimen. It is also intended to publish these standards as ISO standards ISO/DIS 16000-9 to -11. It should be mentioned that these standards are made for the testing of building products, but the emission test chambers and, in the case of planar products, also the emission test cells are applicable for other kinds of materials. The chamber/cell parameters are listed in Table 15.7.

In Fig. 15.16 a general description of an emission test chamber according to EN ISO 16000-9 is shown. In Fig. 15.17 an example of an emission test cell according to EN ISO 16000-10 can be seen.

In the USA small emission test chambers are described in [15.80]. According to this standard small chambers have volumes between a few liters and 5 m³. Chambers with volumes of more than 5 m³ are regarded as large chambers.

Fig. 15.16 General description of an emission test chamber (1: air inlet, 2: air filter, 3: air-conditioning unit, 4: air flow regulator, 5: air flow meter, 6: test chamber, 7: device to circulate air and control air velocity, 8: temperature, humidity, and air velocity sensors, 9: monitoring system for temperature and humidity, 10: exhaust outlet, 11: manifold for air sampling)

Table 15.7 Specifications for emission test chambers/cells

Volume (V)	Not specified
Temperature (T)	23 °C ± 2 °C
Relative humidity (RH)	50% ± 5% RH
Air exchange rate (n)	See q
Product loading factor (L)	See q
Area specific air flow rate (q = n / L)	
Flooring materials	1.3 m³ m⁻² h⁻¹
Wall materials	0.4 m³ m⁻² h⁻¹
Sealing materials	44 m³ m⁻² h⁻¹
Air velocity at the sample surface	0.1–0.3 m/s*
Background concentration	
Single VOC	2 µg/m³
TVOC	20 µg/m³
Minimum standard air sampling times (duplicate sampling)	72 ± 2 h 28 ± 2 d
* only for EN 13419-1, not mandatory for EN 13419-2	

Fig. 15.17 Description of an example of an emission test cell: general description in three dimensions of the field and laboratory emission cell (1: air inlet, 2: air outlet, 3: channel, 4: sealing material, 5: slit)

Fig. 15.18 1 m³ emission test chamber loaded for a test with a flooring adhesive on glass plates (picture [BAM](#))

For Japan small emission test chambers are described in [15.84]. Small chambers in this standard are defined to have volumes between 20 l and 1 m³. The test temperature is 28 °C ± 1 °C, differing from EN ISO 16000-9,10 where it is fixed to 23 °C ± 2 °C.

In Europe as well as in the USA additional standards for the testing of formaldehyde emissions and emissions from wood-based materials exist. These are EN 717-1 [15.85], [ASTM D 6007-96](#) [15.86], [ASTM D 6330-98](#) [15.87] and [ASTM E 1333-98](#) [15.88].

In Fig. 15.18 a 1 m³ chamber is shown loaded with an adhesive applied to glass plates for emission testing. The test specimen is brought into the center of the chamber where the air velocity is adjusted to 0.1–0.3 m/s. Before loading of the chamber the background concentration has been proven to be below the limits described in Table 15.7. The chamber shown [15.89] allows cleaning by thermal desorption at temperatures of up to 240–260 °C in combination with a purging with clean dry air of up to four air exchanges per hour.

Fig. 15.19 20 l emission test chamber – loaded with a flooring adhesive on glass plates (Picture [BAM](#) (Bundesanstalt für Materialforschung und Prüfung/Federal Institute for Materials Research and Testing))

In Fig. 15.19 a 20 l chamber is shown also loaded with an adhesive applied onto glass plates. The conditions of temperature, relative humidity, area specific ventilation rate, air velocity, and clean air supply are the same as for the 1 m³ chamber shown in Fig. 15.18.

In Fig. 15.20 a photograph of a FLEC[®] is shown. The test conditions are the same as described above. Therefore even the FLEC with a volume of only 35 ml allows emission rates comparable to the emission test chambers as long as planar homogenous materials are investigated with a smooth surface where emission from small edges plays no major role.

Larger chambers with volumes of more than 1 m³ [15.84], 5 m³ [15.80], or 12 m³ [15.83] might be useful if complex products like e.g. machines (e.g. printers, copiers) have to be tested for emissions. Emissions from hard-copy devices ([TVOC](#), styrene, benzene, ozone and dust) can also be measured [15.90]. This test method has been published for measurements according

Fig. 15.20 Field and laboratory emission cell (FLEC) according to EN 13419-2) (Picture BAM)

to the German blue-angel mark [15.91–93] and is based on the international standards for emission test chambers EN ISO 16000-9 and ISO 16000-6 for air sampling and analysis, see Sects. 15.2.5 and 15.2.6.

15.2.5 Air Sampling from Emission Test Chambers

The appropriate air sampling method depends on what has to be measured. The most common method for VOC is sampling on Tenax (polyphenylenoxide, based on 2,6-diphenylphenol) as absorbance for enrichment according to ISO 16000-6 [15.94] and ISO 16017 [15.95] followed by thermal desorption and analysis with gas-chromatography mass spectrometry (GC/MS, see Sect. 15.2.6). Another method being of increasing importance is sampling on 2,4-dinitrophenyl-hydrazine (DNPH) cartridges according to ISO 16000-3 [15.96] followed by solvent desorption (acetonitrile) and analysis by high-performance liquid chromatography (HPLC) using a diode-array detector (DAD) or UV detection (Sect. 15.2.6).

For sampling of VVOCs from air a wide spectrum of method exists that strongly depend on what has to be measured.

SVOCs can either be sampled by Tenax up to boiling points of about 360 °C (n-C22-Alkane) [15.97] or, for higher boiling SVOCs, by special polyurethane foam (PUF) [15.98, 99] with subsequent solvent extraction. The sampling of SVOCs on PUF has been practiced successful for biocides [15.100] and flame retardants [15.101].

Table 15.8 gives an overview on sorbents for sampling of volatile organic compounds belonging to different ranges of volatility.

Figure 15.21 shows examples of sorbent tubes used for sampling of volatile organic compounds from (chamber) air.

15.2.6 Identification and Quantification of Emissions

The most common method for the identification and quantification of volatile organic compounds from air is gas chromatography with subsequent mass spectrometry (GC/MS). Using GC (Sect. 1.2) the substance mixtures are separated into the single compounds and, by MS (Sect. 2.1), the mass spectra are generated. Mass spectra can often be used successful for library searches to obtain initial information on the identity of substances. For the confirmation of identity, calibration, and quantification, authentic standards has to be used. High-performance liquid chromatography with either diode-array detectors (HPLC/DAD) or UV detectors (HPLC/UV) (Sects. 1.2 and 2.2) is used for substances for which GC is not suitable, e.g. for substances that are thermally unstable.

Figure 15.22 shows a chromatogram resulting from a chamber test of PVC flooring, air sampled with Tenax TA followed by thermal desorption and GC/MS analysis.

In Table 15.9 the substances are listed with their concentration on different days over the testing time of 28 d. All named substances are quantified by calibration using authentic standards. The unidentified VOCs are quantified by toluene equivalents (according to ISO 16000-6 [15.94]).

Calculation of Emission Rates

From the concentration of VOCs in the chamber air, emission rates (ER) or specific emission rates (SER) can be calculated. The most common for the expression of specific emission rates for materials is the area specific emission rate (SER_a) [15.81, 82], which is calculated from the concentration C at a certain time [e.g. 3 d (72 h) or 28 d] according to

$$SER_a = Cq = CnL^{-1}, \quad (15.3)$$

where SER_a is the are specific emission rate at a certain time [$\mu\text{g m}^{-2} \text{h}^{-1}$], C is the concentration at a certain time [$\mu\text{g m}^{-3}$], q is the area specific ventilation rate [$\text{m}^3 \text{m}^{-2} \text{h}^{-1}$], n is the air exchange rate [h^{-1}], L is the product loading rate [$\text{m}^2 \text{m}^{-3}$].

Table 15.8 Guidelines for sorbent selection [15.102]

Sample tube sorbent	Approx. analyte volatility range	Maximum, Temperature (°C)	Specific surface area (m ² /g)	Example analytes
Carbotrap [®] CarbopackC [®] Anasorb [®] GCB2	n-C ₈ to n-C ₂₀	> 400	12	Alkyl benzenes and aliphatics ranging in volatility from n-C to n-C
Tenax [®] TA	bp 100 °C to 400 °C n-C ₇ to n-C ₂₆	350	35	Aromatics except benzene, apolar components (bp > 100 °C) and less-volatile polar components (bp > 150 °C)
TenaxGR	bp 100 °C to 450 °C n-C ₇ to n-C ₂₆	350	35	Alkyl benzenes, vapor-phase PAHs and PCBs and as above for Tenax TA
Carbotrap [®] CarbopackB [®] Anasorb [®] GCB1 (n-C4)	(n-C ₄)C ₅ to n – C ₁₄	> 400	100	Wide range of VOCs incl., ketones, alcohols, and aldehydes (bp > 75 °C) and all apolar compounds within the volatility range specified. Plus perfluorocarbon tracer gases
Chromosorb [®] 102	bp 50–200 °C	250	350	Suits a wide range of VOCs incl. oxygenated compounds and haloforms less volatile than methylene chloride
Chromosorb 106	bp 50–200 °C	250	750	Suits a wide range of VOCs incl. hydrocarbons from n-C to n-C. Also good for volatile oxygenated compounds
Porapak Q	bp 50–200 °C n-C ₅ to n-C ₁₂	250	550	Suits a wide range of VOCs including oxygenated compounds
Porapak N	bp 50–150 °C n-C ₅ to n-C ₈	180	300	Specifically selected for volatile nitriles; acrylonitrile, acetonitrile and propionitrile. Also good for pyridine, volatile alcohols from EtOH, MEK, etc.
Sphercarb*	–30–150 °C C ₃ to n-C ₈	> 400	1200	Good for very volatile compounds such as VCM, ethylene oxide. CS and CH Cl. Also good for volatile polars e.g. MeOH, EtOH and acetone
Carbosieve SIII [®] Carboxen 1000 [®] Anasorb [®] CMS*	–60–80 °C	400	800	Good for ultra-volatile compounds such as C C hydrocarbons, volatile haloforms and freons
Zeolite Molecular Sieve 13X**	–60–80 °C	350		Used specifically for 1,3-butadiene and nitrous oxide
Coconut Charcoal* (Coconut charcoal is rarely used)	–80–50 °C	> 400	> 1000	Rarely used for thermal desorption because metal content may catalyze analyte degradation. Petroleum charcoal and Anasorb [®] 747 are used with thermal desorption in the EPA's volatile organic sampling train (VOST), methods 0030 and 0031

* These sorbents exhibit some water retention. Safe sampling volumes should be reduced by a factor of 10 if sampling a high (> 90%) relative humidity

** Significantly hydrophilic. Do not use in high-humidity atmospheres unless silicone membrane caps can be fitted for diffusive monitoring purposes. Carbotrap[™], CarbopackC[™], CarbopackB[™], Carboxen[™] and Carbosieve SIII[™] are all trademarks of Supelco, Inc., USA; Tenax[®] is a trademark of the Enka Resean Institute; Chromosorb[®] is a trademark of Manville Corp.; Anasorb[®] is a trademark of SKC, Inc.; Porapak[®] is a trademark of Waters Corporation

Fig. 15.21 Example of the construction of commercially available adsorbent tubes for thermal desorption

Specific emission rates can also be expressed as length, volume or unit specific emission rates. Often specific emission rates are named emission factors (EF) [15.80, 84].

15.2.7 Time Behavior and Ageing

Time behavior of material emissions can also be evaluated by means of emission test chambers. After introducing the test specimen into the chamber, 100% of

the equilibrium concentration is usually reached within a few hours for VOCs, depending on the air exchange rate (Fig. 15.23); the concentration is given by:

$$C = \text{SER}_a(1 - e^{-nt})LV^{-1}n^{-1}, \quad (15.4)$$

where V is the chamber volume [m^3].

This increase of concentration at the beginning of the emission test is mainly of interest if short-time emissions are to be investigated, for example to study the emissions from fast printing hard-copy devices (where printing time is often less than half an hour) in order to consider this for the calculation of emission rates.

If the testing time is long enough at least a trend for the variation of concentration or specific emission rates over time can be evaluated. Typically measurements in test chambers run over 28 d. VOCs during this time usually show decreasing concentrations, as can be seen for example in Fig. 15.24 for terpene emissions from a par-

Fig. 15.22 Chromatogram from the measurement of a PVC flooring on the 28th day 1: methylisobutylketone (MIBK), 2: decane, 3: undecane, 4: cyclodecane (internal standard), 5: butyldiglykol, 6: n-methylpyrrolidone, 7: different VOCs, 8: 2,2,4-trimethyl-1,3-pentanediolediisobutyrate (TXIB)

Table 15.9 List of emitted substances and their concentrations for PVC flooring for different times of testing

PVC	Concentration ($\mu\text{g}/\text{m}^3$)						
	24 h	3. day	7. day	10. day	14. day	21. day	28. day
MIBK (methylisobutylketone)	111	65	53	45	39	32	30
Decane	55	35	28	25	23	20	16
Undecane	44	28	22	20	18	16	13
Butyldiglycol	123	75	40	48	44	35	31
N-Methylpyrrolidon	45	30	17	20	15	13	15
VOCs ($n \approx 23$)	438	308	273	253	221	175	159
TXIB (2,2,4-trimethyl-1,3-pentandioldiisobutyrat)	1251	863	760	698	641	614	539
TVOC	2067	1404	1193	1109	1001	905	803

**Fig. 15.23** Theoretical percent concentration profiles for various air exchange rates**Fig. 15.25** Variation of concentration of a VOC and two SVOCs over time. Notice the increase of concentration for the SVOCs over the first few days**Fig. 15.24** Terpene emissions from a particleboard over the testing time of 29 days ($T = 23\text{ }^{\circ}\text{C}$, $\text{RH} = 45\%$, $n = 1\text{ h}^{-1}$, $L = 1\text{ m}^2\text{m}^{-3}$, $q = 1\text{ m}^3\text{m}^{-2}\text{h}^{-1}$)**Fig. 15.26** Area specific emission rate (SER_a) for the three biocides dichlofluanid, tebuconazole and permethrine. For the increase at the beginning the SER_a has to be regarded as apparent specific emission rate due to adsorption (sink effects) on the chamber surfaces that result in reduced concentrations in air. The experiment was started in 1994 and is still running

Fig. 15.27 Empty chamber connected to the test chamber: permethrin [15.103]

Fig. 15.28 Secondary emissions from a flooring adhesive (solid line with boxes: hexanal, dashed line with boxes: hexanoic acid, solid line with circles: heptanal, dashed line with circles: heptanoic acid)

ticleboard. The terpene emissions result from the pine wood used for the production of the particleboard.

For SVOC emissions the decrease over time is normally not as strong as they have lower vapor pressures and therefore depletion of the boundary layer of the material takes longer. Furthermore they can show a longer increase at the beginning of the test due to adsorption effects (Fig. 15.25).

For extremely-low-volatility SVOC – often called POMs (Table 15.6) – a distinct emission behavior can

generally be observed. For these substances increasing concentrations over weeks and months can be observed as shown in Fig. 15.26 for some biocides [15.100].

The time to reach the maximum concentration was about 125 d for tebuconazole and permethrin. After reaching its maximum, the concentration remained almost constant over time for nearly ten years (tebuconazole) or showed only a slight decrease (permethrin).

Generally it should be stated, that organic substances with extremely low vapor pressure show a tendency to adsorb strongly on surfaces. One result of this is that SVOC/POM are retained by the material itself and thus possibly only show slow migration to the surface of the material, slow desorption from materials surface and therefore delayed emissions. Another reason for slowly increasing concentrations is the adsorption of emitted low-volatility organic substances on inner surfaces of the emission test chamber (chamber walls): so called sink effects. Figure 15.27 illustrates this behavior for the example of a biocide (permethrin) where a second chamber was switched in line to a first chamber that was already in equilibrium [15.103]. As can be seen it took about 250 d until the second chamber was also in equilibrium. Relevant amounts of biocide were adsorbed on chamber walls that acted as sinks. This could be shown by elution of the chamber walls after the end of the test. Knowing the amount of substance transported out of the chamber by air flow together with the amount of substance adsorbed on chamber walls generally allows, even for this very-low-volatility substance, one to calculate emission rates after a shorter testing time.

15.2.8 Secondary Emissions

Secondary emissions are a special case of emissions. Measurements have shown that these emissions do not occur from the beginning of the test. They are sometimes formed during testing, as was shown for emissions from a flooring adhesive [15.104]. At the beginning of the test only typical VOC emissions (mainly solvents) were detected. After more than 28 d, when a test is normally broken off, increasing concentrations of aldehydes and organic acids were already observed (Fig. 15.28). It is supposed that these are secondary products of autooxidation processes of unsaturated oils in the material or on the material's surface.

15.3 Fire Physics and Chemistry

Fire may be defined as an uncontrolled process of combustion generating heat, smoke and toxicity. It is essentially the availability of fuel that controls fire intensity for gas-phase combustion. In fires it is the heat transfer from flames that heats liquid or solid fuels and thereby generating gaseous fumes, which reacts with the oxygen in the air. This feedback process makes fires a generally unstable process that may either grow or go out.

Fires cause a lot of damage to society in the form of deaths and injuries as well as economical losses. In Europe, North America, Australia and Japan the loss of life to fires is between 0.7–2.0 persons per 100 000 each year and many more than this are injured. The direct economical losses are in the order of 0.1–0.3 percent of the annual GDP [15.105]. The cost of fire protection of buildings amounts to as much as 2.5–5% of the total cost of building and construction.

Designers and product developers strive to minimize weight and material consumption by using materials with low densities and making products for the same purpose smaller and smaller. As will be explained below, both low density and small thicknesses make materials prone to ignite and burn faster, so it is important that the issue of fire properties is considered at an early stage when developing new materials and products.

It is obvious that fire is an important aspect of the material–environment interactions treated in this chapter, which may detrimentally influence the performance of materials, products and technical systems.

In the following – based on a brief review of the fundamentals of fire physics and chemistry – methods and techniques to characterize the fire behavior of materials are compiled.

In addition to the methods for fire testing presented in this chapter, methods to characterize the general thermal properties of materials are compiled in Chap. 8 on thermal properties.

15.3.1 Ignition

A mixture of air and a gaseous fuel may *ignite* and burn if the concentration ratio of the fuel and the air is within the upper and lower combustion limits. For instance, the lower flammable limit of methane in air at normal temperature and pressure is 5% by volume, and the upper limit is 15% by volume. In fact, for most simple hydrocarbons the lower and upper flammable limits in air correspond to an equivalence ratio (see page 817) of approximately 0.5 and 3, respectively.

Fig. 15.29 Ignition of the left-side cardboard boxes occurs when the combustible volatiles leave the surface at a sufficient rate (courtesy of SP-Swedish National Testing and Research Institute)

Gas mixtures can be ignited either by *piloted ignition* or by *auto-ignition*. Piloted ignition occurs when a local source of heat or energy is introduced, while auto-ignition may occur simultaneously for the entire volume, normally at much higher temperatures than piloted ignition.

A liquid or solid may start to burn when combustible volatiles leave the surface at a sufficient rate to form a combustible concentration, see Fig. 15.29. Piloted ignition occurs when the concentration of combustible fumes near a pilot (e.g. a small flame or a spark igniter) reaches the lower flammable limit.

The rate of evaporation for a liquid is controlled by the liquid temperature. Therefore liquids will, under certain conditions, reach the lower limit concentration at a given temperature called the *flash point*, depending

Table 15.10 Critical temperatures of some liquids [15.106]

Liquid	Formula	Flash point (K)	Boiling point (K)	Autoignition point (K)
Propane	C ₃ H ₈	169	231	723
Gasoline	Mixture	≈ 228	≈ 306	≈ 644
Methanol	CH ₃ OH	285	337	658
Ethanol	C ₂ H ₅ OH	286	351	636
Kerosene	≈ C ₁₄ H ₃₀	≈ 322	≈ 505	≈ 533

Table 15.11 Ignition temperatures of some plastics, grouped by category [15.107]

Category of solid	Ignition temperature (°C)	
	Piloted	Auto
Thermoplastics	369 ± 73	457 ± 63
Thermosetting plastics	441 ± 100	514 ± 92
Elastomers	318 ± 42	353 ± 56
Halogenated plastics	382 ± 79	469 ± 79

on the ease of evaporation. Table 15.10 gives the flash-point temperature, boiling temperature and auto-ignition temperatures for some liquid fuels.

Time to Ignition

Most common combustible solids ignite by piloted ignition when the surface reaches a temperature of 250–450 °C. The auto-ignition temperature is normally above 500 °C; see Table 15.10 for some liquids and Table 15.11 for some plastics.

The time it takes the surface of a material (solid or liquid) to reach a critical temperature when heated depends on the thermal properties of the material. For thin solids, less than about 2 mm, the thickness is also decisive for the ignition time. Thus for a given net heat flux q to a the body surface and assumed constant material properties, the temperature T can then be calculated as

$$T = T_0 + \frac{qt}{\rho cd},$$

where T_0 is the initial temperature, t is time, ρ is density, c is heat capacity, and d is the thickness. Time to ignition t_{ig} can then ideally be calculated as

$$t_{ig} = \rho cd \frac{T_{ig} - T_{\infty}}{q},$$

or

$$t_{ig} = mc \frac{T_{ig} - T_{\infty}}{q},$$

where T_{ig} is the ignition temperature of the product and m is its weight per unit area.

As an example, a thin curtain suddenly exposed to radiation at an intensity of 20 kW/m² from a fire is an example where the above formula can be used to assess the time to ignition. Assuming typical values of a curtain drapery of $m = 0.1$ kg/m², $c = 800$ Ws/kg and $T_{ig} = 300$ °C, yields a time to ignition, starting from a room temperature of 20 °C, of $t_{ig} = 0.1 \times 800 \times (300 - 20)/(20 \times 10^3) = 1.1$ s.

A similar formula can be derived for thermally thick materials, i. e. where the thickness is larger than $2\sqrt{at}$, where t is time and a is the thermal diffusivity defined as $a = k/(c\rho)$. Here k is the thermal conductivity. Here again for a given net heat flux q and constant thermal properties, the time to ignition can ideally be calculated as

$$t_{ig} = \frac{\pi}{4} (k\rho c) \left(\frac{T_{ig} - T_{\infty}}{q} \right)^2.$$

Thus the above expression indicates that the time to ignition is proportional to the product of the heat conductivity k , the heat capacity c and the density ρ . The combined property $k\rho c$ is designated the *thermal inertia* of the material.

The estimated of times to ignition given above are very crude and based on the assumption of homogeneous materials with constant material properties, not varying with temperature or time. The formulas are, however, very useful for conceptual understanding of which properties govern the ease of ignition of materials.

The thermal inertia depends on the product of density and conductivity and varies over a large range even for common materials. Insulating materials have low conductivities k by definition and low densities ρ . In fact the conductivity increases in general with density. Therefore the influence of a change in density has a considerable influence on a product's fire behavior. The heat capacity, on the other hand, depends on the chemical composition of the material and does not vary much between common materials. Table 15.12 shows how the thermal inertia increases considerably with density for various combustible and noncombustible materials. Note in particular that the thermal inertia of an efficient

Table 15.12 Example of material thermal properties at room temperature [15.106]

Material	Density (kg/m ³)	Conductivity (W/mK)	Heat capacity (kJ/kgK)	Thermal inertia (W ² /m ⁴ K ²)
Polyurethane foam	20	0.03	1.4	0.84
Fiber insulating board	100	0.04	2.0	8.00
Wood, pine	500	0.14	2.8	196
Wood, oak	700	0.17	2.8	333
Gypsum plaster	1400	0.5	0.84	588
Concrete	2300	1.7	0.9	3520
Steel (mild)	7850	46	0.46	166 000
Copper	8930	390	0.39	1 360 000

insulating material like polyurethane foam is less than a hundredth of the corresponding value of wood.

As an example, a low-density wood-fibre board may have a density of 100 kg/m³ and a conductivity of 0.04 W/m K, while a high-density wood-fibre board have a density of 700 kg/m³ and a conductivity of 0.15 W/mK. As such boards can be assumed to have about the same heat capacity, it can be calculated that the thermal inertia of the high-density fibre board is more than 25 times higher of that of the low-density board. The low-density fibre board can therefore ideally be estimated to ignite 25 times faster than the high-density fibre board when exposed to the same constant heating conditions.

Thickness and thermal inertia have also a decisive influence on the flame spread properties of a material or product. Flame spread can be seen as a continuous ignition process and is therefore governed by the same material properties as ignition. Thus the fire hazard of a material or a product can, as a rule of thumb, be estimated based on its density, as this property governs how easily the temperature of its surface can be raised to the ignition temperature. Table 15.12 gives the thermal properties of some solid materials. These values are approximate and indicative and may vary depending on material quality as well as on measuring techniques.

Spontaneous Ignition

Self-heating leading to spontaneous ignition (commonly used interchangeable with spontaneous combustion) can take place in porous materials or in bulks of granulate solids [15.107]. It involves exothermal (heat-generating) processes which raises the temperature of the material. Whether the self-heating process leads to thermal runaway and spontaneous ignition of the material or not is a competition between heat generation and heat dissipation.

The most common heat-generating process is the oxidation of organic materials in the solid phase and oxygen in the gas phase. Therefore porous materials are more susceptible to self-heating than solid materials, as oxygen can diffuse through the material and reach surfaces with combustible substances in the interior of the material. A classic example of spontaneous ignition is a rag with absorbed vegetable oil. Unsaturated fatty acids in the oil are readily oxidized, and with the large surface area and poor heat dissipation of the rag, the temperature rise is fast and commonly leads to ignition.

The problem of self-heating frequently arises in storages of e.g. agricultural products, coal, wood fuels and municipal waste. Another example is self-heating of fibreboards in storage after production [15.108]. Storages of wood chips or pellets are examples of fuels that commonly self-heat and ignite.

In storages of wood fuel like wood pellets, biological reactions dominate at temperatures below 100 °C; when the temperature has reached that level, the rate of chemical oxidation increases and chemical reactions could further increase the temperature. The moisture content is important for the self-heating process, and is necessary for the growth of biological organisms. Generally, wood fuel containing less than 20% moisture does not self-heat [15.109]. Further, the vaporization and condensation of water in the bulk transport heat within the material. The moisture content of the material also influences the heat-conducting properties. The exposure of a storage facility to wind further increases heat-generating reactions by increasing the availability of oxygen.

Glowing and Smouldering Ignition

When a surface of a combustible solid is exposed to heat, it is changed either by melting or charring and liberates gaseous products. The surface of a charring

material may obtain very high temperatures and undergo rapid oxidation, which may be described as *glowing* ignition. When glowing in ambient air the temperature is typically in excess of 1000 °C. A flame may also occur either before or after the glowing ignition of the surface. Wood and fabrics are examples of products that may ignite first by glowing at the surface and then burn by flaming [15.107].

Smouldering can be defined as a propagating self-sustained exothermic-reaction wave deriving its heat from oxidation of a solid fuel. It is a relatively slow combustion process controlled by the rate of air entering the combustion zone. Smouldering can only be sustained if the material is insulating so that the combustion zone does not lose too much heat and a high temperature can be maintained. Smouldering is only common in porous or granular materials that can char. Materials which are known to smoulder under certain circumstances include [15.107]:

- 1. wood and cellulosic products in finely divided form,
- 2. paper,
- 3. leather,
- 4. cotton,
- 5. forest duff, peat and organic soil,
- 6. latex foam,
- 7. some types of polyurethane, polyisocyanurate and phenol formaldehyde foams.

Smouldering may also occur in insulation products of mineral wool containing high levels of binders as well as in cellulose loose-fill insulation.

A smouldering fire may break out into flaming, when the combustion zone reaches for example a wood surface or when for some reason more oxygen becomes available. As smouldering fires are very slow they may last for a long time and may not reach flaming conditions for very long times, in some cases several months.

15.3.2 Combustion

A burning candle may serve as a general illustration of the burning processes. Due to heating from the flame, fuel evaporates from the wick and is transported by diffusion towards the surrounding air/oxygen. Combustion takes place at the flame, which emits light. Hot combustion products are transported upwards, as they are lighter than the cool ambient air. Inside the flame envelope there are fuel vapors and no oxygen and outside it is vice versa, there is no fuel and ambient concentrations of oxygen. A candle flame is an example of a laminar diffusion flame governed by molecular diffusion.

Flames may be categorized as diffusion flames or premixed flames. In *diffusion flames* fuel gas and oxygen are transported into a reaction zone and mixed due to concentration differences. In *laminar flames* the diffusion is by molecular diffusion. In flames larger than about 30 cm the laminar flow breaks up into eddies and we get a *turbulent diffusion flame*. Although laminar flames may be important in the ignition phase of a fire, turbulent diffusion flames are the most significant in real fires.

Burning Rate

Burning rate is defined as the mass loss of solid or liquid fuel consumed by combustion per unit time. A general formula for the mass burning rate may be written as

$$\dot{m}'' = \frac{\dot{q}''}{L}$$

where \dot{q}'' is the net heat flux to the fuel surface and L is the heat of gasification. The latter is a material property. Typical values are given in Table 15.13.

When burning the fuel surface is heated by radiation and convection by nearby flames and hot gases. Heating by *radiation* may also come from remote sources such as flames, layers of combustion gases or hot surfaces. The temperature of the surface of thermoplastics and liquids will, in principle, be at the boiling point. For charring materials such as wood and thermosetting plastics an insulating char layer will form, which will hamper the

Table 15.13 Values of heat of gasification and effective heat of combustion [15.106]

Fuel	L (kJ/kg)	ΔH _c (kJ/kg)
Liquids:		
Gasoline	330	43 700
Heptane	500	43 200
Kerosene	670	43 200
Ethanol	1000	26 800
Methanol	1230	19 800
Thermoplastics:

Polypropylene	2000–3100	43 300
Polymethyl methacrylate (PMMA)	1600–2800	24 900
Nylon 6/6	2400–3800	29 600
Polystyrene foam	1300–1900	39 800
Char formers:		
Polyvinyl chloride (PVC)	1700–2500	16 400
Woods	4000–6500	13 000–15 000

Table 15.14 Yields of carbon monoxide Y_{CO} and mass optical density D_{m} depending on ventilation [15.106]

Fuel	Over-ventilated or fuel-lean conditions Y_{CO} (kg/kg)	D_{m} (m^2/kg)	Under-ventilated or fuel-rich conditions Y_{CO} (kg/kg)
Propane	0.005	160	0.23
Wood	0.004	37	0.14
Polymethyl methacrylate (PMMA)	0.01	109	0.19
Polystyrene	0.06	340	NA
Polyurethane flexible foam 0.03	330	NA	
Polyvinyl chloride (PVC)	0.06	400	0.36

heat flux to the surface and thereby reduce the burning rate.

The *heat release rate* (HRR) or energy release is the most important quantity for characterizing a fire. It represents the size of the fire and relates directly to flame height and production rates of combustion products such as smoke and toxic gas species.

The heat release rate \dot{Q} is the product of the burning rate and ΔH_{c} :

$$\dot{Q} = \dot{m}'' A \Delta H_{\text{c}},$$

where A is the fuel area involved. The effective heat of combustion is a material property (Table 15.13).

Combustion Products

The nature of the combustion products developed in a fire depends on the fuel as well as on the entire fire process. The chemical reactions occurring in the decomposition of the fuel and in the reaction with oxygen depend on temperature, gas flow conditions, the ratio between fuel and air available for the combustion process etc. If more air is available than is needed for a complete burning process the condition is assumed to be over-ventilated or fuel-lean. For less air, the process is termed under-ventilated or fuel-rich. If the fuel-to-air ratio perfectly match the burning process is *stoichiometric*. A parameter that quantitatively represents over- and under-ventilation in fires is the equivalence ratio ϕ defined as:

$$\phi = \frac{(\text{mass of fuel/mass of air})}{(\text{mass of fuel/mass of air})_{\text{stoich}}}.$$

Thus for $\phi < 1$ the fire is fuel-lean and for $\phi > 1$ fuel-rich.

In a similar way as the heat of combustion gives the energy release, *yields* give the mass production rate of combustion product species per unit mass of fuel. As an example the CO mass produced m_{CO} can be

calculated as

$$m_{\text{CO}} = m Y_{\text{CO}},$$

where m is the mass burnt and Y_{CO} is the yield of CO. The yields of various species are reasonably constant if the fire conditions are well ventilated, $\phi < 1$. Under fuel-rich conditions $\phi > 1$, however, the yields changes and the production rates increase for many toxic species. Yields of carbon monoxide are given in Table 15.14.

Light is attenuated by *smoke* mainly due to soot particles. Smoke has in many cases a decisive influence on the ability to escape a fire. Therefore the propensity of a material to release smoke is an essential material fire property. The reduced intensity of light I can be measured with a lamp and a photocell at a distance l away and be expressed as

$$I = I_0 \exp(-\kappa_{\text{s}} l),$$

where I_0 is the original intensity. The parameter κ_{s} is the extinction coefficient with dimensions of one over unit length (m^{-1}). For a given mass of fuel material burnt m in a closed volume V the extinction coefficient κ_{s} may be obtained as

$$\kappa_{\text{s}} = \frac{m D_{\text{m}}}{V},$$

where D_{m} is the mass optical density, with dimensions of mass over area (kg/m^2), which is a material property for over-ventilated conditions. Values for some common products are given in Table 15.14.

Toxic Products

Organic fuels such as wood and polymers contain mainly carbon and hydrogen. Thus when burning with enough oxygen available (fuel-lean conditions) the combustion process may be completed and carbon dioxide and water are mainly generated. However, under fuel-rich conditions or when the combustion process is interrupted due

to cooling (quenching), the combustion process is incomplete and several chemical species are generated, which may be toxic. The most important is *carbon monoxide* which is the cause of most fire casualties. Products containing *nitrogen* such as polyurethane may generate toxic substances such as hydrocyanic acid HCN and *isocyanates* which have a very high toxic potency.

Soot particles may also constitute a toxicological threat as they can transport toxic species from fires adhered to their surfaces deep into the lungs.

Corrosive Products

Some products such as polyvinyl chloride *PVC* generate acid gases such as HCl when burning, which is irritating for the eyes and air passages, although not necessarily fatal during inhalation. This may in particular hamper the evacuation of a building on fire. In addition HCl dissolves in water droplets and forms hydrochloric acid, which is highly corrosive and may deposit on metal surfaces and cause damage. Such corrosive damage may show up long after a fire and cause a great threat to electronic equipment, which in many cases must be discarded after a fire even if it has not been directly exposed to flames or hot gases and may be seemingly undamaged.

Flame Retardants

There are numerous chemical compounds used to inhibit combustion process in materials, mainly plastics. Flame retardants can function by intervening in the combustion process chemically or physically, or through a combination of both. One common feature of all flame retardants is that they interfere early in the combustion process during the heating phase or the ignition phase.

Physically a flame-retardant additive can act as a barrier by forming a layer of char when exposed to heat. This layer then protects the underlying material from heat and thereby from degradation and the ensuing generation of combustible fumes. Further, these flame retardants remove the direct connection between the oxygen in air and the fuel [15.110]. Flame retardants can also act by cooling. In such cases the additive degrades endothermically, thereby cooling and possibly diluting the gas mixture of the combustion process, for example through the production of water vapor. In certain instances additives can be used that act only by diluting the material with inert substances, such as fillers. This will typically reduce the heat release from a certain weight of a material but have little effect on the ignitibility of the material per se.

Chemically flame retardants can act by accelerating the initial breakdown of the material, causing the material to withdraw from or to flow away from the ignition

source or by promoting the generation of a char layer. Other flame retardants may act in the gas phase through the removal of free radicals that are the motor in the exothermic combustion process. The process is shown by the formula below:

where X represents a halogen.

The main families of flame retardants are *halogenated* (i.e., containing chlorine or bromine), *phosphorous* based, *nitrogen* based, inorganics and others (including antimony trioxide and nanocomposites). Many of these systems work either in isolation or together in some systems, exhibiting synergistic effects when used in combination.

Brominated flame retardants have the highest market share in terms of turnover while *aluminium trihydroxide* has the highest market share by weight. A global growth of approximately 3% has been projected by the flame-retardants industry in the near future with inorganic flame retardants (e.g. aluminium trihydroxide) having the highest projected growth rate.

Flame retardants have received broad application in correlation with the ubiquitous use of plastics in our society. While certain plastics have unacceptable ignition and flame spread properties, they also exhibit highly desirable mechanical properties, i.e., their ability to be formed into a myriad of shapes and applications. Thus, the safe application of plastics has at least partially been dependent on the use of flame-retardant additives to modify undesirable ignition and flame spread properties.

In recent years *environmental concerns* about many of these additives has prompted questions about the suitability of their broad use. Legislation is under way in Europe and elsewhere to control the use of these chemicals. Research into quantifiable tools to determine the true environmental impact of the use of flame retardants to obtain a high level of fire safety have, however, clearly identified the need to consider such issues holistically [15.111].

15.3.3 Fire Temperatures

Temperatures in natural fires depend on actual combustion conditions such as the fuel/air ratio and heat losses to the environment, mainly by radiation. Thus the maximum temperature of turbulent diffusion flames of free-burning fires is of the order of 800–1200 °C. Fires in enclosures with limited openings may, at the most, reach temperatures of the order of 1200 °C.

Fig. 15.30 General description of the various stages of a room fire (courtesy of SP)

Mechanically ventilated fires may under certain very favorable conditions for combustion develop extremely high temperatures. Thus fires in tunnels may reach temperatures of nearly 1400 °C with ordinary fuels of cellulosic materials. Temperatures of this order of magnitude were measured in several tests carried out in a tunnel in Norway in 2003 where fires in trailers loaded with wood pallets and furniture were simulated. Such temperature levels expose the surrounding tunnel walls to devastating thermal loads, causing concrete linings to spall and fall off in pieces. Therefore tunnels linings must be designed to resist much higher temperatures than other building structures.

The various stages of a fire in a room or compartment with limited openings are shown in Fig. 15.30. Initially the fire is not affected by the surrounding structures. In this *growth stage*, which may last from a few minutes to several hours, the fire intensity is *fuel-controlled*. As the fire intensity increases the temperature rises and more combustible fumes are released. At a certain stage the fire may start to grow rapidly and eventually *flashover*. After that, in the *post-flashover* stage, the fire consumes all available oxygen inside the compartment; it is then a *ventilation-controlled* or *fully developed* fire. The combustion rate at this stage depends on the amount of oxygen or air that can enter the fire compartment, i.e. it depends on the size and shape of the compartment openings. At this stage the fire generates a lot of heat, smoke and toxic gases, and the temperature is at least 600 °C and rises as the surrounding structures, i.e. walls, floors and ceilings heat up. Excess combustible fumes will at this stage emerge outside the compartment openings and burn as flames shooting out from the openings. *Flashover* represents a crucial event in

Fig. 15.31 The standard time–temperature curve according to EN 1363 or ISO 834

the development of a fire as it goes from being a local fire in one room or compartment to a much more severe fire having the potential to spread heat and smoke throughout a building.

Building components are designed to resist a fully developed fire. Such a fire is then usually simulated by the so-called standard fire curve as shown in Fig. 15.31. This time–temperature curve is meant to simulate a typical fire at the post-flashover stage.

Compartment fire developments can in principle be numerically modeled in three ways [15.112]. The simplest models are the *one-zone models* where the entire compartment gas volume is assumed to be at uniform temperature. Mass flow in and out of the compartment is driven by buoyancy. Hot fire gases are lighter than the ambient air and flow out at the top of the openings and are replaced by cool fresh air. The development of the fire temperature will depend on the thermal inertia of

Fig. 15.32 Two-zone model of a room fire with an upper hot layer and a lower layer at ambient temperature (courtesy of SP)

the surrounding structure and on the size and height of the openings. Lower thermal inertia (in principle, low density) and large openings implies faster fire growth and higher temperatures. One-zone models are suitable for fully developed fires. In *two-zone models* the fire compartment is divided into an upper hot zone with fire gases and lower zone with air at ambient temperature (Fig. 15.32). These models are suited for fires before they reach the stage of flashover. More advanced are the so-called computational fluid dynamics (CFD) models, where the compartment is divided to a large number of volume elements. Arbitrary fire conditions can then be analyzed in terms of temperature as well as concentrations of smoke and (toxic) gas species. CFD models are very powerful but require substantial computer capacity and detailed material property data.

15.3.4 Materials Subject to Fire

Structural Materials

The temperature in structures exposed to fully developed fires with gas temperatures reaching 800–1200 °C will gradually increase and eventually the structures will lose their load-bearing capacity as well as their ability to confine the fire to a limited space. In building codes fire-resistance requirements are usually expressed in terms of the time that a structure can resist a nominal or standard fire defined e.g. in the international standard ISO 834 or the corresponding European standard EN 1363-1, viz. Fig. 15.31. In the USA the corresponding standard for determining fire resistance of building components is ASTM E-119.

Thus *steel* starts to lose both strength and stiffness at about 400 °C, and above 600 °C it loses more than half its strength [15.113]. Therefore structural steel elements must in most cases be fire insulated by sprayed on compounds, boards, mineral wool or intumescent paint to maintain sufficient load-bearing capacity when exposed to fire. An example of a steel structure failure due to fire was the collapse of two World Trade Center towers on September 11, 2001. Each of the towers was hit by a large passenger airplane, see Fig. 15.33. These were tremendous impacts but they did not collapse until after about half an hour afterwards. The jet fuel had started intense fires and when the steel had reached a critical temperature the structures failed.

Concrete also loses strength and stiffness at high temperature [15.114]. This is, however, generally not a problem as concrete has a high density and heat capacitativity as well as a low thermal conductivity. Therefore the temperature rises slowly in concrete structures

Fig. 15.33 The jet fuel started intense fires that caused the World Trade Center towers to collapse on September 11, 2001

and even the steel reinforcement bars are well protected. More problematic is the tendency of concrete to spall when exposed to high temperatures. In particularly high-strength concrete is prone to spall. Spalling is particularly a problem when designing road and railway tunnels where fire temperatures may be extremely high and where a collapse of a tunnel lining may have devastating consequences.

Wood also loses both strength and stiffness at elevated temperature. It burns and chars gradually at a rate of about 0.5 mm/min when exposed to post-flashover fire conditions. The char layer protects the wood behind from being directly heated by the fire and thereby quickly loses its load-bearing capacity. Timber structures therefore resist fire rather very well and can in many cases be used unprotected; see e.g. Eurocode 5 [15.115]. In many cases structural timber members such as wall studs are protected from direct exposure by fire boards and can then resist fire for very long periods of time.

Polymers and Composite Materials

Thermoplastics and thermosetting materials decompose differently when exposed to heat. Thermoplastics can soften without irreversible changes of the material, while

thermosetting materials are infusible and cannot undergo any simple phase changes. They do not have a fluid state.

Many thermoplastics and thermosetting materials form chars when decomposed by heat. This char is in general a good insulator and can protect the underlying virgin material from heat and slow down the decomposition process.

Polymers suffer from different hazards in fires depending on their physical constitution and chemical composition. In general foamed plastics and thin plastics ignite more easily and burn more vigorously. Below some characteristics are given of some commercially important polymers. The thermal stability of *polyolefins* such as polyethylene and polypropylene depends on the branching of the molecule chains, with linear polymers being most stable and polymers with branching less stable. *Polyvinyl chloride (PVC)* has, in general, good fire properties as the chloride works as a flame-retardant agent. However, the hydrochloride HCl generated on burning is irritating and toxic and can impede evacuation from a fire. *Polyurethanes (PU)* contain nitrogen and form very toxic products like hydrogen cyanide and isocyanates. *PVC* and *PU* also generate very dense smoke.

Composite materials consisting of a polymer and suitable reinforcing fibres (typically, glass, carbon or aramide material), also called fibre-reinforced plastics (FRP), have become increasingly used in many areas of construction, such as airplanes, helicopters and high-speed crafts, due to their high strength/weight ratio. These materials are also chemically very resistant and do not corrode or rust. They are, however, combustible and, as they are often meant to replace noncombustible materials, (steel, concrete) they could introduce new fire hazards. Another concern is that inhalable fibres might be generated from FRP materials when burning. These fibres may also penetrate the skin, causing irritation and inflammation, and carry toxic substances into the body. This could be a particular hazard when composite materials are mechanically destroyed, e.g. in an airplane crash, when large amounts of fibres are released and become airborne.

15.3.5 Fire Testing and Fire Regulations

A lot of products to be put on the market need some kind of documentation, approval or certification, on their fire properties. These documents are usually based on some kind of fire tests performed according to various standards. Several organizations issue such standards, which describes in detail how the tests shall be carried out. Na-

Fig. 15.34 Fire-resistance testing of a glazed partition (courtesy of SP)

tionally the most well-known standards organizations issuing fire test standards are the British Standards Institute (BSI) in the UK, the Deutsches Institut für Normung (DIN) in Germany, and the American Society for Testing and Materials (ASTM) and the National Fire Protection Association (NFPA) in USA. Internationally both the European Committee for Standardization (CEN) and the International Organization for Standards (ISO) are very active in the field of fire safety.

There are mainly three categories of fire tests: reaction to fire, fire resistance and fire suppression tests. The *reaction-to-fire tests* evaluate materials and products properties in the early stage of a fire. They measure for example ignitibility and flame spread properties. Tests for measuring the generation of smoke and toxic gases are also often associated with this category of tests. *Fire-resistance tests* measure how long structural and separated building components can resist a fully developed fire from spreading from one compartment to another. A real fire is than simulated in a fire-resistance test furnace (Fig. 15.34), where the temperature develops according to a standardized time–temperature curve

as specified in EN 1363, ASTM E-119 or ISO 834 (Fig. 15.31). One side of a specimen is then exposed to the simulated fire conditions. The temperature is measured on the other, unexposed side and must not rise during the test to the point where ignition can occur, nor must any flames come out of the unexposed side. Load-bearing elements must be able to carry their design load during the entire test period. *Fire-suppression tests* are carried out on extinguishing media, e.g. dry powders and fire-extinguishing foams, and on extinguishing equipment such as sprinklers, portable extinguishers etc. The latter are tested at full scale and classified according to the type of fires, cellulosic fuels, gasoline or electric equipment, and size of fires they can extinguish.

Buildings

A new testing and classification system for building materials and products has been developed within the European Committee for Standardization (CEN) and is gradually being introduced in the national regulations of the European Union (EU) member states. Many building materials and products need to be tested as a basis for fire classification and Conformité Européenne (CE) marking, a harmonized way of declaring certain product properties regulated by member countries.

For *reaction to fire* the so-called Euroclasses A to F with several subclasses have been defined for construction products [15.116]. Class F means that no fire criterion has been met. The classes A1 and A2 mean the products are denoted as more or less noncombustible.

Example of class A1 products are totally inert materials such as steel or concrete. Class A2 products contain limited amounts of combustibles, such as mineral wool insulation where the binder is combustible and may burn. Methods for carrying out the appropriate test are defined in the standards: EN ISO 1182 – non-combustibility, and EN ISO 1716 – Calorific potential. For class A2 tests in the single burning item (SBI) apparatus according to EN 13823 (Fig. 15.35) are required as well.

To reach class B to D, tests have to be done in the SBI apparatus and in the small flame test rig according to EN ISO 11925-2. Typical materials in class B are gypsum boards covered with carton. In class D you find, for example, solid wood panels.

The level of fire safety requirements in various types of buildings and occupancies are specified in national building codes. The level of safety depends on the character of the building in terms of height, occupants and use etc. The most rigorous requirements are in large and tall buildings and in public buildings where people stay overnight e.g. hotels and hospitals. Surface linings in, for example, escape routes must generally have very good fire properties, of class B or better.

Building elements may fail a fire-resistance test either by integrity, insulation or loss of load-bearing capacity. An integrity failure means that flames penetrate through an element meant to separate two rooms or fire cells in a building. Correspondingly an insulation failure means in short that the temperature rise on the unexposed side of a separating element exceeds 140 °C.

Fig. 15.35 In the SBI method (EN 13823) the 1500 mm-high test specimens are placed in a corner (courtesy of SP)

Fig. 15.36 The cone calorimeter measures heat release per unit area when a specimen is exposed to a given heat irradiance (courtesy of SP)

Building elements are classified in terms of their fire resistance time. National building codes then specify the required fire resistance times of structural elements depending on the level of risk of a failure, mostly in the range 30–120 minutes. The former may refer to apartment doors in domestic dwellings and the latter to structural elements in high-rise buildings.

In USA the so-called Steiner tunnel test, [ASTM E 84](#), is the major test method used for determining surface burning characteristics of walls.

Internationally ISO has published similar standards as CEN for testing the fire properties of building products. Of special interest for material developers is the cone calorimeter, ISO 5660-1, as shown in Fig. 15.36, for measuring heat release rates per unit area as a function of time of products when exposed to specified levels of heat irradiance. The results of these tests can, among other things, be used in fire safety engineering to calculate the heat release rates in full-scale scenarios [15.118].

Transportation

Plastics are increasingly used in transportation vehicles for various reasons. They have compared with metallic materials several advantages. However, they all burn to a greater or lesser degree. Therefore sev-

Fig. 15.37 US Federal Motor Vehicle Safety Standard FMVSS 302 rate-of-flame-spread test for motor-vehicle interior components [15.117]

Fig. 15.38 FAR part 25 testing in horizontal position (after Troitzsch [15.119])

eral test methods have been developed in the various sectors of transportation to evaluate their burning behavior. The transportation industry is by nature very international, as vehicles are often marketed worldwide and used in several countries. Rules and regulation as well as test methods are therefore increasingly international. In some cases test methods are published by international standards bodies. In other areas the rules of US authorities have become so dominant worldwide that they, in practice, can be considered as international. Below, some fire test methods used internationally in various sectors are presented briefly.

For *motor vehicles* the US Federal Motor Vehicle Safety Standards (FMVSS) have great influence on the industry worldwide. The most significant standard is the small-scale flame spread test, FMVSS 302 [15.117], for motor-vehicle interior components, Fig. 15.37.

The Union Internationale des Chemins de Fer (UIC) has established a code covering regulations and recommendations for *rail vehicles* or *trains*. The fire tests in this code are mainly simple ignition tests. The code has, however, only partly been adopted in some European countries. Thus there has been work going on within CEN and the European Electrotechnical Standardization Commission (CENELEC) since 1991 to form a harmonised standard named EN 45545 Railway Applications – fire protection of railway vehicles. The new standard will use modern fire test methods such as the cone calorimeter (ISO 5660) and the smoke density chamber (ISO 5659). It will also require smoke toxicity assessment of interior materials in trains.

There are numerous national test standards for trains. In Germany DIN 5510, the vertical Brandschacht test

(DIN 54 837), is the main method regulating ignition, fire spread, smoke and flaming droplets. France uses NFF 16-101 which also includes toxicity assessment of materials. In Great Britain the national standard is BS 6853, which divides train vehicles into operation categories with varying fire requirements, the main test being a radiant panel test for flame spread. The British standard also considers design and demands on fire detection, suppression and alarm systems.

For *aircraft* most countries have adopted, wholly or in its relevant parts, the federal aviation regulations (FAR) [15.120] of the US Federal Aviation Administration (FAA). The methods used to fire-test the materials and components in the holds of transport airplanes are described in FAR part 25. The requirements for military aircrafts are partly similar.

For most parts used in the interior of aircrafts FAR part 25 requires that materials and components should pass so-called Bunsen-burner-type tests, where the specimen is mounted in different angles depending of end use. Figure 15.38 shows the test where the specimen is mounted horizontally, used for demonstrating that materials are self-extinguishing. Other fire tests are specified for components such as seat cushions, cargo-compartment liners, etc. Some tests not used elsewhere are specified for measuring certain fire properties. Thus for example the so-called Ohio State University (OSU) apparatus is specified for measuring heat release and a special *fireproof* and *fire-resistance* test is described in FAR part 23 for materials and parts used to confine fires in designated fire zones.

Safety of international *trading ships* has been regulated by the International Convention for the Safety

of Life at Sea (SOLAS) since 1974. SOLAS includes a set of fire safety regulations in chapter II-2. This chapter is reviewed by the fire protection (FP) subcommittee of the International Maritime Organization (IMO). In 1996, the IMO FP developed the fire test procedures code (FTP code), which contains the test procedures for fire-safe constructions and materials used on board ships.

Electrical Engineering

Combustible plastics are used extensively in electrical engineering because of their durability, corrosion resistance, strength and not least electrical insulation properties. However, plastics can burn and, as any energized circuit inherently is a fire hazard, special precautions must be taken with these products. The International Electrotechnical Commission (IEC) and the European Electrotechnical Standardization Commission (CENELEC) prepare and publish fire test standards for electrical technical products and cables. Thus a comprehensive series of fire tests have been published in the standard IEC 60695 for characterizing various fire properties such as ignitability, flammability, smoke obscuration, toxic potency, and resistance to abnormal heat. In Europe the CEN is in the process of making available a similar classification system for cables as for building materials. It will be based on the preliminary test standard prEN 50399-2.

Furniture

Furniture, in particular upholstered furniture of polymer foams such as foam rubber, can burn intensively and is therefore a potential fire hazard unless properly designed. Most countries have strict building regulations but the fire safety requirements on the building contents like furniture is in general very modest, although a survey in Europe [15.119, 121] shows that fires in furniture cause nearly 50% of all fatal fires in private dwellings.

There are several test methods published by various standardization bodies. The European Standard Organization (CEN) has published four ignition test standards for upholstered furniture and for mattresses. EN 1021-1

Fig. 15.39 Furniture calorimeter for measuring heat release at full scale of pieces of furniture (courtesy of SP)

and EN 1021-2 are cigarette and small-flame tests for upholstered seating, and EN 597-1 and EN 597-2 are cigarette and small-flame tests for mattresses [15.119].

Furniture is a complicated product comprising many different materials and assemblies. Fire may develop in cavities and beneath the covering layer etc. or as pool fires underneath the furniture. Therefore any small-scale test of individual materials is not always suitable for assessing the fire hazard of composites of the cover and filling. To estimate the fire behavior of these in more-realistic fire situations full-scale test data from e.g. the furniture calorimeter, as described in NT FIRE 032, is needed (Fig. 15.39). An internationally widespread method is the full-scale room test according to technical bulletin 133 of the State of California [15.122]. This method is, in part, intended for furniture in high-risk and public facilities such as prisons, health-care facilities, public auditoriums and hotels.

The cone calorimeter, ISO 5660, has been used for testing the burning rates of furniture components and combinations of upholstery and coverings on a small scale. The results have been used to predict burning rates of furniture in full scale in the furniture calorimeter as defined in NT Fire 032 [15.123].

16. Performance Control and Condition Monitoring

Performance

The performance of materials – as constituents of the components of engineering systems – is essential for the functionality of engineering systems in all branches of technology and industry. Instrumental for characterizing the performance of materials are:

1. methods to study and assess the basic damage mechanisms that detrimentally influence the proper functioning of materials, such as materials fatigue and fracture (Chap. 7), corrosion (Chap. 12), friction and wear (Chap. 13), biogenic impact (Chap. 14), materials–environment interactions (Chap. 15),
2. methods to study and assess the performance of materials in engineering applications and to support condition monitoring of materials' functional behavior.

In this chapter the following experimental and theoretical methods for performance control and condition monitoring are compiled:

- nondestructive evaluation (NDE) methods
- methods of industrial radiology
- methods of computed tomography (CT)
- embedded sensors techniques to monitor structural health and to assess materials performance in situ under application conditions
- methods to characterize the reliability of materials with statistical tools and test strategies for structural components and complex engineering systems.

16.1
Nondestructive Evaluation

Nondestructive evaluation is an important method for performance control and condition monitoring. In engineering systems, flaws and especially cracks in the materials of structural systems’ components can be cru-

Fig. 16.1 Direct visual inspection

Fig. 16.2 Indirect or remote visual inspection

cially detrimental to functional performance. For this reason the detection of defects is an essential part of quality control of engineering systems and their safe successful use. Control techniques are often listed under a variety of headings such as nondestructive testing (NDT), nondestructive evaluation (NDE) or sometimes nondestructive inspection. Applications of NDT techniques, however, are much deeper and broader in scope than just the detection of defects. The determination of various material properties, such as elastic constants of solids or the microstructure and texture of solids are also covered under the NDT title.

According to the wide scope of this field, a plethora of physical methods are employed. Established methods include *radiography, ultrasound, eddy current, magnetic particle, liquid penetration, thermography* and *visual inspection techniques*. Applications of NDE in industry are as wide ranging as the techniques themselves and include *mechanical engineering, aerospace, civil engineering, oil industry, electric power industry* etc. A large number of components are also in the focus of interest because engineered structures are an integral part of the technological base necessary for our lives and the public infrastructure. The operation of NDT techniques in several industries is standard practice, for example to support condition monitoring for the proper functioning of the daily use of electricity, gas or liquids in which pressure vessels or pipes are employed and where the correct operation of components under applied stress plays a large role for safety and reliability.

16.1.1
Visual Inspection

Visual examination means, in principle, inspection with eyesight [16.1,2]. (For the fundamentals of optical sensing see Sect. 11.7) In the case of NDT, visual inspection has a much broader meaning. There are differences in the aim of the visual inspection if: (i) *only* surface characteristics, such as scratches, wear or corrosion phenomena are of interest, or (ii) detection of cracks or deformation is included.

The first point (i) can be described as integral visual inspection and the second point (ii) as specific or selective visual inspection. If between the eye of the inspector and the surface of the test object the optical path is not broken then a direct visual inspection is performed (Fig. 16.1). Such inspection is either integral or selective. Direct visual inspection means examination using eyesight and sometimes simple tools such as artificial illumination. Selective visual inspection uses additional equipment including hand lenses, mirrors, optical microscopes and telescopes and, for the documentation of the inspection results, storage media such as photography or cameras in combination with a monitor. If inspection is carried out by the evaluation of photographs, video films or by robotics an indirect or remote visual inspection is performed (Fig. 16.2). Visual inspection can be carried out in almost all areas where preventive maintenance is required. Visual inspection is the oldest and most common form of corrosion inspection, applied to surface corrosion, intergranular stress corrosion, and some kinds of pitting. Several corrosion phenomena are detectable using direct visual inspection techniques. An example showing a corroded surface is presented in Fig. 16.3. Clearly visible is the scarred surface in the elbow region of the pipe. This example illustrates that the visual technique is quick and in most cases economical. Various types of failure are detectable but the reliability of the inspection is highly dependent on the skill and training of the examiner.

Fig. 16.3 Corroded pipe

16.1.2 Ultrasonic Examination: Physical Background

Sound travels in solids, liquids and gases with a velocity depending on the mechanical properties of the material. Imperfections such as cracks, pores or inclusions cause sound-wave interactions which result in reflection, scattering and general dampening of the sound wave [16.3–6]. This dampening of the sound waves is responsible for the distance traveled by the sound. In liquids sound can travel large distances; on the other hand, in coarse-grained solids the traveling distance may be only a few centimeters due to scattering. Sound directions and the estimation of the distance to the source are not easily obtainable by simple methods. More precise techniques are necessary to overcome these problems. This requires the use of narrow sound beams.

In nondestructive evaluation (NDE) narrow sound beams using short wavelengths can be formed when the ultrasonic source size is much larger than the wavelength. Nondestructive testing is carried out using ultrasonic waves at high frequencies above the audible range, higher than approximately 20 kHz and up to the range of some hundred MHz.

Historically, the development of methods for ultrasonic materials testing in the industry started at the end of the Second World War. Although the orientation of bats using sound waves was an established phenomena, the discovery of the piezoelectric effect by Jacques and Pierre Currie 1880 and 1881 [16.3] was of critical importance for the application of ultrasound. The theory of sound propagation in solids was developed by Lord Rayleigh between 1885 and 1910, as well as the development of early electronic devices.

Sound-field generation and reception is performed using special devices, so called ultrasonic transducer or ultrasonic probes. The active sound-field generation tool is in the most cases a special ceramic with piezoelectric properties. A piezoelectric material has the characteristic that, if it is deformed by an external mechanical pressure, electric charges are produced on its surface (for example Fig. 16.4). This effect was discovered in 1880 by the brothers Curie. The reverse phenomenon, according to which such a material, if placed between two electrodes, changes its form when an electric potential is applied, was discovered soon afterwards in 1881 (Fig. 16.5). The first effect is referred to as the direct piezoelectric effect, and the second as the inverse piezoelectric effect. The direct effect is used for measuring and the inverse effect for producing mechanical pressures, deformations and oscillations.

Fig. 16.4 Direct piezoelectric effect

Fig. 16.5 Inverse piezoelectric effect

Generation of Ultrasound

Most transducers used in ultrasonic nondestructive inspection are based on the piezoelectric effect. Generation of ultrasound is achieved using the inverse piezoelectric effect, and the receiving procedure is carried out with the direct piezoelectric effect. The principle of the generation and reception of ultrasound was explained and demonstrated with the help of the quartz crystal. However for the time being other materials with piezoelectric properties can be used to advantage. Today,

piezoelectric ceramic is most commonly used, typical examples include barium titanate (BaTiO_3), lead zirconate titanate ($\text{PbZrO}_3\text{--PbTiO}_3$ solid solution PZT), lead meta-niobate (PbNb_2O_6), barium sodium niobate ($\text{Ba}_2\text{NaNb}_5\text{O}_{15}$) and the polymer polyvinylidene fluoride (PVDF). The manufacturing process and material properties can be varied within certain limits, achieving a large range of acoustical properties, which are normally customized to a specific application. These materials have a much higher so-called electromechanical coupling factor than quartz. The frequency of the ultrasonic signal comes from the thickness of the piezoelectric ceramic plate. The correlation between thickness and frequency f_0 is given by (16.1).

$$f_0 = \frac{c}{2t} ,$$

(16.1)

where c is the velocity of sound, and t is the thickness of the piezoelectric ceramic plate.

With knowledge of the sound velocity c of the piezoelectric ceramic, the frequency f_0 is adjustable by varying the thickness t of the ceramic. In Table 16.1 the average sound velocities of common ceramic materials are listed.

Piezoelectric ceramic materials are mainly used for the preparation of ultrasonic transducers, nevertheless other physical properties can be utilized for generating and receiving ultrasound. Although many of these methods produce weaker signals than are obtainable by the piezoelectric effect, they offer a number of advantages that in special cases makes their application in the testing of materials useful. For many of these alternative techniques the energy is transmitted by electrical or magnetic fields, which in principle make mechanical contact with the metallic test piece unnecessary. The conversion into, or from, acoustic energy takes place in the surface of the workpiece concerned. Compared with the piezoelectric oscillator, which requires direct coupling, normally with a suitable medium, e.g. water, to the workpiece, the surface of the workpiece forms in this a part of the acoustic transducer.

Other possibilities for the generation of ultrasound are the use of mechanical shock or friction effects, the application of thermal effects by heating the surface of a body suddenly (*heat shock*) the exploit of electrodynamic effects based on the Lorentz force and the

Table 16.1 Sound velocities of piezoelectric ceramic materials used for ultrasonic transducers

Material	BaTiO ₃	PZT (P5)	PbNb ₂ O ₆	PVDF
Sound velocity (m/s)	5200	4200	3300	1500–2600

magnetostrictive effect. Apart from the generation of ultrasound using the electrodynamic effect the others methods play at present a small role into the NDE field.

Reflection and Transmission of Ultrasonic Waves at Boundaries

Normal Beam Incidence. The behavior of an ultrasonic wave in an unlimited material is only possible on a theoretical level because in reality every material has boundaries. At such boundaries the traveling wave is disturbed. If the boundary is in a direct contact with a vacuum, transmission of the ultrasonic wave through the boundary is impossible; total reflection occurs. Consider an incident longitudinal plane wave traveling perpendicular to a boundary or interface between two materials, as demonstrated in the schematic diagram in Fig. 16.6 [16.3,4]. For symmetrical reasons only the reflected P_r and transmitted P_t waves are possible. The part of the reflected wave is characterized by the reflection coefficient R and the part of the transmitted wave by the transmission coefficient T . In this special case the reflection and transmission coefficients only depend on the acoustic impedance $W = \rho c_L$ where ρ is the density of the material and c_L the sound velocity of the longitudinal wave. The equation for the calculation of the two coefficients are as follows.

$$R = \frac{W_2 - W_1}{W_1 + W_2} \quad \text{and} \quad T = \frac{2W_2}{W_1 + W_2} \quad (16.2)$$

The indexes 1 or 2 are used to define the two media (Fig. 16.6). It is clearly visible from these equations that 100% of the sound is transmitted through the interface if W_1 is equal W_2 . In reality what happens for a steel–water interface is a combination of impedances often given in ultrasonic examination ($W_1 = 45 \times 10^6 \text{ Ns/m}^3$ for steel and $W_2 = 1.55 \times 10^6 \text{ Ns/m}^3$ for water) for a steel–water

Fig. 16.6 Normal incidence of a sound wave on a boundary

Fig. 16.7 Sound pressure values by reflection at a steel/water interface

interface. With these values a reflection coefficient of -0.935 and a transmission coefficient of 0.0065 is calculated. That means that 93.5% of the sound field is reflected at the steel–water interface (Fig. 16.7). The negative value of the reflection coefficient means that the phase of the reflected ultrasonic wave has changed by 180° compared with the incident wave. If we assume an interface steel–air then R is -0.99998 , i.e. nearly 100%. Such a material combination is given for instance if a crack is located in a steel component. Therefore, when the sound wave strikes the crack surface at a normal angle it can be detected with a high probability.

Fig. 16.8 Wave mode conversion at a boundary

Equations (16.2) are valid if the sound wave is traveling perpendicular to the interface. The behavior is more complex if the sound strikes the surface with an angle $> 0^\circ$ (Fig. 16.8). A mode conversion as illustrated in the figure must be assumed, i. e. an incidence longitudinal wave is reflected at the boundary as well as a shear wave. A longitudinal and a shear wave are transmitted into the second medium. This circumstances must be taken into consideration by the calculation of the reflection and transmission coefficient. The situation is similar if an incidence shear wave is assumed. For each case presented in Fig. 16.8 two reflection and two transmission factors are obtained.

Inclined Beam Incidence. If an ultrasonic longitudinal plane wave strikes a liquid–solid interface at an angle α as demonstrated in Fig. 16.9 one reflected wave and two transmitted waves are generated. The reflected angle α is equal to the incidence angle whereas the transmitted angles are different. These two angles are dependent on the sound velocity for the different wave types corresponding to the two materials. The calculation of these angles can be carried out using Snell's law.

$$\frac{\sin \alpha_1}{\sin \alpha_2} = \frac{c_1}{c_2} \quad (16.3)$$

Using (16.3), all angles can be calculated if the sound velocities and one angle are known. In the following some consequences derived from the Snell's law are considered. The Plexiglas–steel interface is important for ultrasonic angle beam probe construction and therefore we will regard this material combination in the following. The sound velocity for the longitudinal wave is on

average 2740 m/s for Plexiglas (perspex) and 5920 m/s for steel as well as 3255 m/s for the shear wave in steel. Consideration of Snell's law indicates that two critical angles exist with respect to the refraction process on the interface. The first critical angle is given when $\alpha_2 = 90^\circ$, i. e. the total reflection of the longitudinal wave. In this case only shear waves exist in material 2. The second critical angle occurs when the shear refracted angle is 90° . If only shear waves will be used in the practical application the Plexiglas wedge angle β should be between 27.6° and 57.3° . These values are calculated using the above printed sound velocities. Angle beam probes generating shear waves used for the examination therefore have angles of incidence between 35° and 80° .

Ultrasonic Transducers

In the following, the description of generating and receiving ultrasound with transducers (probes) will focus on piezoelectric ceramic material [16.3, 5, 6] due to the importance in practical applications. Such ultrasonic transducers are optimized for different areas of application [16.7–9] but the basic construction principle nearly always remains the same. Figure 16.10 shows schematically typical commercial ultrasonic transducers as a part of the basic equipment for ultrasonic examinations.

A longitudinal wave is generated using a straight beam probe, presented in a schematic sketch in Fig. 16.10a. The piezoelectric ceramic plate is behind a protective coating (wear shoe/plate) and the backing material (damping element) is largely responsible for the pulse form. Together with an electrical adaptation the ultrasonic pulse can be formed and optimized to a particular application. As explained the thickness of the ceramic delivers the middle frequency of the pulse. This kind of probe has such an construction that the waves have a perpendicular (straight) radiation in relation to the test object's surface. The size of the piezoelectric ceramic together with the middle frequency will determine important ultrasound probe parameters, including the near-field length, divergence angle and beam diameter, which are required to perform reliable inspection. All these parameters of an ultrasonic probe can be measured or calculated using simple equations. Figure 16.10b shows the principle drawing of an angle beam probe for shear-wave generation. The shear waves are generated due to refraction of the incident longitudinal wave on the coupling surface. A common ultrasonic angle beam probe can be employed to generate shear waves only. This is achieved if the wedge has an angle between the first and the second critical angle. So far, for the material combination perspex/carbon steel, con-

Fig. 16.9 Inclined incidence at a liquid/solid boundary

Fig. 16.10a,b Normal or straight beam probe (a) and angle beam probe (b)

ventional probes are available generating shear waves with incidence angles of 45° , 60° and 70° . In recent years with the development of electronic beam forming so-called phased array probes [16.3] with variable incidence angles have become available. The principle of the phased array probe can be explained with the help of Fig. 16.11. The crystal is divided into several elements. In the given example, eight elements are illustrated. Each element is connected with the transmitter/receiver part of special ultrasonic controlling equipment (phased array equipment). The time for transmitting the main bang (transmitter pulse) is controlled by the equipment in such a way that different transmitter times can be achieved between the individual elements. When the delay time Δt between the elements is constant decreasing or increasing a variation of the incidence angle will occur. If Δt follows a predetermined curvature (like a lens) the sound field can be focused at a certain distance. Further a combination of both is also possible. With such a phased array probe all incidence angle can be realized for longitudinal as well as for shear waves. For the second case, if Δt is specified by the curvature of a lens, a variation of the focal distance is given by changing the curvature. With advanced phased array equipment both changing the angle and focal distance can be carried out in one stage.

In the following some of sound-field distributions of different kinds of probes are presented.

Sound Propagation in Solids

Sound propagation in materials is always connected with an interaction of the ultrasonic pulse and the structure of the material. Especially for solid materials such as

steel the interaction with the grain size (scattering and reflection) is sometimes not negligible mainly if the wavelength and the grain size are within the same dimensional range. Due to this interaction the sound losses energy i. e. an attenuation of the sound will happen along the propagation direction. Another effect is the frictional motion of the particles of the solid which also has an attenuation effect but is based on the absorption of the ultrasonic intensity. Therefore the total attenuation of the ultrasonic intensity is given as the sum of the scattering and absorption coefficient (16.4)

$$\mu = \mu_s + \mu_a. \quad (16.4)$$

This attenuation must be taken into consideration during the examination.

Fig. 16.11 Principle of a phased array probe

Fig. 16.12a,b Pulse-echo technique (a) and through-transmission technique (b)

Principle of the Pulse-Echo and Through Transmission Methods

Defects in materials caused scattering and reflection of the ultrasonic wave and the detection of the reflected or transmitted waves allows the location of the defect. A general illustration of the *pulse-echo* and *through transmission* methods is shown in Fig. 16.12. The through transmission normally requires access to both sides of a component and is applied if the back-reflection method cannot provide sufficient information about a defect. For example, when small defects are detectable which do not give adequate reflection signals.

The pulse-echo technique requires access to only one side of the component. This is one advantage of this method compared with the through-transmission technique. Another advantage of the pulse-echo method is given due to the time-of-flight measurement because the defect location (distance from the coupling surface) can be estimated from the time required for the pulse to travel from the probe to the discontinuity and back and can be displayed on an oscilloscope. If the horizontal sweep of the oscilloscope is calibrated with the sound velocity into the material to be inspected, the required travel time from the probe to the reflector and back corresponds to the distance of the reflector from the coupling surface. This method is used extensively in practice.

16.1.3 Application Areas of Ultrasonic Examination

The application range of ultrasonic examination is very broad. It covers, for example, wall thickness measurement of structural components and the detection of wall thickness losses due to corrosion, erosion, wear

Fig. 16.13 Principle of wall thickness measurements

etc. Other application areas include the measurement of material properties such as sound velocity, elastic constants and the detection of flaws, e.g. cracks, slag inclusions, lack of fusions, pores. The following examples illustrate the application of ultrasonic examination for performance control of components and engineering systems in various areas of technology and industrial sectors.

Wall Thickness Measurement of Components

During the lifetime of a component their surface are subjected to environmental stresses. Depending on the environment corrosion phenomena must be taken into consideration. A reduction of wall thickness can occur and as a consequence the safety factor that was the basis for the construction may no longer be valid. The principle of thickness measurement is illustrated in Fig. 16.13 [16.10]. A straight-beam longitudinal probe is coupled on the surface and the pulse echo from the parallel flat opposite surface (back wall) is received and displayed on the screen. The transit time of the pulse corresponds with the wall thickness if the equipment was calibrated with the correct sound velocity. This method is sometimes known as a simple length measurement.

Fig. 16.14 Wall thickness measurement using multiple echoes

Another method is to analyze multiple echoes which are observed, i.e. multiple reflections of an acoustic pulse propagating between the coupling surface and the back wall (Fig. 16.14). Since the constant distances between the echoes corresponds to the specimen thickness d , then the whole transit time of the multiple echo indications on the screen is also a multiple of the wall thickness. An example of a corroded aluminum plate from the aircraft industry is plotted in Fig. 16.15. For

Fig. 16.15 Wall thickness measurement

wall thickness estimation the measurement was carried out using a mechanized ultrasonic immersion technique. The different gray scales correspond with different wall thicknesses.

All thickness measurement using ultrasound have in common that the coupling conditions of the transducer must be performed in the same manner, however also care must be taken to use the correct sound velocity in the material.

Weld Inspection

Ultrasonic weld inspection is done extensively around the world, and the pertinent literature is published in a multitude of journals, proceedings and technical reports [16.9]. Usually, a shear-wave angle beam transducer is used to examine the weld and the adjacent region in a halfskip and skip distance (Fig. 16.16). In the figure the method of examining the root, the interior and the top layer of the weld is presented. The skip distance can be calculated (16.5) where d is the thickness of the specimen and α the beam angle.

$$S_k = 2d \tan \alpha \quad (16.5)$$

The examination of welds requires that the skip distance, the beam angle, the beam spread and the probe index point are well known. Further information, such as the surface conditions, coupling media to be used, system of marking welds, system of indicating defects found, access conditions for examination of welds and use of other, possible NDT methods should be known before examination. The number of beam angles depends strongly on the wall thickness of the component to be examined. After the checking sensitivity and setting up of the whole ultrasonic system (transducer and equipment) the inspection procedure can be carried out for the detection of longitudinal defects. The shear-wave probe should be placed on the coupling surface and kept during the movement perpendicular to the weld centerline while swiveling the probe head lightly. The ultrasonic probes used for weld inspection must take

Fig. 16.16 Weld inspection

Fig. 16.17 Turbine shaft

into consideration the geometry of the component and the weld. Different weld joints include square groove, bevel groove, *v*-groove, *u*-groove and weld types including butt, lap, *T*, edge, and corner; although this list is not complete, different ultrasonic probes with special sound-field characteristics must be used to overcome this examination problem. Examination procedure and problems are described in several standards, codes and guidelines. For example the detection of defects direct or in the neighborhood of the coupling surface require so-called transmitter receiver probes. The main measuring principle that justifies the use of such probes is the separation of the transmitter and receiver function which is accomplished by using two crystals in the probe. However the choice of the optimal inspection techniques for reliable examination results requires, in addition to the knowledge of the standards, a skilled examiner.

Examination of Forged and Rolled Machinery Parts

With regard to high machining cost, the examination of large forgings should start in the earliest stages of production. In recent times the inspection of components such as turbine shafts, railway wheels etc. are carried out using mechanized testing. Figure 16.17 shows an example of the examination of a turbine shaft with a diameter of about 2 m. The examination was performed using phased array probes [16.11]. During the shaft rotation the incidence angles for longitudinal waves were changed in a range between -30° and 30° with steps of 3° . For every full circle a echotomogram was reconstructed. After the whole examination of the shaft the defect situation in the shaft, in the radial and axial direc-

Fig. 16.18 Railway axle inspection with phased array probes

tions, was visualized with the help a computer program called *glassy shaft*.

Another example where mechanized testing is used is the inspection of railroad axels with phased array probes (Fig. 16.18). Two coupled phased array probes on the axel surface are presented in the figure (two probes for each side). Thus for this special application case four phased array probes are necessary for the examination of the area beneath the wheels and the disc brakes. Phased array probes with the possibility of steering the incidence angle have advantages because of the limited accessibility between the wheel and the disc brake.

Inspection of Semi-finished Industrial Products

A wide field for NDT is the inspection of semi-finished products such as rods, pipes plates, casting products etc. Defects in this group of products can either be on or near the surface and internal (embedded) defects. In the case of steel rods, manual ultrasonic inspection using the pulse-echo technique is implemented in practice as well as mechanized inspection. Straight and angle beam probes are for the detection of the different defects such as shrinking cracks, inclusions, cavities, pores etc. There are several different techniques for identifying defects, which can be achieved by mechanized inspection. One main difference is the handling of the rod during the inspection, e.g. whether only longitudinal movement or rotation of product is performed. The probe arrangement will depend on the type of mechanical rod movement that takes place. A more or less simple movement of the rod can be carried out if phased array probes or real-time scanners are used. The reason is, that

Fig. 16.19 Array transducers for the examination of longitudinal welds in pipes (GE Inspection Technologies)

a complicated mechanical movement is substituted by the sound movement. One example of such a transducer arrangement is presented in Fig. 16.19. The geometry of the array transducer is adapted to the geometry of the pipe to be inspected. In this case the longitudinal weld of pipes will be examined. In addition with the help of some of ultrasonic transducers a simple mechanized movement of a rod is also possible. Three probe holders in a circumferential position of 120° in each and the combination of angle and straight-beam transducers sufficiently guarantee the detection of embedded and near-surface longitudinal defects.

16.1.4 Magnetic Particle Inspection

The physical principles of magnetic particle inspection have been well known for a long time. At the beginning of the 20th century it was discovered that, when steel parts are machined while held in a magnetic chuck, the iron grindings formed patterns around cracks on the surface. The disturbance of magnetic fields by surface defects in magnetized ferromagnetic specimens is the principle of the magnetic particle inspection method.

Fig. 16.20 Principle of magnetic particle inspection

Fig. 16.21 Crack orientation in relation to the magnetic field

The defect will cause some of the lines of magnetic force to depart from the surface and thus to create a magnetic leakage field. Fine iron (powder) particles, applied to the surface of the specimen, are attracted to the area of flux leakage, creating a visible indication of the flaw. The magnetic leakage field will hold the particles in a ridge on top of the crack (Fig. 16.20). By taking advantage of this effect an accumulation of magnetic particle forms, which is much wider than the crack itself, thus making an otherwise invisible crack visible.

Fig. 16.22 Principle of liquid penetrant inspection

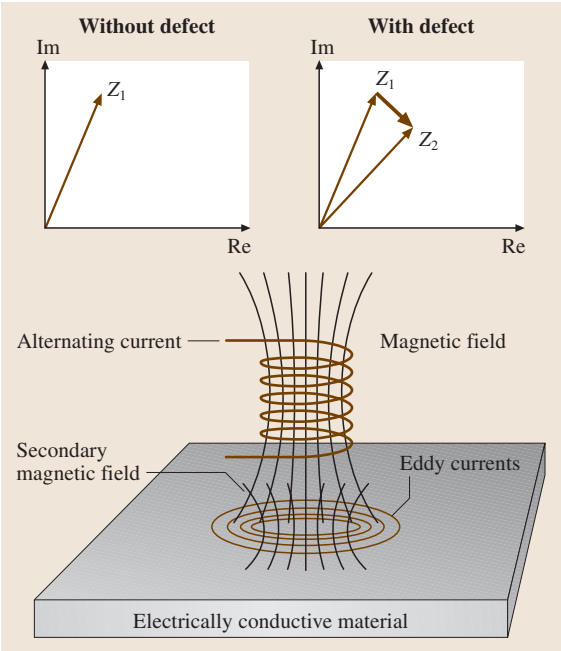

Fig. 16.23 Principle of eddy-current testing

Fig. 16.24 Penetration depth versus eddy-current frequency

If, for example, a crack is oriented perpendicular to the flux lines the effect of disturbance of the magnetic field is at a maximum compared with other orientations.

However, in this situation the leakage field is strongest and provides the clearest indication of a defect. Figure 16.21 demonstrates the orientation of a crack in relation to the direction of the magnetic field. The cylindrical object was magnetized with a solenoid coil that provides longitudinal magnetization of the workpiece, suitable for the examination of transverse cracks. Longitudinal cracks are not visible using this magnetization procedure. From the previous example it is clear that a good magnetic particle inspection should always be carried out with the magnetic field in two different directions, preferable in two orthogonal directions.

16.1.5 Liquid Penetrant Inspection

Liquid penetrant inspection is an old but effective NDT method of examining surface areas for cracks, or discontinuities. In railway and casting fabrication this technique is widely practiced to examine the surfaces by the *oil and whiting* method. This involves dunking parts, such as locomotive parts or big bells (made from bronze), in large tanks filled with heavy oil diluted with kerosene. After removal and cleaning, the surface of the specimen is then coated with a fine suspension of chalk in alcohol so that a white surface layer was formed. The residual oil in the surface-opening cracks seeps out and colors the white coating grey. At the time, more-effective penetrating oils containing highly visible dyes (usually red) were developed to enhance flaw detection capability. This method known as *color-contrast dye penetrant* is still used quite extensively. Due to the reason that this method is relatively simple (although care must be taken because there are several requirements which have to be regarded during examination) to handle. It should be clear that this method is restricted to defects open to the surface. The principle procedure of liquid penetrant inspection is illustrated in Fig. 16.22. The penetrant is drawn down into the open crack by capillary action (a). Excess surface penetrant is then removed (b). Developer powder on the surface draws out penetrant liquid, which seeps into and discolors the powder. The crack becomes visible on the surface. One of the advantages of liquid penetrant inspection is that all materials can be inspected if it is guaranteed that the material is resistant to the liquid used.

16.1.6 Eddy-Current Testing

A varying electric current flowing in a coil (eddy-current probe) generates a varying magnetic field [16.12, 13]. In a specimen with electric conductivity in the prox-

Fig. 16.25 Head checks at the gauge corner

imity of this coil, eddy currents flowing in a closed loop in the surface layer of the specimen are produced (Fig. 16.23). Defects at materials surfaces in the opposite of the eddy-current probe can be detected by the change of the electric coil impedance, which will be, e.g., displayed for evaluation by the test instrument connected to eddy-current probe. Cracks and other surface inhomogeneities or discontinuities modify the eddy currents generated in the specimen. The coil impedance is changed in relation to a surface without defects. Practical application using eddy-current techniques is only possible if sensitive electronic devices are available that are able to measure the very small changes of the magnetic field caused by a defect. An important phenomena of eddy-current testing is the so called skin effect. There is no homogenous current distribution within the specimen; it is mainly concentrated at the contact surface of the eddy-current probe. This physical phenomenon is the reason why eddy-current testing is basically limited to thin test objects or only in a surface layer of thicker objects. The penetration depth δ of eddy current can be calculated using (16.6) and depends on the frequency ν , the conductivity σ , the permeability of the free space μ_0 and the relative magnetic permeability μ_r . For non-ferromagnetic materials μ_r is equal to 1.

$$\delta = \frac{1}{\sqrt{\pi \nu \mu_0 \mu_r \sigma}} \quad (16.6)$$

The frequency used in eddy-current testing ranges from a few kHz to more than 5 MHz. At lower frequencies the penetration depth δ is relatively high, as derived from (16.6), but the sensitivity to the detection of discontinuities is poor, while the opposite is true at higher frequencies. Values of δ versus the frequency are plotted in Fig. 16.24. However, it should be considered that these estimations have been made under simplified assump-

Fig. 16.26 Broken rail caused by head checks

tions. In practical applications the penetration depth δ also depends on the characteristic of the eddy-current probe. For crack detection in and near the surface area, the penetration depth δ must be optimized in relation to the sensitivity of detection. For wall thickness measurement (detection of corrosion phenomena) δ must be at least that of the component thickness.

Figure 16.24 demonstrates that ferritic materials have very high permeability values and therefore only low penetration depth can be achieved (fractions of millimeter). This is the reason why eddy-current techniques cannot be applied to defect detection in certain depths or wall thickness measurements. A magnetizing facility up to the saturation field can be helpful due to the reduction of the relative permeability.

On the other hand austenitic steel or nonferrous materials are suitable for the application of eddy-current methods, and a broad application of this method is in the aircraft industry.

The application of eddy-current techniques embraces a wide industrial field from the aircraft industry, the railway industry to the power-generation industry etc. Out of these wide fields of use, an example from the railway industry will be presented [16.14]. The inspection of railway wheels, known and referred to as the inspection of the railway gauge corner using eddy current, has increased in recent years. In Fig. 16.25 a special defect type is shown: so-called head checks. Head checks are cracks in the gauge corner and can be identified by their high number, having a separation of 2–7 mm. Head checks initially grow into the interior of the rail at an inclination angle of 15°

to 30°. Rail gauge corner inspection is necessary to avoid rail damage such as that illustrated in Fig. 16.26 and is necessary to avoid accidents and save human lives.

However, an increase in surface or near-surface defects, such as head checks (Fig. 16.25) requires inspection techniques with a high detection and sizing potential to facilitate the identification of such defects. Another condition has to be considered, which is the

speed of the inspection train. Inspection can be performed at up to 100 km/h.

To summarize, the eddy-current techniques proved to be most suitable for such application, because eddy-current probes have a high resolution when the head check distance is within the range of a few millimeters and modern technology means measurements can take place at higher speeds, which is an important economic factor.

16.2 Industrial Radiology

Industrial radiology is typically applied for the volumetric inspection of industrial products and installations [16.15, 16]. The basic set up consists of a radiation source in front of the object to inspect and an area detector behind the object. The classical detector is an X-ray film. New electronic area detectors are gradually substituting film. The radiation source can be an X-ray generator, a gamma source or a particle radiator. Objects of all possible materials and thicknesses can be inspected, provided the right radiation source and energy is selected. There exist practical limitations to the upper material thickness, e.g. 50 cm penetration length in steel or 2 m in concrete (at a radiation energy of 12 MeV).

Radiology dates back to the discovery of X-rays by W. C. Roentgen in 1895 and the discovery of gamma radiation by H. Becquerel in 1896. After the development of high-vacuum X-ray tubes with energies up to 100 keV in 1913, radiological techniques have been introduced into industrial practice. The description of the first computerized tomography (CT) system by G. Hounsfield and A. Cormack in 1973 was a further milestone in the development of radiation techniques in medical and industrial applications. In acknowledgement all four scientists received Nobel prizes (for the methods of computerized tomography see Sect. 16.3 and Sect. 16.5). Over the last decades tremendous progress in hardware has occurred, such as the development of radioscopy systems with X-ray image intensifiers, micro-focus X-ray tubes, digital detector systems. This progress was accompanied by an enormous increase in computing capabilities which made the introduction of digital techniques possible, such as digital image processing and enhancement, automated defect recognition, data reconstruction, and three-dimensional CT applications. Nowadays, the increased capabilities of digital detection systems, such as phosphor imaging plates (computed radiography) and

flat-panel detectors (digital detector arrays), indicate a new era in radiology.

16.2.1 Fundamentals of Radiology

Generation of Radiation

Radiation is used in industry, due to its capability to penetrate opaque material to visualize the inner structure of components. The radiation photon has a dual character, acting sometimes like a particle and at other times like a wave. Consequently, the radiation photon is characterized by its energy E or its wavelength λ or frequency ν . Planck postulated that the energy of a photon is proportional to its frequency

$$E = h\nu \quad (16.7)$$

with Planck's constant h . All photons have equal velocity,

$$c = \nu\lambda, \quad (16.8)$$

no electric charge, and no magnetic moment. X-ray or gamma radiation is fully characterized by its energy. They are distinguishable only due to their origin but not due to their properties.

X-rays are usually produced by the deceleration of high-energy electron impinging by a metallic target. Gamma rays are of nuclear origin. Whereas X-rays originate in the electron structure of the atom, gamma rays are emitted by the de-excitation of atomic nuclei in a nuclear reaction. The emission of gamma rays is usually associated with the emission of alpha and beta particles.

X-rays are generated in X-ray tubes, which consist of a cathode and an anode made from heavy high melting metal (Fig. 16.27). Electrons are emitted from the cathode and accelerated to the anode in a high-voltage electrical field. When the electrons with kinetic energy $m_e v^2/2$ hit the target of the X-ray tube the energy is

Fig. 16.27 Principle of the X-ray tube

transformed in several ways yielding the production of: (i) bremsstrahlung with a continuous spectrum, and (ii) characteristic radiation (Fig. 16.28).

Bremsstrahlung is produced when the electron interacts directly with the nucleus of the target atom. The electron is stopped by the nucleus (near field) and all its kinetic energy is transformed into a quantum of radiation. Because most of the impinging electrons also interact with the electrons of the target atoms they lose a part of their energy to remove an electron from an atom. The remaining kinetic energy of the electron can be transformed into an X-ray photon. In general, X-rays photons of many energies are emitted forming the continuous bremsstrahlung spectrum. The voltage of the

Fig. 16.28 Typical X-ray spectrum

accelerating electrical field gives the maximum energy of the emitted X-ray photons.

When an electron is removed from the target atom by the impinging electron, the atom is left in an excited state. Recombination processes within the electron shell yield the emission of one or more photons with energy characteristic for the atom. As a result, the continuous bremsstrahlung spectrum is overlaid by characteristic spectral lines (compare Fig. 16.28).

The target of a X-ray tube can stop all impinging electrons (thick or absorption target) as used in most of the industrial X-ray tubes, or stop only a part of the electrons (thin or transmission target) as used in micro-focus tubes. Because most of the electron's energy is converted into heat (about 95%), overheating of the target has to be avoided. Therefore, the anode to which the target is attached typically consists of a material with high thermal conductivity, such as copper. Often it is necessary to cool the anode by directly injecting coolant. Another way of solving the problem of localized overheating of the target is by using a rotating anode.

Gamma rays are emitted during the spontaneous decay of unstable isotopes. The decay is accompanied by the emission of alpha or beta particles. Each emission transforms the parent isotope into a daughter isotope having a different mass and nuclear charge. This process continues until the daughter isotope is stable. This is described by the half-life T required for one half of the original number of atoms to decay or change to the daughter atoms. The number of atoms disintegrating per unit time can be expressed by

$$N = N_0 e^{-\lambda t} \quad (16.9)$$

with the total number of parent atoms N_0 , and the decay constant λ . The half-life is given by

$$T = \ln 2 / \lambda = 0.693 / \lambda \quad (16.10)$$

Artificially produced isotopes such as Ir-192 or Co-60 are widely used as sources of radiation for technical radiography. The emitted gamma-ray spectrum consists of separated lines with energies characteristic for the particular isotope. Both isotopes are obtained by neutron bombardment of the naturally existing stable isotopes Co-59 and Ir-191

Figure 16.29 shows the disintegration scheme for Co-60. As a result two gamma lines with 1.173 MeV and 1.332 MeV are observed.

Fig. 16.29 Disintegration series of Co-60

Interaction with Matter

Attenuation Law. Photons interact with a nucleus or an orbital electron of the attenuating material. The interaction of photons with matter can be classified into three predominant types: (i) the photoelectric effect, (ii) scattering, and (iii) pair production. Photodisintegration is neglected due to its minor contribution. The attenuation law is described assuming a narrow beam geometry and monochromatic radiation (Fig. 16.30). Considering an incremental attenuating layer of thickness dx at depth x , the change in the beam intensity dI in dx is proportional to the intensity I at that depth x and the thickness of the layer dx

$$dI = -\mu I dx \quad (16.12)$$

with the proportionality constant μ , which is the linear attenuation coefficient given in one per unit length. Integration of (16.12) yields

$$I_P = I_0 e^{-\mu d} \quad (16.13)$$

Fig. 16.30 Attenuation law

where I_0 is the intensity of the incident beam and I_P is the primary intensity after penetrating material of thickness d . Equation (16.13) is referred to as the attenuation law. The linear attenuation coefficient is given by the sum of the interaction coefficients for each of the various processes mentioned above

$$\mu = \tau + \sigma_S + \pi \quad (16.14)$$

Here τ is the attenuation coefficient due to the photoelectric effect, σ_S that due to scattering, and π that due to pair production.

Photoelectric Effect. If a photon of energy E transfers its total energy to an electron in some shell of an atom, the process is called the photoelectric effect Fig. 16.31. The energy of the photon can be sufficient to lift an electron from an inner to an outer shell or to remove the electron completely and to ionize the atom. In the second case, the photoelectron obtains a kinetic energy given by the difference between the photon's energy and the binding energy of that particular electron. As the energy of the photon increases absorption becomes possible by inner shell electrons. When the energy of the photon reaches the binding energy of a particular shell of electrons the absorption coefficient increases abruptly because more electrons are available for interaction. The energy at which this sharp increase occurs is called an absorption edge, which is characteristic for every atom. Otherwise the absorption coefficient decreases with increasing photon energy. The energy dependence of the linear absorption coefficient for lead is shown in Fig. 16.32. As secondary effects, recombination processes within the electron shell yield either X-ray fluorescence (Fig. 16.31) or the emission of Auger electrons.

Fig. 16.31 Photoelectric interaction of an incident photon with an orbital electron may yield X-ray fluorescence due to recombination of electrons from a higher to a lower orbital

Fig. 16.32 Linear attenuation coefficient μ for lead as a function of energy $h\nu$: τ photoelectric effect, σ_R Rayleigh scattering, σ_C Compton scattering, and π pair production

Scattering of Photons. Scattering can be incoherent, which is known as Compton scattering, or coherent, which is called Rayleigh scattering (Fig. 16.33). Whereas a photon transfers its total energy to an orbital electron while undergoing an absorption event, it loses no or only a part of its energy and is redirected if a scattering event occurs.

The analysis of the Compton process shows that the energy of the scattered photon E' is always less than that of the primary photon $E > E'$. The remaining energy is transferred to the struck electron as kinetic energy. The energy shift predicted depends only on the scattering angle θ and not on the nature of the scattering medium. The larger the scattering angle the larger the energy shift observed. The relationship between the scattering angle and the energy shift can be found from the conservation of energy and momentum during the collision when assuming particle properties of the photon. The scattering of a photon by a free electron is described by the Klein–Nishina formula, providing an accurate prediction of the differential cross section with respect to the solid scattering angle. If considering electron binding effects the Klein–Nishina formula has to be corrected by the incoherent scattering function, which decreases the free-electron cross section in the forward direction, for low energies E , and for high atomic numbers Z . The linear Compton coefficient for lead can be found in Fig. 16.32. In general it decreases with the photon energy, starting at an energy characteristic of the material.

The coherent or Rayleigh scattering involves no energy loss of the photon upon being scattered by an atom.

Fig. 16.33 Scattering effects: Compton scattering in which an incident photon ejects an electron and a lower-energy photon (left); Rayleigh scattering of a photon without energy loss

It is only a photon process that does not produce electrons. The angle distribution for coherent scattering of a photon by a free electron does not depend on the photon's energy and is given by the Thomson formula, which is equivalent to the Klein–Nishina formula at zero energy. To take account of electron binding effects, the Thomson formula has to be corrected by the coherent atomic form factor. It yields a strong forward directionality of Rayleigh scattering, which increases with the photon energy. Rayleigh scattering occurs only for soft radiation for which the binding energy of the electrons in their atomic shell is important. It is most important for elements of low atomic number Z and high photon energies E . The Rayleigh cross section decreases with energy (compare Fig. 16.32). The contribution of this type of scattering to the total attenuation coefficient is never greater than about 20%.

Pair Production. If the photon energy exceeds double the electron mass of rest, i. e. if $E = h\nu > 1.022 \text{ MeV}$, the photon is converted in the electrical field of the nucleus into an electron and a positron. This process is called pair production Fig. 16.34. Photons with lower energy are not able to produce an electron–positron pair. The photon energy that exceeds the

Fig. 16.34 Pair production (left) and positron–electron annihilation (right)

Fig. 16.35 Relative importance of photon interactions

needed minimal energy for producing an electron-positron pair appears as the kinetic energy of the pair. The probability of occurrence of this process increases approximately logarithmically with the energy above the threshold value and then levels off for extremely high photon energies (compare Fig. 16.32). The produced pair loses its kinetic energy within a very short time of about 10^{-12} s. The remaining resting electron positron pair has a lifetime of about 10^{-9} s before annihilation. As a result two gamma photons are emitted in opposite direction with energy of exactly 511 keV.

As seen in Fig. 16.32, different attenuation mechanisms are dominant at different energies. The photoelectric absorption is the dominant effect for lower energies, whereas Compton scattering becomes important for medium photon energies. For higher energies pair production is the most probable interaction mechanism. Figure 16.35 shows the relative importance of the different photon interactions with matter. The lines show the values of the atomic number Z and the energy for which the two neighboring effects are of equal importance.

Image Quality

The image quality is the characteristic of a radiographic image that determines the degree of detail it shows. It is influenced by a large variety of influencing factors originating in the inspected object (material, thickness), the radiation source (radiation quality), the imaging system (detector properties), and geometry (focal spot size, source-to-object distance, object-to-detector distance). Image quality can be measured by image quality indicators (IQI).

Fig. 16.36 Image formation

Contrast. The formation of a radiographic image can be easily explained in terms of a simple step object Fig. 16.36. The intensity or density difference seen between two thicknesses at a given detection intensity I or density in an object on a radiograph represents the radiographic contrast in the image (approach for small thickness differences):

$$C_1 = I_1 - I_2 \quad (16.15)$$

with the intensities I_1 and I_2 after penetrating a material of thickness d_1 and d_2 , respectively. Introducing $I_P = I_{P1}$ as a reference primary intensity, a linear relation follows between the absolute contrast ΔI and the thickness difference from the attenuation law (16.13)

$$\Delta I = I_P \mu \Delta d. \quad (16.16)$$

For the interpretation of radiographs the relative contrast with which an indication is imaged is important

$$C_r = \frac{\Delta I}{I} \quad (16.17)$$

where $I = I_S + I_P$ gives the total intensity. For small thickness differences, it follows from using (16.16) that

$$C_r = \frac{I_P \mu \Delta d}{I_S + I_P} = \frac{\mu}{1+k} \Delta d = C_{sp} \Delta d \quad (16.18)$$

with the scattering ratio $k = I_S/I_P$ and the specific contrast $C_{sp} = \mu/(1+k)$. Hence, the relative and the specific contrast increase with the attenuation coefficient, but decrease with increasing scattering ratio and increasing material thickness. As result, high-energy radiation yields higher contrast for large thicknesses (steel > 50 mm; aluminium > 100 mm) than lower energy radiation because the increase of contrast due to decreasing scatter ratio is larger than the decrease of contrast due to decreasing attenuation coefficient. This effect can be

achieved either by using higher-energy sources (increase of kilovoltage for X-ray tubes, application of gamma radiation) or by using filters to increase the quality of radiation.

Noise and granularity. The perception of any indication depends on the contrast-to-noise ratio (CNR). The image noise is measured quantitatively as the standard deviation of the mean value of the intensity or density in a projected area of constant object thickness. Density fluctuations are described as the granularity of film systems. The visual impression is the graininess. The term *noise* is used dominantly in digital radiology. The CNR increases with the square root of the required exposure time of a film system or digital detector. This is the reason why slow film systems provide higher contrast sensitivity than fast ones. The human perception depends on the shape of the object. Linear edges, cracks and wires are already recognizable at $\text{CNR} > 0.7$. For the perception of small volumetric objects or flaws (e.g. balls, pores) the required CNR is > 2.5 .

Unsharpness. The sharpness of the outline of an image is directly affected by the geometrical unsharpness generated by the source size, the source-to-object and the object-to-detector distances (SOD, ODD), and the inherent unsharpness u_i of the detector.

The blurring of an edge image due to a final focal spot size S is defined by the geometrical unsharpness u_g (Fig. 16.37, left)

$$u_g = \frac{b}{a} S = (M - 1) S \quad (16.19)$$

with the magnification factor M according to Fig. 16.37 (right).

$$M = \frac{a + b}{a} . \quad (16.20)$$

Additionally the detector system contributes to the system unsharpness. Due to the properties of the detector an additional edge blurring is observed. In the case of film radiography there can be drawbacks, e.g. to the use of intensifying screens and to the scattering of photons or electrons in the film emulsion. This contribution is called inherent unsharpness u_i .

The total unsharpness u_t observed in a radiograph when neglecting the effect of motion during exposure can be approximated by

$$u_t = \sqrt{u_i^2 + u_g^2} . \quad (16.21)$$

Fig. 16.37 Geometrical unsharpness (left) and magnification (right)

The optimal geometry for taking radiographs with minimum effective unsharpness (u_t divided by magnification) can be determined if the inherent and geometrical unsharpness are chosen equivalent. From this condition the optimal ratio of the SOD and SDD follows

$$\left(\frac{a}{b}\right)_{\text{opt}} = \frac{S}{u_i} . \quad (16.22)$$

As long as the projection $d' = Md$ of an object of size d is larger then the total unsharpness the contrast of the indication is not decreased and follows (16.16). If the unsharpness exceeds d' a decrease of the indication contrast is observed (compare Fig. 16.38).

Image-quality indicators (IQI). Image-quality indicators are standardized devices consisting of a series of elements of graded dimensions, which enable a measure of the image quality to be obtained. IQIs are usually included in every radiograph to check on the adequacy of the radiographic technique. The elements of IQIs are commonly wires and steps or plates with holes. IQIs together with their usage are described in detail in the

Fig. 16.38 Influence of unsharpness to image contrast

European standards EN 462 part 1–5 and, in the USA, standards ASTM E 747, E 1025, and E 2002.

Wire-type IQIs consist of wires that are arranged by diameter, all with the same length Fig. 16.39a. The

Fig. 16.39a–c Selection of image-quality indicators (IQI), described in European standards: (a) wire IQI; (b) step hole IQI; (c) duplex wire IQI

wire material is chosen to match the material of the investigated object. It measures the thickness resolution of the radiographic technique.

The European step hole IQI system is based on a series of steps of different thickness d and holes of diameter equal to the step thickness Fig. 16.39b. The material is chosen to match the material of the investigated object. The image-quality value is given by the number of the smallest hole that is visible on the radiograph.

The American plate hole IQI (ASTM E 1025) consists of a small rectangular or circular piece of metal usually containing several holes, the diameters of which are related to the thickness of the plate. The ASTM penetrometer contains three holes of diameters T , $2T$, and $4T$, where T is the thickness of the plate. The material is again chosen to match the material of the investigated object. The IQI gives the equivalent penetrometer sensitivity (EPS) in terms of contrast resolution, which is a measure for the minimal resolvable thickness difference together with the minimal resolvable detail influenced by the total unsharpness (compare Fig. 16.38).

Duplex wire indicators (Fig. 16.39c) are used when it is necessary to evaluate and measure the total image unsharpness (spatial resolution) separately from contrast sensitivity measurements. Every element consists of two circular wires of certain diameter, which equals the spacing between the wires. Highly attenuating material, such as tungsten and platinum, is chosen for the wires. The largest element without identifying space between the images of the two wires is taken as the limit of discernibility.

16.2.2 Particle-Based Radiological Methods

X- and γ -ray radiography are the most important and well-accepted methods in industry. Nevertheless there also exist other methods that are based on the attenuation of neutrons, positrons and electrons. Neutron radiography is dominant in the aircraft and military industries and in research. The attenuation of neutrons in materials follows other laws than X-ray and γ radiography. Figure 16.40 shows the different attenuation coefficients for

Fig. 16.40 Comparison of mass absorption coefficients for the elements for both X-ray and thermal neutrons. (after: Thewlis, Argonne National Laboratory)

thermal neutron- and X-radiography as function of the element number in the periodic system. Materials which contain the elements H, B, Li, Cd, Gd, Sm and Eu attenuate neutrons much more than construction metals as Al, Fe, Co and Ni. This enables the radiography of organic components in metallic encapsulation such as rocket motors and ammunition with high contrast of structures and flaws of the organic materials (e.g. explosives). Moisture in aircraft components can also be detected at high contrast. More details about n-radiography as well as positron and electron radiography can be found in the ASNT handbook [16.16].

16.2.3 Film Radiography

Radiography in medicine and industry is carried out under different considerations. Medical applications have to be performed with minimum exposure dose for the patient. Therefore, the typical film system consists of fluorescence screens and film. The optical film density is typically between 1 and 2. Industrial applications for nondestructive testing (NDT) generally use exposure dose values which are 10–100 times higher. The resulting NDT image quality is characterized by higher sharpness and contrast sensitivity. Industrial radiographic films contain usually a higher silver content, which allows higher optical density (blackening) to be obtained. NDT films are applied for density values of 2–4.5. Special high-brightness viewing stations are required. Medical viewing equipment is not sufficient. NDT film systems consist of double-layered films with thin lead screens at the front and back side. The X-rays penetrate the film and expose the front and back sides. The lead screens convert X-rays to fast electrons, which expose the film more efficiently than the X-rays. These screens are used for intensifying the exposure, in particular for high-energy X-rays. Since the lead screens convert the photons to electrons instead of light, the exposed radiographs are not blurred by scat-

tered light. Radiographs taken with fluorescence screens have an unsharpness of 0.2–0.4 mm, depending on the screen thickness and X-ray energy. Film lead screen systems have an unsharpness of 30 μm to a few hundred microns, depending on the screen thickness and energy.

NDT film systems are classified corresponding to the standards ISO 11699, EN 584, JIS K 7627 and ASTM E 1815. The classification requires the user to select the film type and the developer as well as the certified developer temperature and immersion time to prove conformity with the standards.

16.2.4 Digital Radiological Methods

Users of industrial radiology, who are interested to move from classical film radiography to digital industrial radiology (DIR), should know which particular field they want to enter. Basically there exist unregulated and regulated areas (standards, guidelines and others). Table 16.2 describes the four basic application areas.

Before new methods and detectors will be described, the advantages of traditional film radiography should be summarized. One of the major advantages of X-ray film radiography is its practicability. Important X-ray film properties are:

- They are dust- and waterproof packed;
- They consist of flexible and break-proof material;
- The storage period after development is > 50 years (expected shelf life > 500 years);
- The readability is independent of technological development (e.g. independent of data format).

Film Digitization

Film digitization systems can be classified by the sampling technology (see Table 16.3).

For example, digitization with a laser scanner proceeds as shown in Fig. 16.41. The film passes a collection

Table 16.2 Application areas of digital industrial radiology (DIR)

Digital Industrial Radiology			
Film replacement		New industrial areas	
Standards, Regulations	Non-standard applications	Serial part inspection	Computed tomography
Welding	Wall thickness, corrosion, erosion	Automated defect recognition (ADR)	3D-casting inspection
Casting	Buildings, bridges	Completeness test	Ceramic composites, plastics
Electronics	Plastics, composites	Dimensional check	Special applications
	Food, tires, wood ...		

Table 16.3 Classification of digitization systems by technology

Principle	Scanner type
Point-by-point digitization	Laser scanner
Line-by-line digitization	CCD line scanner
Array digitization	CCD camera

tube. A laser beam (wavelength about 680 nm, red) with a fixed diameter (e.g. 50 μm) scans the film. The diffuse transmitted light through the film is integrated by the collection tube and registered by a photomultiplier (PMT) on top of the collection tube (not shown in Fig. 16.41). During the scan the folding mirror deflects the laser beam and moves the spot along a horizontal line on the film. The film is advanced with a constant speed. The resulting voltage at the photo multiplier is proportional to the light intensity behind the film. After logarithmic amplification a digitization with 12 bits yields grey values that are proportional to the optical density of the film.

The essential difference to other digitization principles is the reversed optical alignment. The laser scanner illuminates with focused light and measures the diffuse light intensity behind the film. All other methods illuminate the whole area of the film with diffuse light (the film is illuminated with a diffuser) and measure the light intensity that passes the film in one direction at each spot (camera objective or human eye in classical film inspection).

Complementary metal–oxide–semiconductor (CMOS) cameras, which generate a logarithmic output signal relative to the input light intensity, are also available. In this case the digitized grey values will be proportional to the film density, and do not follow the exponential characteristics as digitized with charge-coupled device (CCD)

chips. This is an advantage over CCD chips for the digitization of radiographic films, but the signal-to-noise ratio for CMOS detectors is usually considerable lower than for CCD chips.

The standard ISO/EN 14096-1/2 defines the qualification procedure and the minimum requirements for film digitizers in NDT. This is particularly important for microradiography. NDT applications employ X-ray energies of 50–12 000 keV. The standards require a spatial pixel size of 15–250 μm depending on the energy. This corresponds to a required spatial resolution of 16.7 lp/mm (line pairs per millimeter) for energies < 100 keV and e.g. 1 lp/mm for 1300 keV.

On the basis of the image quality of film radiography the standard requires three quality classes: DA, DB and DS. The user may select the testing class based on the needs of the problem:

- DS: the enhanced technique, which performs the digitization with an insignificant reduction of signal-to-noise-ratio and spatial resolution; application field: digital archiving of films (digital storage);
- DB: the enhanced technique, which permits some reduction of image quality; application field: digital analysis of films; films have to be archived;
- DA: the basic technique, which permits some reduction of image quality and further reduced spatial resolution; application field: digital analysis of films; films have to be archived.

Image Processing

A digital image is physically not more than a data file in a computer system linked to a program capable of displaying its contents on a screen or printout dot by dot. That means it consists of an array of individual image points. These are called picture elements (pixel). The pixels are in practice small rectangles (squares) showing a certain color and brightness.

The image resolution depends on the number of pixels within a given area; the more the better (Fig. 16.42). Radiography commonly deals only with grey-level images.

The numerical values of any pixels within an image can be subjected to various kinds of calculations. Each pixel is characterized by a grey (intensity) value, which is proportional to its brightness. The most trivial step is to adjust brightness and contrast. This allows one to overcome the lower brightness of monitors compared to commercial film viewers. While the human eye can only distinguish between some 60–120 grey values

Fig. 16.41 Principle of a laser scanner (“LS 85”, Kodak, USA)

Fig. 16.42a,b Radiographic image of a test weld BAM5, (a) 1024×512 pixels; (b) 64×32 pixels

(at a given adaptation, equivalent to 6–7 bits of information) a digital image may contain up to 65 536 grey levels (i. e. 16 bits). The contrast and brightness operations are essential to select the range of interest. The *gamma* transformation alters the linearity of the transfer from the original digital values listed in the image file to its brightness displayed on the screen, taking into account the brightness sensitive perception of human eyes.

Multiple-point calculations take advantage from relationships between adjacent pixels of the image (matrix operations). They are based on a variety of so-called filter algorithms that are supposed to extract the desired features from the total image information. They may eliminate unwanted large, patchy intensity fluctuations or noise masking other image details. Typical filters are describes in Table 16.4. Processing of radiographic images shows astonishing results that can

Table 16.4 Typical image-processing filters

Filter	Advantage	Disadvantage
Low-pass filter (smoothing)	Increases the signal-to-noise ratio	Reduces the spatial resolution
High-pass filter	Increases the contrast of fine details in relation to intensity changes in a wide range	Reduces the signal-to-noise ratio
Median filter	Increases the signal-to-noise ratio, removes single peaks and outliers (single white or black pixels such as “salt and pepper” distortions), does not smooth edges	Reduces the spatial resolution
Edge filter	Enhances edges or extracts edges to lines	Increases the noise

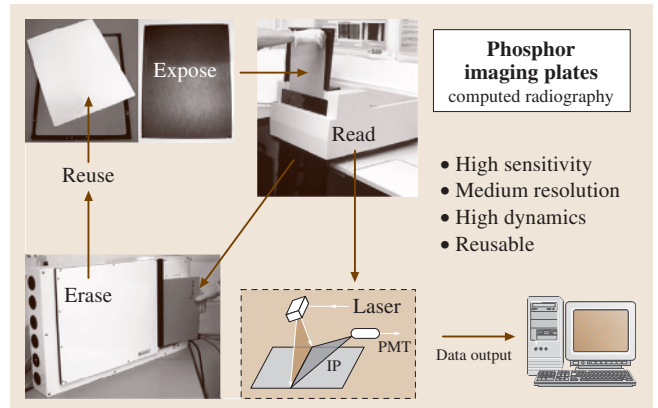

Fig. 16.43 Principle of application of phosphor imaging plates (IP) for computed radiography (CR). The plate is exposed in a lightproof cassette. The scanner reads the IP with a red laser beam. All exposed areas emit stimulated blue light. The photomultiplier collects the blue light through a blue filter and converts it into an electrical signal. The signal intensity values are converted to digital grey values and stored in a digital image file. Remnants of the image on the IPs are erased by intensive light. They can be used usually 100–1000× if they are handled carefully

be found, together with *filter recipes*, in different textbooks [16.17, 18].

Computed Radiography and its Industrial Application

Phosphor imaging plates (IP) are image media for film-less radiography. The technique is also called computed radiography (CR). IPs are routinely used in medicine and biomedical autoradiography. Different systems are available for NDT applications. Novel applications in addition to film radiography emerge taking advantage of the higher sensitivity (shorter exposure time) and the digital processing as well as the capability to analyze digital radiographs with affordable computer systems. A set of standards was published 2005 in Europe and

USA, which defines the classification and practice of CR systems [16.19].

IPs are handled nearly in the same way as radiographic films. After exposure, they are read by a laser scanner producing a digital image instead of being developed like a film (Fig. 16.43). Any remaining latent image can be erased with a bright light source so that the same IP can be recycled up to more than 1000 times. An IP consists of a flexible polymer support which is coated with the sensitive layer which is sealed with a thin transparent protective layer. The sensitive layer of the most common systems consists of a mixture of BaFBr doped with Eu^{2+} . X-ray or gamma-ray quanta result in an avalanche of charge carriers i.e. electrons and holes in the crystal lattice [16.20].

These charge carriers may be trapped at impurity sites i.e. electrons at a halogen vacancy (F-center) or holes at an interstitial Br_2^+ molecule (H-center). Red laser light (600–700 nm) excites electrons trapped in a Br^- vacancy (F_{Br} -center) to a higher state from which they may tunnel and recombine with a nearby trapped

hole. Transfer of the recombination energy excites a nearby located Eu^{2+} ion. Upon return to its ground state this Eu^{2+} ion emits a blue photon (390 nm). This process is described as photostimulated luminescence (PSL).

The advantages of IP technology are:

- Linearity with radiation dose.
- High dynamic range, up to 10^5 .
- Sensitivity higher than with film.
- Reusable for 1000 cycles.
- No chemical darkroom processing.
- Capability for direct image processing.

The disadvantages are

- Limited spatial resolution, except in new high-definition systems.
- High sensitivity in the low-energy range,
- Sensitive to scattered radiation.

The available systems of phosphor imaging plates and corresponding laser scanners cover radiation dose differences of up to 10^5 . This feature reduces the number of exposures for objects with a high wall-thickness difference. It also compensates partly for incorrectly calculated exposure conditions. The number of so-called test exposures is reduced. The IP reader is typically separated from the inspection site. CR is based on flexible IPs [16.21]. High-definition CR systems can provide a spatial resolution of better than $25\ \mu\text{m}$. This is sufficient for weld and casting inspection of small components at lower X-ray voltages as well as large components.

Measurement of Pipe Wall Thickness for the Evaluation of Corrosion, Erosion and Deposit

A typical application of the CR technology is radiographic corrosion inspection in the chemical industry. Figure 16.44 presents a typical example with a thermally insulated pipeline. The insulation is covered with an aluminium envelop. The radiographic inspection can be performed without removing the insulation. This is a considerable advantage relative to the other known methods. Radiographic pipe inspection for corrosion and wall thickness measurement is a major NDT technique for predictive maintenance. CR is also more and more applied for inspection of valves and armatures for functionality check and deposit search.

Radiography with Digital Detector Arrays (DDA) Flat-Panel Detectors. Two types of DDAs, also called flat-panel detectors, are available on the market. The

Fig. 16.44 Computer-based inspection of an insulated pipe by projection radiography. The wall thickness is measured by image processing in the marked areas

Fig. 16.45 Scheme of a flat-panel detector: The scintillator converts X- or γ -rays into light, which is detected by the photodiodes. They are read out by thin-film transistors (TFT) on the basis of amorphous silicon, which is resistant to radiation

first design (Fig. 16.45) is based on a photodiode matrix connected to thin-film transistors (TFT) [16.22]. These components are manufactured of amorphous silicon and they are resistant against ionizing radiation. Alternatively to the amorphous silicon panels CMOS arrays can be applied. The photodiodes are charged by light which is generated by a scintillator converting the incoming X- or gamma rays. This scintillator can be a polycrystalline layer that causes some additional unsharpness by light scattering or a directed crystalline system which acts like a face plate with lower unsharpness due to inhibited light scattering (Fig. 16.46). The next generation (second type of DDAs) of flat panels is based on a pho-

toconductors like amorphous selenium [8] or CdTe on a multi-microelectrode plate, which is also read out by TFTs (Fig. 16.47b). Direct converting photodiode systems (Fig. 16.47a) are not used in NDT yet, due to their low quantum efficiency.

Fig. 16.46a,b Principle of amorphous-silicon flat panels with fluorescence screens. **(a)** Additional unsharpness is generated in the phosphor layer due to light scattering. **(b)** Needle crystals of CsI on the surface of the photodiodes improve the spatial resolution because the crystals conduct the light to the photodiodes like fiber light conductors

Fig. 16.47a,b Principle of direct converting flat panels with amorphous silicon thin-film transistor arrays for read out. There is no light scattering process involved. The spatial resolution is determined by the pixel size of the detector array. **(a)** Photodiodes convert directly the X-ray photons to electrons. This technique is suitable for low-energy applications. **(b)** A semiconductor (e.g. amorphous selenium or CdTe) is located on microelectrodes in a strong electrical field. Radiation generates charges, which can be stored in micro-capacitors

Fig. 16.48 View of the line scanner. The X-ray tube and camera are mounted on a manipulator for mechanized inspection of pipes

DDAs are suitable for in-house and in-field applications. In-field applications are characterized by harsh environmental conditions in some areas, which implies the risk of hardware damage and restricts the mobile application of DDAs. Alternatively, digital data may be obtained by film digitization or directly by the application of CR.

Line Detectors. The classical concept of NDT with line detectors is based on a fixed radiation source, moving objects and a fixed line camera. This is the typical concept for baggage, car and truck inspection. Line detectors are available with a resolution of 0.25–50 mm. The most

common principle is the combination of scintillator and photodiodes. The scintillator is selected in accordance to the energy range.

Mechanized X-ray Inspection of Welds. High-resolution lines have been introduced for weld inspection [16.23]. Figure 16.48 shows a mechanized X-ray inspection system, which is based on an X-ray tube, a manipulation system and a line camera. The camera consists of an integrated circuit with about 1200 photodiodes. A GdOS scintillator screen is coupled to the diodes. New applications take advantage of TDI (time-delayed integration) technology to speed up the scan [16.24]. Several hundred lines are used in parallel. The signal is transferred from line to line synchronously with the movement of the object or the scanning system. The information is integrated on the chip and the speed enhancement corresponds to the number of lines used.

Specialized tomographic routines were developed to reconstruct a three-dimensional (3D) image of the weld [16.23]. This method is very sensitive to cracks and lack of fusion. The depths and shape of these defects can be reconstructed and measured. Figure 16.49 shows the image of a reconstructed crack in an austenitic girth weld in comparison to a cross-sectional metallography.

Automated Evaluation of Digital X-Ray Images: Serial Inspection in Automotive Industry

Fast digital X-ray inspection systems are used in the serial examination of industrial products since this technique is capable of detecting flaws rather different in their nature such as cracks, inclusions or shrinkage. They enable a flexible adjustment of the beam direction and of the inspection perspective as well as online viewing of the radioscopic image to cover a broad range of different flaws. This economic and reliable technique has become of essential significance for different applications. The configuration of such systems is schematically represented in Fig. 16.50.

The object, irradiated from one side by X-rays, causes a radioscopic transmission image in the detector plane via central projection. The relation between the focus–detector distance (FDD) and the focus–object distance (FOD) determines the geometrical magnification of the image. An image converter such as an X-ray image intensifier, a fluorescence screen or a digital detector array (DDA), also called a flat-panel detector, converts the X-ray image to a digital image.

Light alloy castings are widely used, especially in automotive manufacturing. Due to imperfections of the casting process, these components are prone to material

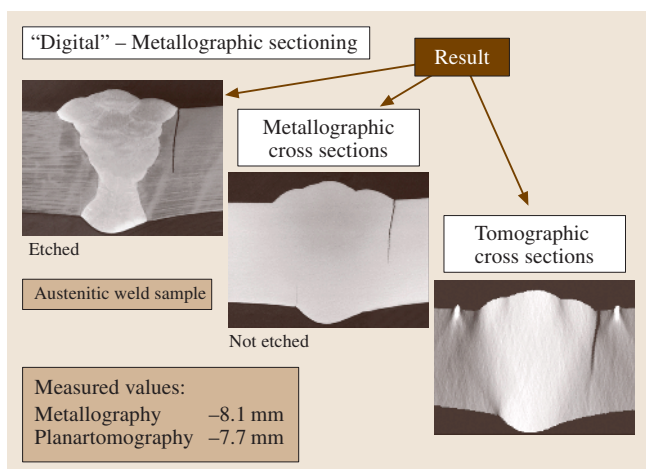

Fig. 16.49 Reconstructed crack in an austenitic weldment compared to the metallographic cross sections

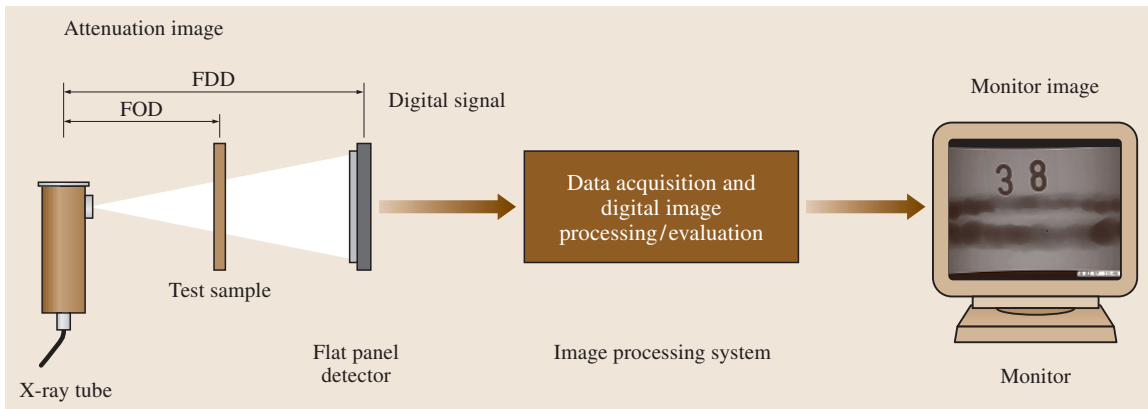

Fig. 16.50 Schematic set up of a digital industrial radiology system

defects (e.g. shrinkage cavities, inclusions). These parts are frequently used in safety-relevant applications, such as steering gears, wheels and increasingly wheel suspension components. These parts have to undergo a 100% X-ray inspection for safety.

A fully automated X-ray inspection system for unattended inspection can guarantee objective and reproducible defect detection (see example in Fig. 16.51). The decision whether to accept or to reject a specimen is carried out according to the user's acceptance specification. These systems are known as automated defect-recognition (ADR) units.

Automated X-ray inspection is also used for a novel field of application: the check of completeness and function. For example, when the presence and deformation of parts have to be checked. Furthermore distances and spatial dimensions can be examined.

16.2.5 Applications of Radiology for Public Safety and Security

Public safety and security is yet another application field of digital industrial radiology. Since explosives entail a considerable threat it is a central issue of all security measures to detect them in time. There exist a variety of different methods for explosive detection [16.25].

Inspection of Unexploded Ordnance (UXO)

Grenades containing warfare substances are identified by the presence of a liquid surface visible in the respective radiograph (Fig. 16.52). They have to be inspected to assign them to the appropriate way of safe disposal. To detect a putative liquid filling, the suspected ammunition is radiographically inspected in a tilted position. If this shows the surface of the liquid, then the grenade

is filled with a warfare substance (such as e.g. mustard gas or phosgene). Image processing reveals further details. Figure 16.53 shows how the digital radiograph of a shrapnel grenade was enhanced by image processing.

Dual-Energy Radiography for Baggage Control

The dual-energy technique is widespread in modern baggage-inspection equipment. It provides additional

Fig. 16.51 Defect detection with an automated system. *Left*: original image; *right*: detected flaw

Fig. 16.52 Inspection of a grenade of World War I, filled with chemical warfare. The chemical agent can be detected, by visualization of the liquid-level line inside the grenade

Fig. 16.53a,b Radiograph of a shrapnel grenade: (a) original image, and (b) high-pass-filtered image

information about the chemical composition of the inspected material. The technique takes advantage of the fact that radiation of different energy is absorbed dif-

ferently by the various elements. The absorption is a function of the atomic number of the absorbing elements. As a consequence, radiographs taken at a lower and a higher X-ray energy level are not identical. The ratio between the logarithmic grey values of such a pair of images represents the chemical composition of the absorbing material and is independent of its layer thickness. Figure 16.54 shows a dual X-ray tube set and a typical dual-energy radiograph of a bag. This technique provides the operator with color-coded images, where the color indicates the chemical composition of the inspected specimen. This can provide hints of the presence of explosives or contraband. Advanced versions of inspection units include an additional spectrometer to measure the spectrum of the scattered radiation. This method is rather sensitive and allows the detection and specification of various chemical compounds within the object.

Fig. 16.54 Dual X-ray tube assembly for dual-energy inspection of baggage and typical image of a bag. The atomic number of the components in the object are usually represented by the color: blue – high atomic numbers (e.g. metals); green – medium atomic numbers (e.g. glass, polyvinyl chloride); yellow to brown – low atomic numbers (e.g. carbon hydrates)

16.3 Computerized Tomography – Application to Organic Materials

For tasks of materials performance control, tomography with X-rays supported by computers, in short computerized tomography (CT), is gradually spreading in industry. Tomography, born in the medical field, makes it possible to show 0.1% differences in the density of materials. Moreover, the tomographic section of an object under study, which is reconstructed in three-dimensional space, is not affected by the rest of the volume exposed to irradiation, and the geometry is well defined. The section-by-section reconstruction

makes it possible to achieve a complete exploration of the object. For materials classes like polymers, such as natural rubber (NR) or styrene butyl rubber (SBR), and composite materials, such as polymer matrix composites, this method is efficient, gives high resolution and reliable results. However, industrial application of a medical scanner, as presented here, is applicable only for low-density materials ($4 < \text{g/cm}^3$). The application of CT to materials of higher density is discussed in Sect. 16.4.

We can discern four application fields for computer tomography:

1. Nondestructive testing of big components;
2. Nondestructive of small pieces;
3. Materials study;
4. Microtomography.

In this section, we will present the method and the terminology within the scope in which the medical scanner is commonly used. Then, we will deal with examples chosen to share the performances of this technique for industrial applications.

16.3.1 Principles of X-ray Tomography

When X-ray tomography is used, a collimated beam goes through the tested object before being received by a row of detectors opposite the X-ray source. The object is then rotated through an angle of 180° . During the rotation, the attenuation of the intensity of the X-ray beam is measured in a finite number of angular increments. Data acquisition is achieved by a computer that carries out the reconstruction of the object with the help of a suitable algorithm.

A χ -ray CT is essentially based on the measurement of the different absorption coefficient of the materials crossed by a penetrating beam such as X- or γ -rays [16.26–34]. The CT image gives linear attenuation coefficients in the slice for each point, which depend on the physical density of the material, its effective atomic number and χ -ray beam energy. The attenuation in the intensity of a single X-ray beam is then defined by the equation of Lambert–Beer as the

following;

$$I = I_0 \exp(-\mu L), \quad (16.23)$$

where I_0 is the incident intensity, I is the transmitted intensity, μ is the linear attenuation coefficient and L is the thickness of the absorber.

Thus, a tomographic system measures the attenuation of intensity from different angles to determine cross-sectional configuration with the aid of a computerized reconstruction. The general view of the medical scanner (χ -ray CT) equipped with a mechanical test device – electrical jack plus carbon-fibre tube and also the scanning system – is shown schematically in Fig. 16.55. It consists of an X-ray source, a collimator, a detector array and a computer system with data-storage media.

When going through a material, a beam of X-ray undergoes an absorption that depends on the three following parameters:

1. The nature of the materials, or more exactly the respective densities of the elements that make up the material that is put in the path of the radiation (the linear absorption coefficient);
2. The thickness of each of these elements;
3. The incident intensity of the radiation.

The attenuation of the radiation through an object complies with the Lambert–Beer law, which governs every absorption phenomenon

$$I = I_0 e^{\mu X}. \quad (16.24)$$

The medical scanner is able to measure the X-ray attenuation in Hounsfield units or tomography density even if it does not give local mass density. To obtain this, it is necessary to make a calibration versus a reference

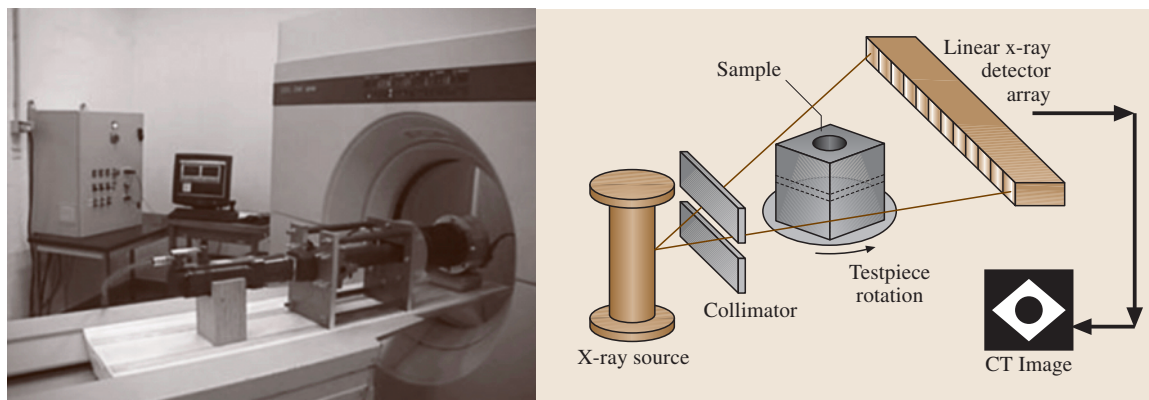

Fig. 16.55 Medical scanner equipped with a mechanical test device (electrical jack plus carbon fibre tube) and schematic of computed tomography system

which is water. The tomography density (DT) is a relative measure of the attenuation coefficient with regard to the water. For this reason, we need to know the value given to water in the tomography scale in Hounsfield units (H). Basically with a constant X photon energy, the DT depends of the attenuation coefficient by a theoretical relation where K is a constant equal to 1000

$$D = \frac{\mu - \mu_w}{\mu_w} \quad (16.25)$$

This relation of conversion between the attenuation coefficient and the tomographic density is based on water attenuation coefficient value, which is 1.8 cm^{-1} at 73 KeV, corresponding to density zero in the Hounsfield tomography scale.

This conversion is done in two steps:

- An intermediate scale is chosen. In this new scale, for the water, there is a relation between K and C of

$$K = C\mu_w \quad (16.26)$$

and the attenuation coefficient for a given material is given by

$$\mu_{\text{int}} = \frac{K}{\mu_w} \mu \quad (16.27)$$

The tomographic density is linear with regard to the intermediate attenuation μ_{int} and the water density must be equal to zero.

- Make a translation in order to fulfil the condition

$$\text{DT} = \mu_{\text{int}} - K, \quad (16.28)$$

so that

$$\text{DT} = \frac{K}{\mu_w} \mu - K = \frac{\mu - \mu_w}{\mu_w} K \quad (16.29)$$

Table 16.5 Attenuation coefficients and tomographic densities of some materials obtained with a medical scanner

Material	$\mu(\text{cm}^{-1})$	DT (H)
Polyethylene	0.172	-72
Water	0.191	-0.4
Nylon	0.210	90
Polyester	0.217	139
Araldite	0.219	147
Rubber 18160/52	0.224	165
Delrin	0.262	349
Ebonite	0.288	434
Rubber 19199/48	0.340	729
Teflon	0.340	729

Calibration has been done with several materials in order to have an empirical relation average DT of materials and respective attenuation coefficient. Table 16.5 presents some results.

Conventional radiography makes it possible to show defects bound up with variations of density compared with the material as a whole. Thus, under most circumstances, inclusions, cracks, porosities, etc. can be shown.

Nevertheless, radiography takes into account everything the beam meets while going through the material and gives a plane projection of them. That is why cracks perpendicular to the beam are liable to escape detection.

Tomography breaks free from the drawbacks of X-radiography by exploring the object with a 180° rotation, thanks to three-dimensional reconstruction, so it is possible to know the absorption density of any point within a given volume.

The units of absorption density are those used in medicine. The following references are given:

$$\begin{array}{ll} 1000\text{H (Hounsfield) units} & \text{Density of dried bone} \\ 0 & \text{Density of water} \\ -1000\text{H units} & \text{Density of air} \end{array} \quad (16.30)$$

This scale is suitable for composite materials whose H density is about a few hundred units because of their nature. The standardization carried out to associate the medical unit with the density of the bulk $\Delta\rho$ gives for one H unit: $\Delta\rho = 1 \times 10^{-3}$ with a 120-kV X-ray source.

This implies that the medical scanner makes it possible to show variations of volumetric density of about a thousandth.

The highest Z material that can be evaluated with a medical scanner is aluminium.

The objectives of this paragraph are to present the performances of X-ray tomography in order:

- to detect internal geometric defects,
- to perceive the evolution of mechanical, physical, chemical damage,
- to display homogeneous variation related to processing,
- to observe differences in texture, chemical concentration at the meso- and nanoscale.

16.3.2 Detection of Macroscopic Defects in Materials

Using a medical scanner, metal matrix composites processed by squeeze casting have studied. The first step was to test the alumina preforms, which are disks with

Fig. 16.56 Defects in ceramic preform

85 mm diameter and 15 mm thickness. In some disks, spherical defects were introduced during the processing. Figure 16.56 presents the results of the tomographic examination. The average Hounsfield density of the ceramic preform is about -215 . However, there is a large difference of X-ray attenuation between the center of the specimen and the edge, where the density is a maximum of 118 . In fact, the density is lower in the center of the specimen because the volume fraction of alumina is smaller than near the edge. Thus, it is possible to check the processing of the preform with tomographic observation as well as the repartition of alumina platelets which is very difficult using regular experimental methods. Of course, it is very easy to detect defects in ceramic preforms, as is shown in Fig. 16.56.

16.3.3 Detection of the Damage of Composites on the Mesoscale: Application Examples

Putting aside the mechanical interpretation of composite damage in polymers, is it possible to characterize the damage of these materials based on a single method that combines the physical and chemical interpretations? The answer must evidently be no. The problems calls for nondestructive testing methods, which include ultrasonics, X-rays, thermography, and others methods. At the microscopic level, an electron or acoustic microscope is the required nondestructive evaluation tool.

Fig. 16.57 Three cross sections of the specimen after impact

Between the macroscopic and microscopic levels, there exists a very important middle domain, typical of composite materials, which is treated at the mesoscopic level: that of transverse cracking, distribution of reinforcements and of porosity, that is, the domain of sequential cells. It is very difficult today to characterize defects at these different levels other than by radiography.

The various applications of X-ray tomography allow for the study of composite materials at any level, macroscopic, mesoscopic or microscopic. This instrument is well adapted to reveal defects on a centimeter scale, such as a delamination, but it is also capable of revealing the distribution of the reinforcements on a millimeter scale, and of detecting fiber cracking as well as cracking along fiber matrix interfaces on a micrometer scale. In addition, the attenuation of X-rays, which depends on the physical and chemical nature of the composites constituents, can be measured by X-rays scanners.

Changes in the polymeric matrix due to aging, or even the transformation of amorphous polymers into crystallites, can be studied by X-ray tomography. This astonishing tool, long used by the medical field, is also well adapted to the study of composite materials and polymers due to its ability to detect defects on a wide range of scales, as well as its ability of physical and chemical analysis by measuring X-ray attenuation.

X-ray scanning can thus provide information on the physical and chemical aspects of the material and on the geometry of flaws and damage on any scale. This tool provides solutions to many problems faced by the materials scientist, as demonstrated in the following results.

Damage in a Carbon Epoxy Composite Plate Specimen After an Impact

The specimen studied is a rectangular coupon whose dimensions are $255 \times 172 \times 8.5$ mm. It is made up of 64 plies of carbon-epoxy fiber. The stacking sequence is (45/90/−45/0) 8 s.

The specimen was subjected to the impact of an aluminium ball 12.7 mm in diameter moving at a speed of 120 m/s. Then it was cycled in compression under 110 MPa to intensify the damage.

In this case, the scanner examination has been complemented by radiography, zinc-iodide-enhanced X-ray, and by optical microscopy. This was done in collaboration with the NASA Langley Research Center in Hampton, Virginia.

Global Examination of the Plain Specimen

A study on the axial slices and on the frontal slices has been carried out. On the frontal views, we note a strongly

damaged area whose density is higher than 550 H, slightly elliptical shaped, and whose largest dimension is orientated in the compression direction (Fig. 16.57).

Modeling of the Damage

The damage of this composite specimen is complex because of the great number of plies. The envelope of the damaged area has the shape of a barrel, delaminations being more numerous in the center of the plain specimen than near the surface.

Synthesis of the Observations Made on the Impacted Specimen

To facilitate the interpretation of observations made with medical scanners, damage to the impact specimen is examined by radiography at a microscopic scale and by scanning electronic microscopy at a microscopic scale.

A comparison between radiography and tomography is made Fig. 16.58. We would like to note that the scanner provided much better resolution of the outline of the damaged area. Nevertheless, enhanced X-ray radiography was required to reveal the very complicated network of microcracks.

To conclude, we emphasize that the resolution of the images of the microcracks with the medical scanner is not satisfactory at the moment.

Fig. 16.58 Comparison of radiography (*right*) and tomography (*left*) of delamination

Damage in Rubber Submitted to High Hydrostatic Pressure

It is well known that triaxiality of stresses including a high hydrostatic pressure has a large effect on the mechanical behavior of rubbers and particularly on fatigue mechanisms.

In a pancake specimen loaded in tension the hydrostatic pressure is about 2.5 times the shear modulus of rubber for an elongation of 20% in NR. From observations by X-ray tomography, it seems that the first cavities are formed in the center of the specimen at 20% of elongation for a fracture at 380% (Fig. 16.59).

It must be pointed out that no other NDT method is available to observe cavitation in rubber.

16.3.4 Observation of Elastomers at the Nanoscale

The damage caused by fatigue and cracking in rubber or in composites with elastomer matrices seems to be considerably influenced by the transformation from an amorphous to a crystalline phase, when this latter phase exists. This hard-to-detect transformation is generally studied by X-ray diffraction, a method by which we cannot detect the gradients of transformation within the rubber nor make local observations.

In contrast, X-ray tomography allows for the observation of the crystalline transformation of rubber and its localization owing to the images generated by scanner. The attenuation of the intensity of the X-ray beam, similar to X-ray diffraction, reveals the existence of crystallites.

In order to validate this hypothesis, test samples of natural, crystallisable rubber NR and of synthetic, noncrystallizable rubber (SBR) were studied at different temperatures, knowing that low temperatures induce a partial crystallization of NR.

The crystallization of rubber (NR) may be observed on the samples, which were cooled down to -200°C . This microscopic phenomenon can clearly be evaluated by means of X-rays CT on the mesoscopic scale, which is another benefit of medical scanning. To show this effect, some of the tests were carried out on the axisymmetric hourglass-shaped specimens of NR and compared with SBR, which does not show this phenomenon as it is always amorphous. Hourglass-shaped specimens are very suitable for this test due to their large outer surface [16.27, 28]. So, the variation of mean values of the TD becomes complex; the TD value is maximal at the level of 227 K (-46°C) (Fig. 16.60), it exceeds

Fig. 16.59 Cavitation growth due to high hydrostatic pressure (NR)

1180, whereas at lower temperatures (83 K, -190°C) the value is 1135.

This variation in TD displayed a crystallite state between 300 K (27°C) and 227 K (-46°C) above which the amorphous state again becomes predominant between 227 K (-46°C) and the transition temperature (T_g) of rubber. When there is no crystallization, variation in density certainly modifies the attenuation (TD).

In the case of SBR, which is always amorphous, only the density varies with temperature, related to the dilatation. An increasing in the temperature causes naturally the increasing of the volume and the decreasing of the density and finally the decreasing of the TD (pixel). Figure 16.60b shows the evolution of the TD curve as a function of the temperature for the SBR specimens. It decreases from 1185 to 1120 in the temperature range from 175 (-98°C) to 300 K (27°C). However, it shows a transition zone at the level of 200 K (-73°C), corresponding to the transition temperature, T_g , between the glassy and rubbery phase. This zone is found be-

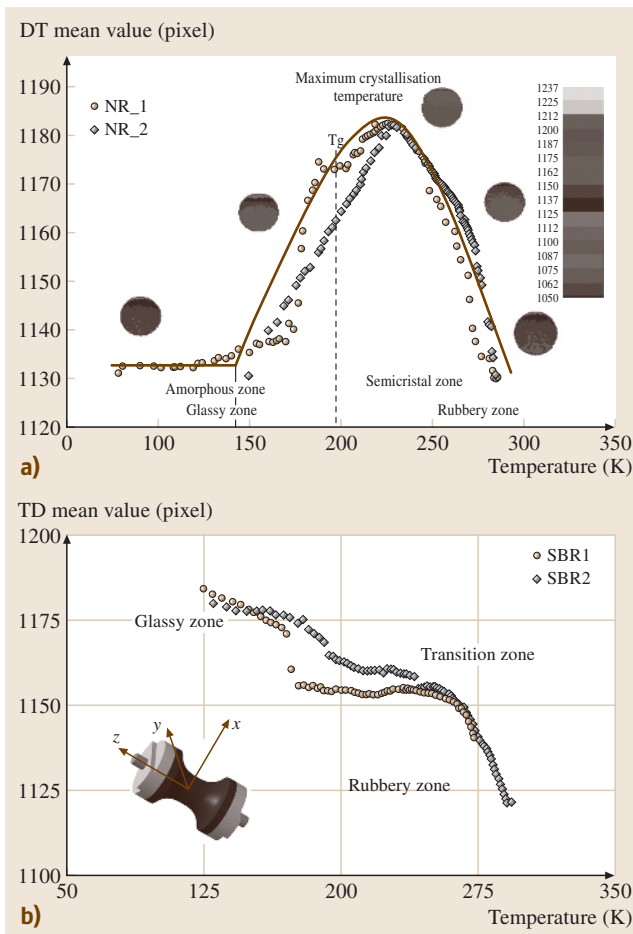

Fig. 16.60 Evolution of the TD depending on the temperature in NR (a) and SBR (b)

of composite materials from a technical point of view and if we do not take into account the price of the device. The advantages of the method have been presented with its excellent results. They confer on the medical scanner a double role, which may form the subject of two developments:

1. a nondestructive testing instrument with an industrial purpose,
2. an instrument comparable to the electronic microscope with a more scientific purpose and able to give information at a microscopic scale (several hundreds of microns).

In the first case, the resolution power of the medical scanner is good enough for a device of classical NDT. We have found only one major inconvenience, namely the lack of reliability of the scanner to make precise measurements of the dimensions of the defects within more than 25%.

In the second case, the resolution of the scanner is not good enough to study the transverse cracks in the matrix. We can estimate the spatial resolution of the scanner at some hundreds of micrometers, whereas we would need 10 μm . We are dealing here with an important need which needs more investigation.

Nevertheless, we should point out that the resolution in density of the scanner is of the order of 10^{-3} , which makes it possible to resolve all the defects contained by composites whether they are cracks, delaminations, fiber bundles, or porosities. The variation of the Hounsfield density must be related at the volumetric density but also to the modification of the chemical microstructure of the materials. From this point of view, the scanner enables studies of the crystallization of polymeric matrix of rubbers, for example. This means that X-ray tomography is a multiscale NDT method.

tween 1155 and 1160, corresponding to this glassy transformation.

16.3.5 Application Assessment of CT with a Medical Scanner

The application examples show quite obviously that the medical scanner is adapted to nondestructive evaluation

16.4 Computerized Tomography – Application to Inorganic Materials

The study of volume properties as well as of dimensional features with computed tomography requires an optimized selection of source–detector combination depending on the material composition (energy-dependent linear attenuation coefficient μ), the size of the samples and the maximum thickness of material that has to be

irradiated, *d*. Additionally the manipulator system and the mounting need to suffice the required accuracy. The maximum SNR of a CT measurement of a homogenous sample is given for $\mu d \cong 2$, corresponding to a transmission of about 11% [16.35]. This value is valid only for line detectors with a sufficient detector collimator and

shielding between single detector elements. Due to some limitations, especially for flat detectors, the conditions for optimum image quality differ from this theoretical value.

For organic materials with low atomic numbers and low density, medical scanners can be applied in many cases. As an example fibre-reinforced helicopter blades have been investigated for many years by computed tomography, using commercial medical scanners [16.36]. Inorganic materials require radiation sources with higher energy and appropriate detector systems. The different kinds of computed tomography equipment developed at Federal Institute for Materials Research and Testing (BAM) represents the state of the art on this field and are described in the following knowing well that commercial solutions are in general more efficient with regard to saving of time and user guidance.

16.4.1 High-Energy CT

This field covers roughly the energy range given by 420 kV X-ray tubes over some radionuclide sources up to electron linear accelerators with a maximum energy of 12 MeV. Most of the high-energy scanners used have line detectors which can be shielded against the scattered radiation. Starting with a translation/rotation scanning principle and multi-detector systems, today line detectors are common with several hundred detector elements and scanning times in the range of some minutes and lower. At BAM a scanner for a 380-kV X-ray tube and a ^{60}Co radionuclide source was described

as early as 1985 [16.37]. This universal scanner was extended for measurements with a 12-MeV electron linear accelerator (LINAC, Raytech 4000) in combination with a multi-detector system with step-motor-controlled collimator slits [16.38]. The actual research covers the study of some effects of high-energy cone beam CT with a LINAC and ^{60}Co using an *a*-Si flat-panel detector (Perkin Elmer, 16-bit ADC, 256×256 pixel, pixel size is (0.8 mm^2)). Due to the focal spot size of high-energy radiation sources, which is on the order of about 1.5 mm, the spatial resolution is limited to a few tenths of a mm.

16.4.2 High-Resolution CT

Using magnification techniques a much higher spatial resolution can be reached. The condition hereby is that the focal spot size can be lowered to the micrometer range, which is possible with micro-focus X-ray tubes. The usable energy range of commercial X-ray tubes extends up to 225 kV. For many objects it would be desirable to extend the energy range of micro-focus X-ray tubes. As an example most cellular metals are made from aluminium and thus have a high penetration depth for X-rays. However, they are often used to produce objects of irregular shapes (with an outer cover of a different material or the foam skin itself). This produces artefacts due to the high-attenuation parts. In some applications foams of high-attenuation materials (up to iron) are used. In these cases the choice of an X-ray energy as high as possible reduces the artefacts from beam hardening and exponential edge-gradient effects.

Fig. 16.61 (a) Attenuation curve for iron as function of X-ray energy (b) 320-kV micro-focus tube

Figure 16.61a gives a graph that shows the gain in attenuation possible with an extended range of kV. For CT measurements the maximum absorption to free beam ratio is about 20. From the graph it is seen that this means an extension of measurable *material in object thickness* from 20 mm to 30 mm of steel. At the end of 2002 a 320-kV micro-focus X-ray tube [MX-5 tube, build by YXLON, Halfdangsgade 8, 2300 S Copenhagen] was integrated into a CT system (Fig. 16.61a). The bipolar tube is build up from a standard –200 kV tube. The original probe head is changed to the bipolar part which has a build in anode with an additional high voltage supply of up to +120 kV. The distance between X-ray spot to tube outside is enlarged to 25 mm because the target position is no longer at ground voltage level. This means that the tube in this modification has a lower maximal magnification, but this corresponds to the bigger object size. For example with 320 kV and 0.1 mA the optimum spatial resolution is about 35 μm .

In practical operation the second part is fixed to +120 kV while the variation in energy is done with the first. A range of 130 kV to 320 kV results. To the first part a standard micro-focus target can be attached and the tube can thus be used as normal 200 kV micro-focus tube with high magnification. As detector an α -Si flat-panel detector (Perkin Elmer, 16-bit ADC, 1024×1024 pixel, pixel size is (0.4 mm^2)) is used [16.39].

16.4.3 Synchrotron CT

With transmission target X-ray tubes the focal spot size can be lowered to 1–5 μm , corresponding to a spatial resolution of less than 10 μm . Due to the limited intensity given by electron scattering and the heat generated, which can melt the target, measuring times are increas-

ing to some hours and more. Synchrotron radiation sources offer photon flux densities, which are several orders of magnitude higher compared to laboratory X-ray tubes. The additional advantage is the fact that the high photon flux density can be reached with monochromatic radiation giving some advantages over tomography, such as the absence of beam-hardening artefacts.

To extend the usable energy range at the Berlin Electron Storage Ring Company for Synchrotron Radiation (BESSY) a 7-T wavelength shifter with a critical energy of 13.5 keV has been installed in the storage ring to operate the first hard X-ray beam line at BESSY, called **BAMline**. The main optical components of the beam line are a double crystal monochromator (DCM) and, for the first time for imaging, a double multilayer monochromator (DMM, 320 double layers of W and Si, with thicknesses of 1.2 nm and 1.6 nm, respectively). The latter is preferred for use in tomographic facilities, giving a factor of 100 higher photon flux due to the increased bandwidth of 2% compared with 0.01% of the DCM [16.40–42]. The detector system consists of a 2048×2048 photometric camera system together with a scintillator screen of GdOS. Depending on the lens combination used nominal voxel sizes of 1.5–7.2 μm can be used.

16.4.4 Dimensional Control of Engine Components

A current research topic is the improvement of dimensional control with CT. As an example Fig. 16.62 shows a cross section of an aluminium test sample investigated with the 320-kV equipment. This sample was measured additionally with the LINAC CT. Standard operation for a comparison is the conversion of the voxel

Fig. 16.62 Test sample of aluminium (\emptyset about 100 mm). The image (left) shows a cross section of the measurement with the 320-kV equipment (320-kV X-ray: 220 kV, 100 μA ; prefilter: 1.5 mm Sn; projections: 900/360°; exposure time: 2.28 s per projection; voxel: (0.12 mm^3) ; matrix: $1023 \times 1023 \times 605$). The image (middle) shows the deviation against the CAD data and the image (right) the deviation against the measurement with LINAC (10.5 MeV, 20 Gy; prefilter: 90 mm Fe; projections: 720/360°; exposure time: 0.8 s per projection; voxel: (0.65 mm^3) ; matrix $255 \times 255 \times 201$)

Fig. 16.63 Vertical and two horizontal cross sections of a glass-fibre cable

data in a point cloud and the analysis of files in the stereolithographic data format (STL).

The comparison performed using the STL data shows principal deviations between the computer-aided design (CAD) model and real sample, which are due to the limited energy of the 320-kV equipment and especially the smoothed edges in the LINAC measurement due to the limited detector pixel size.

Fault Detection in Telecommunication Equipment

The transmission characteristics of glass-fibre cables can be changed after installation or during lifetime. To localize such flaws optical time-delay reflection (OTDR) methods are frequently used. The location of flaws can

be determined with an accuracy of a few mm. An analysis of the type and size of flaws together with geometry control of the complex-shaped cable can be performed with CT. Figure 16.63 shows a vertical slice of a section (length 48 mm) of the cable together with two horizontal slices. The bunches of four glass fibres are embedded in a protective covering. One of the seven coverings contains no fibres. The diameter of each glass fibre is 125 μm . The outer diameter of the cable is 16 mm. Some protective coverings show flaws (Fig. 16.63 bottom right) and an incomplete embedding of fibre bunches. To avoid the influence of sample preparation the investigated sample volume was part of a 15-m-long cable segment.

Flaw Extraction in Cu Samples

As a first example results are shown for flaw extraction in electron-beam-welded Cu samples (size about $40 \times 100 \times 300$ mm) using high-energy 3D CT (Fig. 16.64). For studies of probability of detection (POD) a 100% inspection of volumetric flaws are performed. Due to the limited size of the flat-panel detector the sample was measured in three positions and the overlapping data sets are joined after the image reconstruction. The reconstructed images show some artefacts given by scattered radiation, beam hardening and inherent detector effects. Therefore a filter was used to reduce these artefacts. Figure 16.64 shows as result a cross section through the sample.

The flaws are evaluated twofold; by a local threshold operation using some image-processing modules (e.g. an STL converter module) developed for the image-processing system AVS and the Volume Graphics (VG Studio Max) image-processing tool. The geometry of the envelope and the voids are lead together and converted to STL format for comparison with ultrasonic results and for theoretical simulation of the irradiation process. The volume of all flaws of the sample is 1100 voxels, determined with the AVS system, which is in good agree-

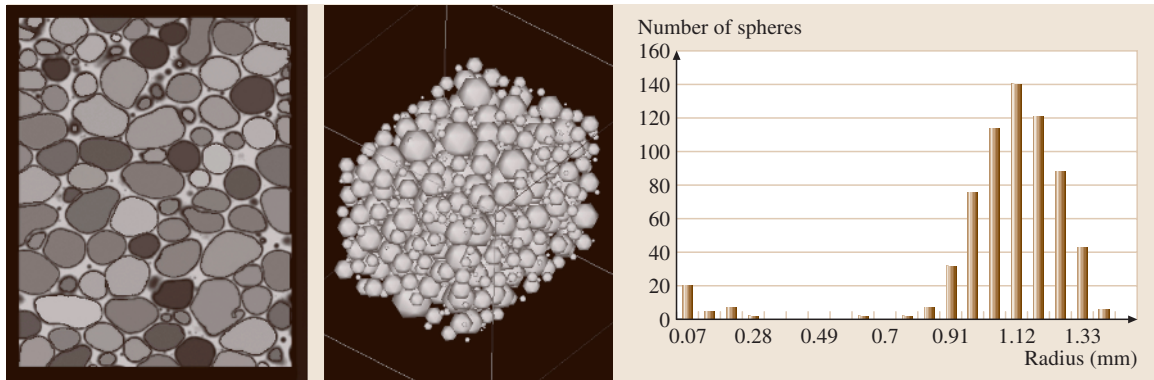

Fig. 16.66 Pore detection (*left*). Spheres with a diameter as calculated from the volume of found pores (*right*) at position of pore centers. The pore size distribution is shown in the diagram on the *right*

ment with the result from the VG system, which gives a volume of a 1072 voxel. The total volume is 4 304 500 voxels.

Calibration of NDT Methods

The CT imaging method combined with the geometrical correctness of the dimensions of the investigated

samples are the main advantages to the use of CT for the calibration of other NDT methods, such as ultrasonic technique (UT) or eddy-current techniques. As an example Fig. 16.65 shows the investigation of flaws of coated turbine blades. With optical methods only the flaws in the coating layer can be visualized but not in the matrix material. With high-resolution CT the crack configura-

Fig. 16.69 Enlarged detail (fivefold magnification), marked in Fig. 16.68 by the white square

tion was analyzed. The result was used for calibration of other NDT techniques (the eddy-current method).

Pore Detection and Pore-Size Calculation in Al Foam

Depending on the type of foam there are two ways to measure the size of the pores inside:

- If the pores are closed, a threshold operation is first used to obtain the binary area of all pores. Starting on one edge, an algorithm then searches in 3D for the first marked voxel and colors all adjacent as belonging to the same pore until no more connected

voxels are found. The searching algorithm then goes on to the next pore. Figure 16.66 (left image) shows the result; the image is a slice through the searched foam, the different colors of each pore are used to detect pores, which were not separated. The size distribution is given in Fig. 16.66 (right image). While the volume is searched for pores, the volume and the center of gravity are also stored, and further parameters can be calculated. From these parameters a simplified model of the foam can be generated and calculation of real foams with finite-element method (FEM) programs becomes possible. The center image of Fig. 16.66 shows the same foam, representing the pores as spheres with the same diameter.

- If the pores are open, the inverted non-metal part has to be 3D-eroded until single areas result for all the pores. The pore radius can then be calculated from the number of voxels counted per pore. Knowing the number of erode steps, the pore radius has to be enlarged by this value.

Internal Deformation

The failure mechanisms of strength-tested foams were studied on samples before compression and after compression. 3D CT images of the samples were used to find out where foam deformation has started, for which a program for image comparison in 3D was developed. First the size of the region to be compared with the region of the sample after the compression test has to be defined. This region has to be bigger than the mean pore

size. The region is moved in different directions in 3D until it fits best with the initial sample, and the shift of the parts of the strength-tested sample is written to an array. In this way, for all small regions of the probe we obtain shifts with respect to the initial sample in three directions: Δx , Δy and Δz .

The displacement after the compression test is shown (unit mm) using different grey levels, which are painted over the original foam structure, in order to show the displacement of compressed foam compared to original foam (Fig. 16.67).

Art Objects

Nondestructive methods such as X-ray techniques have been focused on art objects since the discovery of

X-rays by W.C. Roentgen. In a long-standing collaboration with the Antikensammlung Berlin several large Greek and Roman bronzes were examined, to evaluate work traces and the interior of these archaeological samples. In 2000 the interior of the hellenistic *Getty Bronze* and the early Augustan *Idolino* in Florence were investigated at BAM [16.43, 44]. From the still being results Fig. 16.68 shows a digital radiography (left image) which is used to localize the precise location of cross sections. The tomogram (right image of Fig. 16.68) gives a view of the interior of the statue, with parts of the structure fitting the different cast parts. A detail of the tomogram shown in Fig. 16.68 is presented in Fig. 16.69 with a fivefold enlargement.

16.5 Computed Tomography – Application to Composites and Microstructures

In computed tomography (CT) the interface contrast of heterogeneous materials can be strongly enforced by to X-ray refraction effects. This is especially desirable for materials with low absorption or mixed phases of similar absorption that result in low contrast. X-ray refraction [16.45, 46] is an ultras-small-angle scattering (USAXS) phenomenon. Refraction contrast has also been applied for planar refraction topography, a scanning technique for improved nondestructive characterization of high-performance composites, ceramics and other low-density materials and components [16.47].

X-ray refraction occurs when X-rays interact with interfaces (cracks, pores, particles, phase boundaries), preferably at low angles of incidence, similarly to the behavior of visible light in transparent materials, e.g. lenses or prismatic shapes. X-ray optical effects can be observed at small scattering angles of between several seconds and a few minutes of an arc, as the refractive index n of X-rays is nearly unity ($n \cong 1 - 10^{-5}$). In other terms, due to the short X-ray wavelength below 0.1 nm, X-ray light scattering is sensitive to inner surfaces and interfaces of nanometer dimensions.

16.5.1 Refraction Effect

In analogy to visible optics the interaction of X-rays with small transparent structures with dimensions above several nanometers results in coherent scattering governed by wavelength, structural dimensions and shape, local

phase shift and absorptive attenuation. However, differently from optical conditions, the refractive index of X-rays near 1 causes beam deflections into the same small-angle region of several minutes of arc as diffraction. Thus the resulting interference is due to phase modulation due to the refractive index and the absorptive and Raleigh diffraction, both of which depend on the path length through matter.

However if the dimensions of the scattering objects are much larger than several tens of nanometers, as is common in classical small-angle scattering, the interference fringes are no longer observable by classical small-angle cameras as they are too narrow. The resulting smeared angular intensity distribution is then simply described by a continuous decay according to the rules for refraction by transparent media, e.g. applying Snell's law [16.46]. This purely geometrical refraction approach is appropriate for small-angle X-ray (and neutron) scattering effects by micrometer-sized structures and is applied in the following.

If ε is the real part of the complex index of refraction n , ρ is the electron density and λ is the X-ray wavelength, then n is

$$n = 1 - \varepsilon, \quad \text{with} \quad \varepsilon \approx \rho \lambda^2 \quad \text{and} \quad \varepsilon \cong 10^{-5} \quad (16.31)$$

for glass under 8 keV radiation. In contrast to optics convex lenses cause divergence of X-rays as $n < 1$. Figure 16.70 demonstrates the effect of small-angle scattering by refraction of cylindrical lenses: a bundle of

Fig. 16.70 Effect of oriented small-angle scattering by refraction of glass fibres; n index of refraction, ε real part of n , λ wavelength

15- μm glass fibres (for composites) deflects a pinhole X-ray beam within several minutes of an arc. In fibres and spherical particles the deflection of X-rays occurs twice, when entering and when leaving the object (insert Fig. 16.70). The oriented intensity distribution is collected by an X-ray film or a CCD camera while the straight (primary) beam is removed by a beam stop. The shape of the intensity distribution of such cylindrical objects is a universal function independent of materials, if normalized to the *critical angle* θ_C of total reflection (Fig. 16.71) defined by the refractive index $\theta_C^2 = 2\varepsilon$. The intensity of the deflected X-rays becomes nearly zero at the critical angle Fig. 16.71, with a small contribution from total reflection.

Applying a Kratky-type high-resolution small-angle scattering camera with slit collimation a cross section of 10^{-3} of the fibre diameter contributes to the detectable intensity typically above 2 min of arc. Total reflection of X-rays occurs as well but only 10^{-6} of the cylinder diameter is involved and this is therefore negligible, although planar surfaces may scatter all the primary intensity if well aligned. Based on Snell's Law the angular intensity distribution of cylinders has been modeled and fitted to measurements on most different fibres, as il-

Fig. 16.71 The normalized shape of the angular intensity distribution of cylindrical objects; *PP*: polypropylene

lustrated by Fig. 16.71. The refracted intensity I_R^* of a cylinder (without absorption effects) can be expressed by [16.46]:

$$I_R^*(2\theta') = \frac{J_0 2R}{\varepsilon} \sin^3 \left(\arctan \frac{\varepsilon}{\theta'} \right) \cong \frac{J_0 2R \varepsilon^2}{\theta^3} \quad (16.32)$$

J_0 is the irradiation density of the incident X-rays, R is the cylinder radius and $2\theta' = \theta$ is the scattering angle. In the case of spherical particles or pores I_R^* becomes

$$I_R^*(2\theta') \cong \frac{J_0 2R \varepsilon^2}{\theta^4} \quad (16.33)$$

The conventional understanding of *continuous* small-angle X-ray scattering (SAXS) is governed by the interpretation of diffraction effects. Both the well-known *Guinier's* theory [16.48] for separated particles and *Porod's* theory [16.49] of densely packed colloids are based on diffraction of Rayleigh scattering. Nevertheless Porod approximates the same angular intensity decay as in (16.33). However both diffraction approaches are about scattering objects two orders of magnitude smaller.

16.5.2 Refraction Techniques Applying X-ray Tubes

The SAXS instrumentation with an X-ray fine-structure tube and a Kratky camera is relatively straightforward.

Fig. 16.72 Schematic of a SAXS instrumentation with a collimated X-ray beam, sample manipulator, refraction detector for refracted intensity, I_R with sample or I_{R_0} without sample, and an absorption detector for the attenuation intensity, I_A or I_{A_0} of the primary beam

Fig. 16.73 X-ray scanning topography; *left*: model composite of polymer matrix and embedded bonded (*top*) and debonded (*bottom*) 140-μm sapphire fibre; *middle*: X-ray refraction topograph of C-values resolving debonding spatially: an interface image, free from absorption effects; *right*: absorption projection

Fig. 16.74 X-ray computed tomography (CT) of carbon/carbon ceramic matrix composite (C/C-CMC); *left*: sample arrangement, *middle*: crack pattern by conventional (X-ray absorption) CT, *right*: highly contrasted cracks by refraction computed tomography

The camera needs an additional scattering foil for the primary-beam attenuation measurement and a micro-manipulation device for the sample (Fig. 16.72). For practical measurements the refraction detector remains at a fixed scattering angle $2\theta'$, so that the relative surface density C of the specimen can be measured according

to [16.47]:

$$C = \frac{1}{d} \left(\frac{I_R I_{A_0}}{I_{R_0} I_A} - 1 \right), \quad (16.34)$$

where I_R and I_{R_0} are measured by the refraction detector with and without sample, respectively, I_A and I_{A_0} are measured by the absorption detector, and where d the wall thickness of a sample. Apart from the choice of materials the relative surface density C depends solely on the scattering angle and the radiation wavelength. The absolute *inner surface density* (specific surface, surface per unit volume) is determined by comparison with a known calibration standard at retained boundary conditions (wavelength and scattering angle).

As well as the inner surface of pores and particles, interfaces and cracks such as fibre debonding in composites can also be determined. A model composite has been made to demonstrate the refraction behavior of a bonded and a debonded 140 μm sapphire fibre in a polymer matrix (Fig. 16.73, left). Figure 16.73 (middle) shows the resulting intensity distribution of a two-dimensional refraction scan of the model composite. The upper ray crosses the bonded fibre–matrix interface, causing a small amount of deflected intensity. At the debonded fibre and at the matrix surfaces (lower ray) many more X-rays are deflected, due to the larger difference of the refractive index against air. The polymer channel is clearly separated from the fibre surface. For comparison a mapping of I_A yields the transmission topograph containing only the absorption information of the projected densities, like in conventional radiography (Fig. 16.73, right). In the case of a real composite material the much thinner fibres are not spatially resolved, but the higher refraction signal of debonded fibres reveals quantitatively the percentage of debonded fibres.

Beyond the capabilities for two-dimensional topographs the set up of Fig. 16.72 can be employed for conducting computed tomography of a transversal section. This requires vertical linear scans and rotation of the sample to gain multiple projections for the parallel-beam reconstruction procedure. A section of a C/C ceramic matrix composite (CMC) for high-temperature applications is investigated to image the different crack patterns developing during manufacture by pyrolysis. The three samples (Fig. 16.74, left) are based on different phenolic resin carbon-fibre-reinforced polymer (CFRP) green bodies of good, intermediate and bad fibre/matrix bonding.

The absorption signals are reconstructed according to the rules for *parallel-beam filtered back-projection*

as shown by Fig. 16.74, center. The resulting transversal sections reveal major cracks and homogeneous domains.

The refraction and the absorption intensities permit the reconstruction of the relative inner surface density according to (16.34) (Fig. 16.74, right) which shows a significantly higher number and finer cracks. Additionally the average intensity levels reveal the quantitative crack density without resolving individual cracks. These findings have proved for the first time that the degree of fibre debonding is retained during processing from the green state to high-temperature treatment [16.50].

16.5.3 3D Synchrotron Refraction Computed Tomography

2D refraction CT by conventional X-ray tubes has disadvantages. It is limited to low X-ray energies from characteristic Cu and Mo radiation and thus restricted to low-density materials. The thickness of the investigated layer is as large as 1 mm and the measurements require over 10 h. To overcome these limitations 3D synchrotron

refraction CT is employed. At the **BAMline** at BESSY, Berlin the available monochromatic energy ranges from 5 keV up to 60 keV. Further advantages are the high photon flux, the selectable energy and the highly parallel photon flux.

The experimental set up is sketched in Fig. 16.75 [16.51]. A parallel monochromatic beam (up to 60 keV) at about 2% bandwidth is delivered by a double multilayer monochromator (DMM). At the experimental stage a beam of several 10 mm² is reflected sequentially by two Si(111) single crystals at their Bragg condition for the chosen energy. An X-ray-sensitive **CCD** camera of about 5 × 5 μm² resolution is placed behind the second crystal. A small inclination of the second crystal varies the reflected intensity. The resulting *rocking curve* width is 4 × 10⁻⁴ deg full width at half-maximum (FWHM) (Fig. 16.75, circles). In contrast to the set up for phase-contrast CT, the sample is positioned between the two crystals. Thus the most-parallel beam traverses the specimen and is attenuated according to the mass distribution. Additionally, the beam is deflected due to the refraction

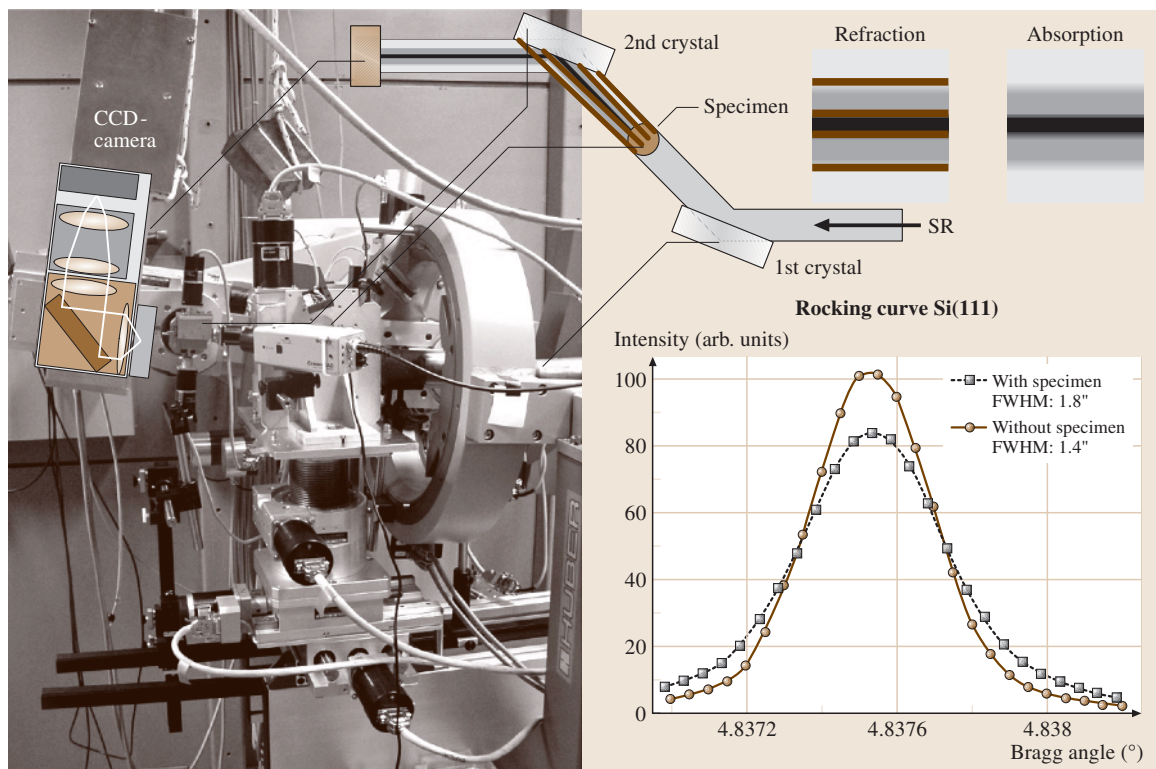

Fig. 16.75 Experimental set up for 3D refraction CT at the synchrotron **BAMline**; left and top: goniometer and beam components, right: rocking curve of the second Si(111) crystal (symmetric) with specimen (squares) and without specimen (circles)

Fig. 16.76 Conventional CT reconstruction of the absorption measurement on Ti-SiC MMC sample after fatigue; fine-focus tube, 100-kV single-slice 3D measurement

Fig. 16.77 Synchrotron refraction CT of same slice (Fig. 16.76); monochromatic 50-keV radiation, sample between two crystals at maximum reflection [16.51]

effect at all interfaces (Fig. 16.75, top right). This leads to a broadening of the rocking curve (Fig. 16.75, squares).

The presented investigation is performed on cylindrical tensile test samples of metal matrix composites (MMCs, MTU Aero Engines, München). The most advanced new material for aero engine compressor components with high tensile strength at low specific weight is based on a Ti matrix embedding SiC fibres. Their mechanical properties depend on the fibre/matrix bonding and their high crack resistance under high loads. Both characteristics require non-destructive characterization.

First a conventional 3D CT investigation is carried out employing a fine-focus X-ray tube. Figure 16.76 shows the density reconstruction of one out of 300 planes at 100-kV tube voltage and $5 \times 5 \times 5 \mu\text{m}^3$ voxel resolution (720 projections, rotation about cylinder axes, Fourier-filtered back-projection). It shows a transversal section of a low cycle fatigue (LCF) sample. Higher density appears brighter. The reinforcing SiC fibres appear as dark discs with a slightly darker (carbon) core. Solely in the selected plane of Fig. 16.76, bottom, a dark shaded crack area appears due to reduced absorption.

Synchrotron refraction computed tomography of the same sample is performed at the BAMline with the described set up at 50-keV radiation and $5 \times 5 \times 5 \mu\text{m}^3$ detector voxel resolution (360 projections, Fourier-filtered parallel-beam back-projection). The reconstruction of Fig. 16.77 images the same cross section of the MMC LCF sample, but now the crack area appears bright (color enhanced) and is much more detailed. Also some

debonded fibres can be identified by bright surrounding rings. In contrast to conventional absorptive CT measurements the refraction contrast provides crack indications in about 20% of the 300 reconstructed slices of the sample [16.51].

The high inverse contrast (compared to Fig. 16.76) originates from the rejection of deflected X-rays by the second Si crystal in front of the CCD detector due to refraction and total reflection interaction at the crack boundaries. The refraction contrast is nearly indepen-

Fig. 16.78 3D nano-refraction CT; reconstructed plane of steel micro-drill from 19-keV projections; dark tubular pores below $1 \mu\text{m}$ diameter; refraction contrast at outer edges and around pores; magnification by Fankuchen-cut single-crystal Si (at the center of the rocking curve)

dent of the width of the cracks as it is a surface effect. However, the contrast depends strongly on the angle of the incident beam, which is only effective at 0 ± 1 deg (plane crack). In the given set up, with both Si crystals set to the top of their rocking curves, the image information from absorption and refraction effects are both present. If desired they can be separated by different operation of the Si crystals.

Much higher spatial resolution can be achieved, when the second crystal (Fig. 16.75) is replaced by an asymmetric-cut crystal (Fankuchen cut). In this the crystal surface is inclined against the reflecting lattice plane, resulting in a broadened exit beam of up to 100× magnification. An example of such nanometer-resolution refraction CT is given by Fig. 16.78, which presents the reconstruction of a horizontal section of a standing steel

micro-drill (100 μm diameter) using 19-keV radiation. Dark tubular pores below 1 μm diameter, and refraction contrast at the outer edges and around pores are visible.

16.5.4 Conclusion

The presented findings demonstrate the high performance of refraction CT for inner surfaces and interfaces, including microcracks. Even beyond the spatial resolution of the reconstruction average crack densities are determined. The techniques are expected to close an essential gap in the spectrum of nondestructive techniques for a better understanding of microstructures of materials down to the nanometer scale and their behavior under thermal and mechanical loads.

16.6 Structural Health Monitoring – Embedded Sensors

The final decade of the 20th century brought many technological achievements, not only in regard to the development of innovative and high-performance materials but also in regard to advanced sensing techniques. The embedment of sensors into materials or structures opens up new possibilities to detect, e.g., the presence of cracks or the onset of failure, to estimate the extent of degradation, and to locate damaged zones. This is the basic idea of structural health monitoring, which has gained more importance within the last years. This is an emerging technology that deals with the development of techniques and systems for the continuous monitoring, inspection and damage detection of structures. Today structural health monitoring can be found in a wide area of industrial applications: starting from A for aircraft and ending at Z for Zeppelin. Innovative bridge design, higher safety requirements, extended operation time, reduction of maintenance and inspection costs (e.g. less or no visual and NDT inspection) are the driving forces for the usage of structural health monitoring systems. The ultimate goal is to eliminate current schedule-based inspection and replace it with condition-based maintenance or repair.

This chapter introduces the concept of structural health monitoring, gives an overview of state-of-the-art sensing techniques used for performance control and condition monitoring, and reviews topical applications from different industrial areas. Further detailed descriptions of a wide range of practical applications can be found e.g. in [16.52–56].

16.6.1 Basics of Structural Health Monitoring

The basic idea of structural health monitoring (SHM) can simply be described as the integration of a type of sensing system that provides information on demand about any significant change or damage occurring in an aerospace, civil and mechanical engineering infrastructure [16.57]. The structural health monitoring process involves the observation of a structure over time using periodically sampled dynamic response measurements from an array of sensors. The extraction of damage-sensitive features from these measurements and the statistical analysis of these features is then used to determine the current state of structural health. For long-term structural health monitoring, the output of this process is periodically updated information regarding the ability of the structure to perform its intended function in light of the inevitable aging and degradation resulting from operational environments. After extreme events, such as earthquakes or blast loading, structural health monitoring is used for rapid condition screening and aims to provide, in near real time, reliable information regarding the integrity of the structure [16.58]. During operational use structural health monitoring attempts to measure the inputs to and responses of a structure before damage so that regression analysis can be used to predict the onset of damage and deterioration in structural condition.

By combining the information of structural health monitoring, current environmental and operational con-

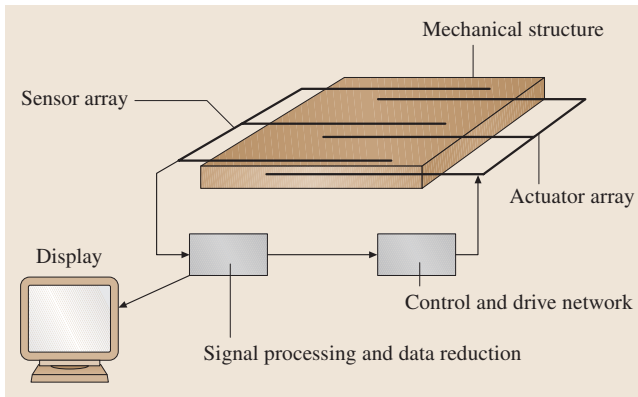

Fig. 16.79 Conceptual diagram of a smart structure (after [16.59])

ditions, previous component testing, nondestructive testing, and numerical modeling, a prognosis is possible to estimate the remaining useful life of the structure. By adding an actuator network and a related control and drive system, the structure can be improved to a so-called *smart material* or *smart structure*. It is able to monitor itself and/or its environment to respond to changes in its conditions Fig. 16.79 [16.59].

As mentioned before the detection and prediction of onset of damage is the main target of structural health monitoring. Damage in engineering structures is defined as intentional or unintentional changes to the material and/or functional or geometric properties of these structures, including changes to the boundary conditions and system connectivity, which adversely affect the current or future performance of that structure. All damage begins at the material level and, under appropriate loading scenarios, progresses to component- and structure-level failure at various rates. Materials degradation and failure can occur in different ways:

- Gradually (e.g. fatigue, creep, corrosion, wear, biodegradation, chemical degradation);
- Suddenly and unpredictably (e.g. fracture, fiber breakage, matrix cracking, fiber splitting, delamination, debonding).

All material degradation and failure precedes a change of mechanical and/or chemico-physical characteristics of the material. In this context mechanical characteristics (e.g. elasticity, strength) and chemico-physical characteristics (e.g. thermal expansion, temperature distribution, humidity, oxidation or corrosion status) have special meaning. These characteristics and/or associated auxiliary variables (such as, e.g., strain) must be detected by means of physical sensor effects or measurable quan-

Fig. 16.80 Cross section of a fiber-optic sensor embedded into concrete (after [16.60])

tities and converted into a useful output signal. In all cases the sensing system must be able to resolve the parameter of interest as a function of both position and time throughout the structure. The spatial and temporal bandwidths that are required to address these detection needs must be adapted to the special requirements of the structure being monitored.

Sensing capabilities can be given to materials or structures by externally attaching sensors or incorporating them within the material or structure during manufacturing. In the first place the incorporation of the sensing system must be in compatibility with the material structure. This means that the functional characteristics and performance of the material may not be impaired by the sensor integration. The embedding of piezoelectric sensors into fiber-reinforced composites or of fiber-optic sensors into concrete are typical examples for such a way of integration (Fig. 16.80). On the other hand the sensor must be robust enough to survive the manufacturing process (e.g. high temperatures during curing process), withstand chemical attacks from the material (e.g. very high pH environment in concrete), and withstand extreme mechanical loads (e.g. highly elastic behavior of plastics) (Fig. 16.81 and Fig. 16.82).

A wide range of physical sensor effects can be used to detect changes of mechanical and/or chemico-physical characteristics of a material. Preferably electrical (e.g. piezoelectric materials) or optical sensing effects (e.g. optical fibers) are used. Table 16.6 gives an overview about common sensor effects, which are used today for smart materials or structures.

To monitor a complete structure or a part of material, different architectures of sensor arrangement can be used. Basically the following variations are of practical interest [16.59]:

- A *point sensor* is one that monitors a particular parameter at a closely confined point defined by the effective cross-sectional area of the sensor element. In principle, the point sensor only sees a sample of the measurand at one particular point.
- An *integrating sensor* is one that takes an average value of a particular measurand over an area or length that is comparable to the area or length of the structure being monitored. Integrating sensors are sometimes spatially weighted (e.g. by variation of sensitivity) to ensure that they are sensitized to particular spatial distributions and not others.
- A *distributed sensor* is capable of evaluating the parameter of interest as a function of position throughout the geometry of the sensor element. The ability to perform distributed measurements is particularly important in structural health monitoring since it enables the derivation of the measurand at a large number of points throughout the structure using a single interrogation port and thereby eliminates the need for complex wiring harnesses.
- A *multiplexed sensor system* is one that combines a number of point, integrating, or distributed sensors into a complex system. It could go through an electronic interface and use techniques derived from the field. It can also be implemented at the sensor technology level. Here the multiplexing may be effected on the measurand subcarrier.
- A *quasi-distributed sensor system* combines a number of integrating sensors into a single system that is multiplexed in the measurand carrier domain.

Finally the role of *signal processing* in structural health monitoring should not be understated. Signal-processing procedures can be divided into basic and advanced methods [16.58]. A typical basic procedure is *data normalization*. Data normalization is a procedure to normalize data sets so that signal changes caused by operational and environmental variations of the structure can be separated from structural changes of interest, such as structural or material deterioration or degradation.

The purpose of *data fusion* is to integrate data from a multitude of sensors with the objective of making a more robust and confident decision than is possible with any one sensor alone. In many cases, data fusion is performed in an unsophisticated manner, as when one examines relative information between various sensors. At other times, such as those provided by artificial neural networks, complex analyses of information from sensor arrays are used in the data-fusion process.

Data cleansing is the process of selectively choosing data to accept for, or reject from, the feature selection process. The data-cleansing process is usually based on knowledge gained by individuals directly involved with the data acquisition.

Feature extraction is the process of identifying damage-sensitive properties, derived from the measured vibration response, which allows one to distinguish between the undamaged and damaged structure. The best features for damage detection are typically application specific. Numerous features are often identified for a structure and assembled into a feature vector. In general, a low-dimensional feature vector is desirable. It is also desirable to obtain many samples of the feature vectors. There are no restrictions on the types or combinations of data contained in the feature vector. A variety of methods is employed to identify features for damage detection. Past experience with measured data from a structure, particularly if damaging events have been previously observed for that structure, is often the basis for feature selection. Numerical simulation of the damaged structure’s response to postulated inputs is another means of identifying features. The application of artificial flaws, similar to those expected in actual operating conditions, to laboratory specimens can identify parameters that are sensitive to the expected damage. Damage-accumulation testing, during which structural components of the system under study are subjected to a realistic loading, can also be used to identify appropriate features. Fitting linear or nonlinear, physical-based, or nonphysical-based models of the structural response to measured data can also help identify damage-sensitive features.

Statistical model development is concerned with the implementation of the algorithms that operate on the extracted features to quantify the damage state of the structure. The algorithms used in statistical-model development usually fall into three categories. When data are available from both the undamaged and damaged structure, the statistical pattern-recognition algorithms fall into the general classification referred to as supervised learning. Group classification and regression analysis are supervised learning algorithms. Unsupervised learning refers to the class of algorithms that are applied to data not containing examples from the damaged structure.

The damage state of a structure can be described as a five-step process [16.62]. The damage state is described by answering the following questions:

1. Is there damage in the structure (existence)?
2. Where is the damage in the structure (location)?
3. What kind of damage is present (type) ?
4. How severe is the damage (extent)?
5. How much useful life remains (prognosis)?

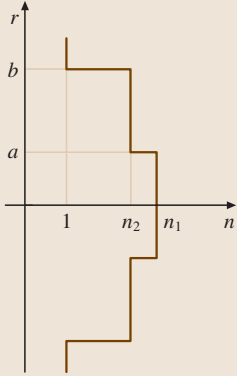

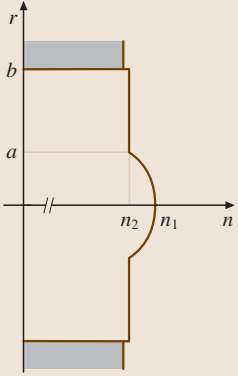

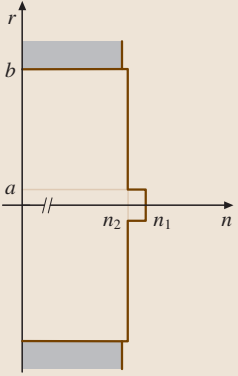

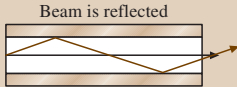

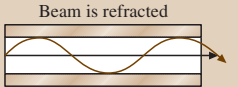

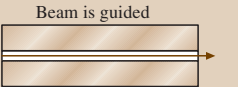

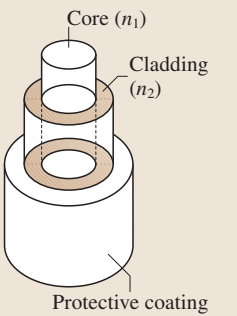

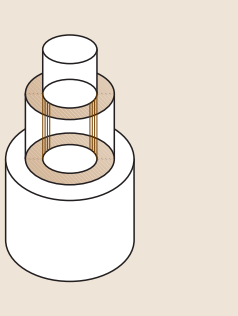

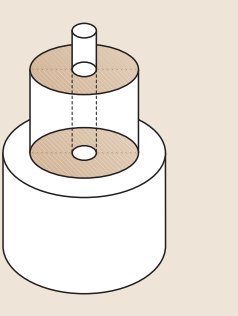

Answers to these questions in the order presented represent increasing knowledge of the damage state. The statistical models are used to answer these questions in an unambiguous and quantifiable manner.

16.6.2 Fiber-Optic Sensing Techniques

Basics

Basic element of a fiber-optic sensor is a thin optical fiber made of a highly transparent glass or plastic (polymeric) material. The optical fiber consists of a core having a re-

Table 16.7 Overview of most common types of silica optical fibers used for sensors

Fiber type	Multimode step index	Multimode graded index	Single-mode step index
Refractive-index profile			
Light propagation (schematic)			
Geometry			
Typical diameter	core: 50 μm cladding: 125 μm coating: 140 μm to 250 μm	core: 50 μm cladding: 125 μm coating: 140 μm to 250 μm	core: 6 μm (870 nm) 9 μm (1300 nm) cladding: 125 μm coating: 140–250 μm

fractive index n_{core} and a surrounding cladding having a refractive index n_{cladd} . In such a fiber the propagation of light can be explained by different models. The models are based on some fundamental postulations and have certain limits of application. Ray optics explains the kinematics of propagation. Wave optics explains diffraction and interference phenomena. Electromagnetic optics makes possible an exact analysis of the phenomena of classic optics, including the effect of energy at the interfaces. Finally quantum optics explains all the known optical phenomena, including interaction of light with matter. In this section the explanations are

limited to ray and wave optics, because they allow a simple and practical understanding of fiber optic sensing techniques. A comprehensive and detailed introduction to all models (including Maxwell's equations) can be found in [16.63, 64].

Based on ray optics, light propagation in an optical fiber can be understood as follows. When light is launched into one end of the fiber and $n_{\text{core}} > n_{\text{cladd}}$ is true, it propagates along the fiber to the other end corresponding to the physical effect of total internal reflection. Only light that is launched for $0 < \Theta < \Theta_{\text{max}}$ can be guided along the fiber (assuming that Θ_{max} is

Fig. 16.83 Light propagation in a multimode fiber

the maximum value of the range of the accepted angles Θ) (Fig. 16.83). It is continuously reflected at the interface between the core and the cladding; the critical angle α_{\max} must not be exceeded. Light that strike the end face of the fiber at an angle greater than Θ_{\max} is no longer completely reflected at the core/cladding boundary; instead it is partly refracted into the cladding so that it is no longer completely available for further propagation.

The properties of light guidance through a fiber are governed largely by the profile of the refractive index of the core and cladding. In a step-index-profile fiber the refractive index is constant across the entire cross section of the core and cladding (Table 16.7) while the light rays propagate along straight lines in the core and are completely reflected at the core/cladding boundary. The individual light rays cover different distances, so that there are considerable differences in their respective transit times. This is called a multimode fiber. Very small core diameters ($< 10 \mu\text{m}$) allow only one mode to travel through the fiber (called single-mode fibers). Fibers with a graded-index profile are made up of a core having a radius-dependent refractive index and a cladding with a constant refractive index. Those rays converging in the center travel a shorter distance, but because of the higher refractive index there, they travel at a lower speed. On the other hand, the smaller refractive index near the cladding causes the rays traveling there to have a higher velocity, but they have a longer distance to travel. By choosing a suitable profile exponent it is possible to compensate for these differences in transit time.

An optoelectronic unit, which contains a light source and a detector, and a processing unit for data acquisition, data processing and instrument control complete the fiber-optic sensing system (Fig. 16.84). Depending on the sensor type, semiconductor laser diodes (LD), vertical-cavity surface-emitting lasers (VCSEL), or light

emitting diodes (LED) are used preferably. As detectors photo diode with p-i-n semiconductor structure (PIN diode), avalanche photodiodes (APD), or miniaturized spectrometers are mostly integrated into the optoelectronic unit. A comprehensive and detailed explanation of common light sources and detectors for fiber-optic sensing techniques can be found in [16.63, 64]. For special or high-resolution measurements more complex measuring equipment like an optical time-domain reflectometer (OTDR) or a high-resolution optical spectrum analyzer are used.

Fiber Fabry–Pérot Interferometer

A *fiber Fabry–Pérot interferometer* sensor consists of a cavity defined by two mirrors that are parallel to each other and perpendicular to the axis of the optical fiber. There are two arrangements of Fabry–Pérot interferometer (FPI) sensors: first, the (intrinsic) in-fiber FPI sensor, where the cavity is formed by two mirrors at locations in the length of the fiber. The maximum distance of the mirrors (cavity length) can reach some mm and defines the gauge length. The second type is the extrinsic FPI sensor (EFPI). The optical cavity is formed by the air gap (usually about $10\text{--}100 \mu\text{m}$) between two uncoated fiber faces (Fig. 16.85). The most widely used design is to fix into position the two fiber ends in a hollow tube. The fiber end-faces act as mirrors and produce the interference fringes.

The functional principle of an FPI sensor is as follows. The incoming light reflects twice: at the interface glass/air at the front of the air gap [the reference (Fresnel) reflection] and at the air/glass interface at the far end of the air gap (sensing reflection). Both reflections interfere in the input/output fiber. The sensor effect is induced by force-induced or temperature-induced axial deformation of the hollow tube. This leads to a shift of the fiber end-faces inside the tube (because they are only

Fig. 16.84 Principle set up of a complete fiber-optic sensor system

Fig. 16.85 Common types of fiber Fabry-Pérot interferometer (after [16.65])

fixed at the ends of the tube), which results in changes on the air gap length (gap width s). From this follows a phase change between the reference reflection and the sensing reflection that is detected as an intensity change in the output interference signal.

FPI sensor systems are commercially available for strain, temperature and pressure measurements [16.66]. They allow local measurements of strain in a range between $-5000 \mu\text{m/m}$ (shortening) and $+5000 \mu\text{m/m}$ (elongation) with a resolution of up to $0.1 \mu\text{m/m}$. Available gauge lengths are in the range 1–20 mm. Because of their excellent response time behavior of up to 2 MHz, they can also be used for detection of mechanical vibrations and acoustic waves. However, the interrogation unit used defines the dynamic behavior. With regard to measuring performance and applicability, the fiber Fabry-Pérot interferometer (FPI) sensor is the most often applied interferometric *point sensor* type for structural health monitoring.

Fiber Bragg Grating Sensor

The discovery of the photosensitivity in germanium-doped fibers by Hill and coworkers in 1978 was the basis for fabrication of *in-fiber reflective Bragg grating* filters with a narrow-band, back-reflected spectrum. They discovered that the refractive index n of a fiber increases when ultraviolet (UV) light is incident upon such a fiber. Today fiber grating manufacturing is well established at special wavelengths with a given periodically changing refractive index and spacing between the individual grating planes (grating period or pitch Λ).

Fig. 16.86 Fiber Bragg grating sensor

Fiber Bragg gratings (FBG) are usually 1–25 mm long and act as *typical point sensors*.

The distance Λ between the grating planes can vary; the common FBG satisfies the condition $\Lambda < \lambda$ where Λ is less than $1 \mu\text{m}$ (in contrast to so-called long-period gratings with $\Lambda \gg \lambda$, where Λ is 100–500 μm). Fiber Bragg gratings for sensor applications are primarily referred to as uniform gratings: the grating along the fiber has a constant pitch and the planes are positioned normally to the fiber axis (Fig. 16.86). The principle of function is as follows: when a broadband light signal passes through the fiber Bragg grating, only a narrow wavelength range λ_B which satisfies the Bragg condition

$$\lambda_B = 2n_{\text{eff}}\Lambda \quad (16.35)$$

is reflected back due to interference between the grating planes (n_{eff} is the effective refractive index of the fiber core and Λ is the grating period). The quantity of the Bragg resonance wavelength λ_B is determined by the grating pitch Λ manufactured and corresponds to twice the period of the refractive index modulation of the grating. The grating periodicity is relatively small, typically less than $1 \mu\text{m}$. From (16.35) it can be derived that the Bragg resonance wavelength λ_B will change when n_{eff} changes (for example by temperature variation) or Λ changes (due to pitch changes by fiber-grating deformation). That means that changes in strain or temperature (or both together) will shift the reflected center wavelength. In general, λ_B increases when the fiber is strained ($\Delta\epsilon > 0$) and decreases when the fiber is compressed ($\Delta\epsilon < 0$). By means of a spectrum analyzer this wavelength shift can be measured. In this way, one can determine strain variations (for constant temperature) or temperature variations (without any deformation of the grating).

Assuming uniform axial strain changes in the grating area and the absence of lateral deformation of the grating, the strain seen by a grating can be computed by

Table 16.8 Typical strain and temperature sensitivities of FBGs

Wavelength	Strain sensitivity (pm/με)	Temperature sensitivity (pm/K)
800 nm	0.63–0.64	5.3–5.5
1300 nm	1.0	8.67–10.0
1550 nm	1.15–1.22	10.0–13.7

a simple linear equation:

$$\varepsilon = K \frac{\Delta\lambda_B(\varepsilon_z)}{\lambda_B} + \xi \Delta T,$$

(16.36)

where K has to be estimated by a calibration procedure. The strain sensitivity depends on the wavelength used (Table 16.8). With regard to thermal sensitivity the Bragg resonance wavelength shift is dominated by the temperature-induced change of the refractive index. Only a very small thermal-induced wavelength change comes from the thermal expansion of the glass material (coefficient of expansion of optical fiber glass is 0.55 K^{-1}).

Bragg grating sensors possess a number of advantages that make them attractive compared with other sensor arrangements:

- *Linear response.* The Bragg wavelength shift is a simple linear response to the sensor deformation as shown in (16.35). In contrast to FPI sensors the sensor signal has no ambiguity for strain/compression changes.
- *Absolute measurement.* The strain or temperature information obtained from a measurement system is inherently encoded in the wavelength (strain and/or

temperature, index changes due to cladding affection); an interruption in the power supply does not lead to a lost of measurement information.

- *Line neutrality.* The measured data can be isolated from noisy sources, e.g. bending loss in the leading fiber or intensity fluctuations of the light source.
- *Separation of the interrogation unit from sensor.* Removal of the reading unit or exchange of leading cable using special connectors with polished angled end-faces do not influence the signal response.
- *Potential for quasi-distributed measurement with multiplexed sensing elements.* Because a number of gratings (sensor array) can be written along the fiber and be multiplexed, a quasi-distributed sensing of strain and temperature is possible by serial interrogation of a limited number of gratings. The distance between the gratings can be designed according to the requirements.

There are different techniques to read the grating response under the influence of a measurand. The basic operation principles of fiber-grating-based Bragg grating sensors are monitoring either the shift in the wavelength or change in intensity of the return signal due to measurand-induced changes. To get high-precision monitoring of wavelength shift, laboratory-grade instrumentation based on highly resolving monochromators or optical spectrum analyzers (OSA) have to be used. For applications that do not have high requirements on strain resolution in the submicron or micron range low-cost portable reading units are commercially available (Table 16.9). These interrogation units fit laboratory as well as on-site requirements. When choosing a reading

Table 16.9 Commercially available interrogation units for FBG sensors

Parameter	si 720 Micron Optics	StrainaTemp JENOPTIK	Spectraleye™ SE600
Wavelength range	1510–1590 nm	850 nm	1527–1565 nm

unit for on-site applications, a set of requirements has to be considered, e.g. scan frequency, number of gratings to be read simultaneously, long-term reproducibility of wavelength shift, immunity to optical power fluctuations, low sensitivity to temperature and vibrations, easy handling and a reasonable price.

To exploit the multiplexing capability of FBG sensor, two different methods can principally be used. Because of the wavelength-encoded nature of grating, each sensor in the fiber can be designed to have its own wavelength within the available source spectrum. Then, using wavelength multiplexing, a *quasi-distributed sensing* of strain, temperature or other measurands associated with spatial location of the measurand is possible. The number of sensors depends on the bandwidth of the source (typically about 70 nm), on the Bragg reflection bandwidth (typically 0.4 nm) and on the wavelength range needed for pulse shifting due to measurand changes (sometimes up to ± 3.5 nm). Using this method, up to 20 sensors can be interrogated in series (Fig. 16.87).

Low-Coherence Interferometry

An *integrating* or long-gauge-length sensor can be realized by the concept of *low-coherence interferometry*. It is based on a double Michelson interferometer and a low-coherence source (e.g. a LED or a thermal light source) (Fig. 16.88). A sensing interferometer uses two fiber arms – a measurement fiber that is in mechanical contact with the structure, and a reference arm, which compensates for the temperature dependence of the measuring fiber. The reference fiber must not be strained and needs to be installed loose near the first fiber. When the measurement fiber is contracted or elongated, deformation of the structure results in a change of the length difference between the two fibers. By the second interferometer, which is placed in the portable reading unit, the path-length difference of the measurement interferometer can be evaluated. This procedure can be repeated at arbitrary times and, because the displacement information is encoded in the coherence properties of the light (coherence length of a typical LED: 10–100 μm) and does not affect its intensity. Due to its physical principal and easy set up, not only the precision but also the repeatability of measurements is high for this sensor type. The measurement system can be switched off between two measurement events or components such as connectors or cable can be exchanged without zero-point data loss.

Typical parameters of commercially available long-gauge-length sensor are:

Fig. 16.87 (a) Distributed strain measurement in a composite structure of a rotor blade for a windmill by three FBG; (b) FBG signals after 10 Mio. cycles of dynamic loading during reliability testing

- Measuring length: 50 cm to several 10 m
- Measuring range: 0.5% in shortening, 1.0% in elongation
- Precision in measurement: 2 μm (error of measurement: $\Delta\epsilon = \pm 1.25 \times 10^{-5}$)
- Proportionality factor between the measured delay and the applied deformation: $(128 \pm 1) \mu\text{m}/\text{ps}$.

Such sensors can be provided as tube sensors or as flat tape sensors. Tape sensors allow its integration into composites or into interface zone of

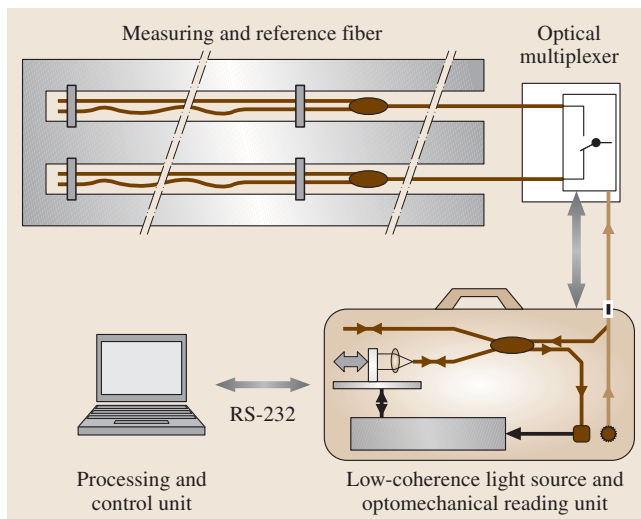

Fig. 16.88 Fiber-optic low-coherence interferometry sensor system, after [16.67]

multilayer materials. Several sensors can be interrogated by multiplexing.

Optical Time-Domain Reflectometry

A *quasi-distributed sensor system* within a material or construction can be realized by fiber-optic techniques in the following way. By measurement of the time of flight of a ultrashort light pulse transmitted into the fiber and backscattered on markers (splices, photoinduced reflectors, or squeezing points) at the end of these sections, the measurand can be determined at definite locations along the fiber (Fig. 16.89). An elongation (compression or contraction) of a measuring section, determined by two reflector sites on the fiber, changes the time of flight of the pulse: $\Delta\epsilon \sim \Delta t_p [(c/2L_0)n]$, where c is the speed of light and n the index of refractive. Based on this relationship, the changes in the average strain of a chain of marked sec-

Fig. 16.89 Quasi-distributed fiber-optic sensor based on backscattering signal evaluation

tions along the fiber can be interrogated by an **OTDR** device.

This method allows the evaluation of strain profiles in large components without using sensor fibers containing discrete sensor points along the fiber. The **OTDR** device used determines the strain resolution achievable. A high-resolution picosecond **OTDR** device enables the resolution of elongation to 0.2 mm, assuming the minimum distance between two reflectors in the measuring section is not less than 100 mm [16.68]. Using this method, a reflector shift of 0.35 mm can be resolved, however only long-term reproducibility of reflector shifts of 0.85 mm can be achieved. This value is sufficient to recognized dangerous changes in the material or loss of bonding integrity. Automatic scanning run takes between one and some ten seconds depending on the wanted precision. The sensor sections are interrogated one after another. Offline measurements are preferred because the rather expensive **OTDR** devices should alternatively be used for other measurement tasks, too.

The length of the fibers evaluated by conventional **OTDR** technique is limited by the permissible power loss along the fiber (quality of the markers), and can reach up to several hundreds meters, or tens of sensing sections. This method has a serious advantage: determination of the position of all reflectors can be referred to one stable position (reference reflector). Therefore, there is no propagation of error due to propagating from one reflector to the next one.

The examples considered above were focused on strain or deformation measurement in direction of the fiber axis. However in composites, transversely applied pressure, arising forces or beginning delamination might be of interest. For such purposes, single-mode birefringent fibers can be embedded. Internal birefringence can be induced by using a non-circular core geometry of the fiber or by the introduction of stress anisotropy around the core such as done in panda or bow-tie fibers. The refractive-index difference of the two orthogonal polarization modes produces a differential propagation velocity. Any damage or parameter change in the composite or material structure will perturb the birefringence parameters in the sensor fiber. Using the time-delay measurement technique, the intensity and position of the perturbation can be located with an uncertainty of about 10 cm [16.69]. However, a reproducible correlation between affecting external events and optical effects in the fiber is quite difficult because the interface zone of the

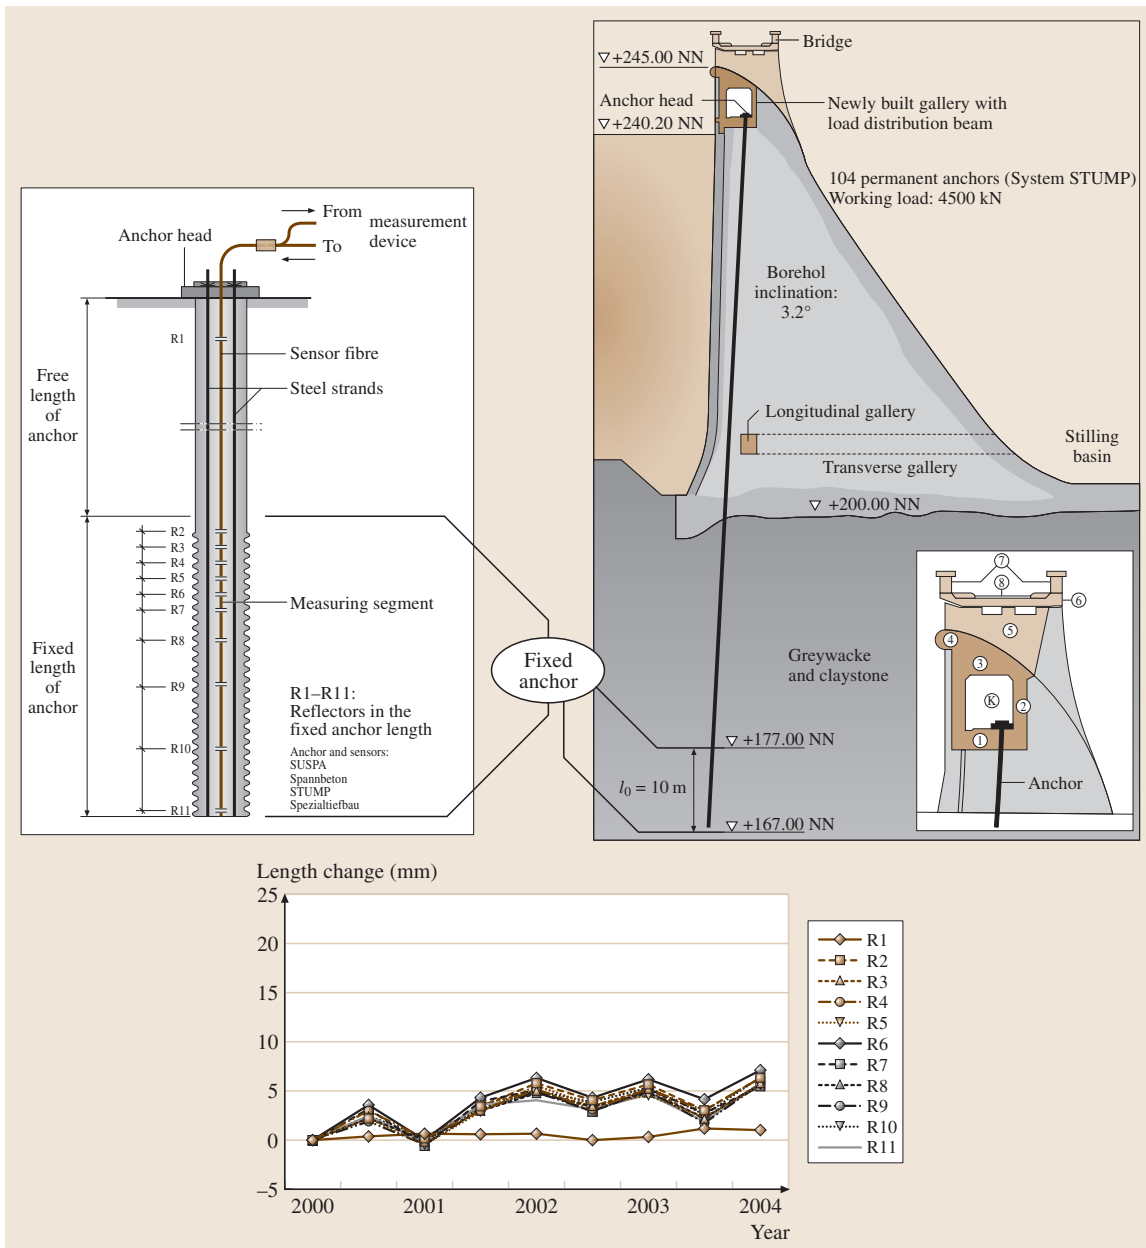

Fig. 16.90 Monitoring of the bonding behavior along the fixed anchor length by quasi-distributed fiber-optic sensors (Eder Gravity Dam Germany) after [16.71]

sensing fiber strongly influences the response of the sensor. Nowadays, fiber Bragg gratings will be written into birefringence fibers to make multiple parameter sensing with the capability to discriminate between them [16.70].

Brillouin Scattering

In optical fibers *Brillouin scattering* arises due to the interaction of light with phonons. Phonons are quantized acoustic waves. In essence, the light is scattered from variations in the index of refraction associated

with acoustic waves. Light which is scattered off these phonons is frequency shifted by an amount of determined by the acoustic velocity of the phonons. The acoustic velocity is in turn dependent on the density of glass and thus the material temperature. The Brillouin frequency shift is given by

$$\nu_B = 2n \frac{V_a}{\lambda}, \quad (16.37)$$

where V_a is the velocity of sound in glass and is a function of (T, ϵ) , n is the effective index of refraction, and λ is the free-space wavelength of operation. The frequency shift is linearly dependent on both the temperature and strain in the fiber [16.73, 74]. The sensitivity of the fre-

quency shift is of the order $4.6 \times 10^{-6} \mu\epsilon^{-1}$ for strain and $9.4 \times 10^{-5} / ^\circ\text{C}$ for temperature.

Since this technique was first published, several developments and technical innovations have led to dramatic advances in the capabilities of the Brillouin approach. One typical example is an arrangement where the sensing fiber follows a double path in the structure to be monitored. One path is attached to the structure or embedded in the material and is thus subjected to both temperature and strain. The return path is loosely installed, measuring only the temperature profile. By such an arrangement a temperature resolution of 1°C and a strain sensitivity of $25 \mu\epsilon$ with a spatial resolution of approximately 1 m have been achieved [16.75].

Figure 16.91 shows zones of shifted Brillouin frequencies with an 11-km-long optical fiber [16.72]. A closer look on these zones demonstrates the temperature and strain resolution of such a set up. The peak difference of both indications is in the order of 3 MHz, which represents a temperature resolution of 2.6°C or a strain resolution of 0.006%.

16.6.3 Piezoelectric Sensing Techniques

Basics

The origin of the *piezoelectric effect* is related to an asymmetry in the unit cell of the crystal and the resultant generation of electric dipoles due to mechanical distortion. However, it was not until 1946 that scientists discovered that barium titanate (BaTiO_3) ceramics could be made piezoelectric by application of an electric field. The polycrystalline ceramic materials have several advantages over single crystals, such as higher sensitivity and ease of fabrication into a variety of shapes and sizes. In contrast, single crystals must be cut along certain crystallographic directions, limiting the possible number of geometrical shapes. After the BaTiO_3 ceramics, scientists discovered a number of *piezoceramics* and in particularly the lead zirconate titanate (PZT) class in 1956. With its increased sensitivity and higher operating temperature, PZTs soon replaced BaTiO_3 and are still the most widely used piezoceramics. In the sixties, new varieties of piezoelectrics were developed based on both ceramics and polymers. Piezoelectrics are available in different forms, such as film, powder, paint, multilayered or single fibre. They are available in several types, such as polyvinylidene fluoride (PVDF) lanthanide-modified piezoceramic (PLZT) or the popular class of lead zirconate titanate piezoceramics. This list is not complete, because the composition of the piezoelectric materials allows a large variety of piezoelectrics, and new piezo-

Fig. 16.91 Zones of shifted Brillouin frequencies within an 11-km-long optical fiber (*upper*). A closer look at these zones demonstrates that the resolution of 3 MHz represents a temperature resolution of 2.6°C or a strain resolution of 0.006% [16.72]

electric classes are expected to be developed in the near future [16.76]. The properties of piezoceramics have attracted a large group of industries such as the aerospace and automotive industries.

The piezoceramics offer a large selection of materials with different electromechanical properties [16.77]. The common electromechanical properties are the coupling factor, piezoelectric charge constant, piezoelectric voltage constant, mechanical quality factor, dielectric loss and relative dielectric constant. The *coupling factor* is defined as the ratio of the mechanical energy stored to the electrical energy applied, at a given frequency or frequency range. It could also be defined as the ratio of the electrical energy stored to the mechanical energy applied. The coupling factor characterizes the coupling between the electrical and mechanical properties of the piezoceramic. The *piezoelectric constant*, d , also called the charge constant, is the ratio of the electric charge generated per unit area to an applied force. It can also be defined as the ratio of the strain developed by the applied electric field. Another piezoelectric constant exists, called the voltage constant, which is derived from the charge constant. The piezoelectric voltage constant, g , is the ratio of the strain developed to the charge applied or the electric field developed to the mechanical stress applied. The *mechanical quality factor* is the ratio of the reactance to the resistance in the series equivalent circuit (RS, CS) identifying a piezoelectric resonator. The relative dielectric constant, also called the relative permittivity, is defined as the ratio of the material dielectric constant, ϵ , to the free-space dielectric constant, ϵ_0 . The dielectric loss, also known as loss tangent in the literature, is defined as the ratio of the imaginary component of the complex dielectric to its real component.

However, the most important electromechanical properties are the coupling factor and the piezoelectric constants. A high coupling factor gives a greater sensitivity to the piezoceramic in converting the Lamb waves into an electrical signal. A high piezoelectric charge constant is desirable for materials intended to generate ultrasonic waves such as Lamb waves, because for an applied electric field, or excitation signal, a large developed strain is necessary to propagate over a long distance.

Other non-electromechanical parameters also exist and play a large role in the selection of the PZT; the most important are the mechanical elastic constants, the Curie temperature and thermal coefficients of expansion. The value of the elastic constants needs to be as low as possible to reduce the local stress inside the PZT as well as in its vicinity. The Curie temperature is the temperature at which the piezoceramic loses its piezo-

electric properties. The Curie temperature has to be as high as possible to allow a large working-temperature range and must be higher than the curing temperature of the composite laminate to prevent the loss of piezoelectric properties. Typically, the working temperature has to be 100 °C lower than the Curie temperature. The thermal coefficients of expansion have to be similar to those of the composite to reduce the stresses in the transducer and the composite.

Four main piezoceramic materials are commercially available; lead zirconate titanate, modified lead titanate, lead metaniobate and bismuth titanate. For transducers used in damage detection as well as sensitive detectors and actuators, the class of PZT is considered to be a suitable material because of its high coupling factor, high charge constant, high Curie temperature, low mechanical quality factor and thermal coefficients similar to those of composites. The dimension of the embedded piezoceramic element has a direct influence on the way the PZT works, that is, the functioning characteristics of the PZT. Some PZT coefficients, such as the coupling factor, the relative dielectric constant or the mechanical quality factor, are dependent on the PZT dimensions. Moreover, the piezoceramic dimensions are chosen by analytical methods based on the properties of wave propagation in the composite.

Embedment Techniques

Two principle configurations with embedded piezoceramic transducers are described in the literature. The technique concerns how to embed the PZT transducer in the composite. Some researchers have chosen to cut the composite plies surrounding the embedded piezoceramic transducer, as done by Elspass et al., Hagood et al., Moulin et al. or Warkentin and Crawley [16.78–80]. Other researchers directly embedded the PZT transducers to avoid cutting the fibres, as done by Bourasseau et al., Neary et al. or Shen et al..

Elspass et al. manufactured a piezoceramic transducer to be embedded in carbon-fibre-reinforced thermoplastic composites [16.78]. The material in the interconnectors was the same as the composite. The two interconnectors were placed on each side of the piezoceramic element. The electrical insulation from the upper and lower interconnectors was achieved by two glass-fibre-reinforced thermoplastics, as shown in Fig. 16.92. Cutouts in the glass- and carbon-fibre-reinforced thermoplastic were performed to allow electrical contact between the terminals and the embedded piezoceramic element. The manufacture of such a lay out was complex.

Fig. 16.92 Piezoceramic element embedded in a carbon-fibre-reinforced thermoplastic composite

Hagood et al., similar to *Elspace et al.*, used a cut-out technique to embed piezoceramic transducers in glass-fibre-reinforced polymer (GFRP) laminates. A cut-out window had about the same dimension as the PZT element. Slits were also cut in the plies directly above and below the piezoceramic element to allow the connectors to be drawn out to the edges, as shown in Fig. 16.93. The connectors were wires that were soldered to the

Fig. 16.93 Piezoceramic element embedded in a glass/epoxy laminate

faces of the piezoceramic element. *Hagood* also embedded the piezoceramic element in conducting material, such as carbon-fibre-reinforced polymer (CFRP). To electrically insulate the piezoceramic transducer from the surrounding material, a polyamide layer was often used to encapsulate both the piezoceramic element and the connectors, as shown in Fig. 16.94.

A research group of Stanford University developed a commercial transducer called the Stanford multi-actuator receiver transduction layer (SMART Layer™). The SMART Layer™ was similar to the transducers used by *Mall* and *Hsu* [16.81]. The transducer SMART Layer™ could be customized in a variety of sizes, shapes and complexity, allowing its embedment in many composite structures, such as pressure vessels, pipes or wings, as shown in Fig. 16.95. The PZT elements were PKI-400, with a thickness of 254 μm . The connector was made of a copper layer bonded on a polyamide film. The connector was shaped to provide a perfect fit to be embedded in the composite. The conductive adhesive linking the PZT element to the connector was probably a silver/epoxy compound. The transducer could withstand over 200 °C, required for embedment in aerospace composite structures.

Damage Detection Using Lamb Wave Response

Lamb waves are sensitive to damage in the composite, resulting in changes in the Lamb wave response. The interaction between damage and Lamb waves is complex and difficult to predict. Two different approaches to research on Lamb waves for damage detection have been seen in the literature. There are research groups that try to simplify Lamb wave generation, and others that directly postprocess the Lamb wave response without simplifi-

Fig. 16.94 Insulation of a piezoceramic transducer

Fig. 16.96 Decomposition in symmetric and antisymmetric modes

cation in the Lamb wave generation. To generate simple Lamb waves, researchers use wedged PZT to create an incidence angle between the PZT and the composite plate, which allows the generation of specific Lamb wave modes. In the case of this thesis, the piezoceramic transducers were embedded in the composites, which excluded the use of wedges with the transducers. Nevertheless, it is still possible to improve the generation of Lamb waves by means of PZT size optimization or simplify them by using arrays of embedded transducer. The latter has so far only been done on surface-bonded PZT transducers. This section deals then with postprocessing techniques that are used to track damage information in the Lamb wave response.

In 1885, the English scientist *Lord Rayleigh* demonstrated theoretically that waves can be propagated along the boundary of an elastic half-space and vacuum or sufficient rarefied medium (for example air). It was only in 1914 that *Stoney* generalized the propagation of waves in two different solids. In 1917, *Lamb* introduced a third solid defined as a thin layer of finite thickness. This allowed the study of wave propagation in multilayered materials, such as in composites. The waves propagating in this multilayered material were then called Lamb waves. The term Lamb waves refer to elastic waves

Fig. 16.97 Example of an excitation signal (upper) and a multimode response

propagating in a solid plate with free boundaries. The displacements of the Lamb waves occur both in the direction of the wave propagation and perpendicularly to the plane of the plate. A comprehensive description of physical theory and application of Lamb waves can be found in [16.82].

Lamb waves consist of several waves γ_i of the same waveform γ that propagate with different propagation velocities v_i called the group velocities. The waveform is often called a mode. Each Lamb wave mode can propagate symmetrically or antisymmetrically within the laminate, as shown in Fig. 16.96.

The amplitude of γ_i depends on the composite used. Up to now no theory exists that can exactly predict the amplitude of the Lamb waves. Figure 16.97 shows an example of multimode signal containing three modes [16.82]. The time t_i is the time of flight of the Lamb wave mode γ_i . In the present case, the Lamb wave generator and receiver are separated by a distance d . The response given in Fig. 16.96 does not correspond in detail to Lamb waves, because a real Lamb wave response would be too complex for the educational purpose of this section.

Indeed, a Lamb wave response would include not only the Lamb wave modes but also their reflections, which do not exist in the multimode response of Fig. 16.97. Besides, it is possible that at the excitation frequency, some Lamb wave modes might be dispersive,

Fig. 16.98 Phase velocity for the cross-ply laminate $[0_4/90_4/0_4/90_4/0_2]_s$

Fig. 16.99 Group velocity of Lamb waves propagating in the laminate $[0_4/90_4/0_4/90_4/0_2]_s$

meaning that their corresponding waveform may not be similar to the waveform of the excitation signal. The group velocity v_i of the mode γ_i is given by:

$$v_i = \frac{d}{dt_i} \quad (16.38)$$

However, the number of waveforms, or modes, propagating in a laminate as well as their time of flight can be predicted by the dispersion curves. Two types of dispersion curves are mostly used for the Lamb wave technique: the phase velocity c and group velocity v , as shown in Figs. 16.98 and 16.99, respectively. The phase velocity corresponds to the ratio of the spatial component, i. e. the wavenumber ξ , to the temporal component, i. e. that is the angular frequency $\omega = 2\pi f$, of a harmonic

wave. The group velocity may be described as the energy velocity of the Lamb wave modes in relation to the laminate. The phase-velocity curves are mainly used to determine whether or not the Lamb wave modes will be dispersive, and also to obtain the wavelength λ of each Lamb wave mode generated in the laminate, using the following relationship:

$$\lambda = c/f, \quad (16.39)$$

where f is the frequency spectrum of all Lamb wave modes generated in the laminate. To find out if a Lamb wave mode is dispersive or not, the derivative of the phase velocity is used. If, at a given excitation frequency, the derivative of the phase velocity is zero, then the Lamb wave modes should be nondispersive. Most of the time, nondispersive Lamb waves are chosen, because their corresponding waveforms generally remain the same throughout the propagation. Moreover, the phase and group velocities of a nondispersive wave are theoretically identical. Indeed, both velocities are governed by the following equation:

$$\frac{1}{v} = \frac{1}{c} \left(1 - f \frac{dc}{df} \right). \quad (16.40)$$

For a nondispersive wave $\frac{dc}{df} = 0$ and therefore (16.40) leads to $v = c$.

The wavelength of each Lamb wave mode is directly related to the sensitivity of the Lamb waves to the detection of damage. In principal a Lamb wave of wavelength λ is able to interact with damage on the order of or greater than λ . The dispersion curves depend on the composite material and lay out used. Often the dispersion curves are given as a function of the product fh (*frequency by half laminate thickness*). Two examples of dispersion curves are given in Figs. 16.98 and 16.99, for a stacking sequence of $[0_4/90_4/0_4/90_4/0_2]_s$ and the composite material HTA/6376C. In the figures, S and A stand for symmetric and antisymmetric modes, respectively, and the subscript corresponds to the mode number.

The dispersion curves are important for characterizing the active system that detects damage in the composite [16.83]. The frequency spectrum of all Lamb wave modes is, in principal, equal to the frequency spectrum f of the excitation signal of the Lamb wave generator. In the example shown in Fig. 16.99, the frequency of the excitation signal is 240 kHz for a composite thickness of 4.83 mm. Figure 16.99 therefore shows that the only Lamb wave modes that can exist in this composite would be the modes A_0 , S_0 and A_1 with group velocities of 1.6 km/s, 5.8 km/s and 4 km/s,

respectively. Figure 16.98 further allows determination of the wavelengths of those modes A_0 , S_0 and A_1 , which are about 6 mm, 28 mm and 41 mm, respectively. In such an example, the mode A_0 would be able to detect damage of at least 6 mm or larger, with the condition that its amplitude is large enough for the mode to be measured. Note that for higher frequencies, the wavelength of the mode A_0 , for example, is smaller than 6 mm. This would therefore allow the detection of damage smaller

than 6 mm. Unfortunately, the propagation distance of the Lamb wave modes tends to decrease with increasing frequency.

Several developments have occurred in this area since the technique was first reported, which have led to new possibilities and advances in the capabilities of structural health monitoring [16.84, 85]. Special focus has been given to the monitoring of composites for aircraft applications [16.86].

16.7 Characterization of Reliability

Reliability is a statement of whether or not a device fulfills its function after a certain time of operation. The scientific definition of reliability reads as follows [16.87]: *Reliability is the probability that an item will perform a required function without failure under stated conditions for a stated period of time.*

As the lifetime of a device *scatters*, reliability is a quantity that can only be described by means of statistic tools, which will be introduced briefly in the first Sect. 16.7.1. Additionally, we will show that the scatter in lifetime originates from the scatter of both the strength of the device and the scatter of the stresses to which it is exposed. Both can be described by distribution functions, and the region of interference of both distributions will be shown to be a measure for the failure probability.

In Sect. 16.7.2, the Weibull analysis will be introduced, as it has become the major tool in science and industry to analyze failure data. Due to the importance of this issue, this section is the longest in this chapter.

Section 16.7.3 will show different test strategies. Those address the basic problem of how to characterize reliability with a small number of sample devices with the smallest possible time effort.

A similar question is addressed in Sect. 16.7.4, introducing the important acceleration techniques. The basic idea is to apply higher stresses to the device than under real-life conditions to provoke failures. By means of physical models describing the degradation process, the lifetime under real conditions can be estimated.

In the last Sect. 16.7.5, quantitative reliability estimation for complex systems will briefly be discussed. The failure behavior of a complex system consisting of single components can be calculated from the component reliabilities. Here, we restrict discussion to the simple case where the system solely consists of components with serial and parallel functionality.

In this chapter, special emphasis will be placed on the following:

- Enabling the reader to become familiar quickly with the basic concepts of reliability
- Restricting discussion to the main tools presently used in science and industry

For further reading, key literature is given. To completely understand this material it is inevitable that more-sophisticated literature, which deals with special topics in more depth than is possible here, will have to be consulted.

A *literature survey* on reliability shows that there are some standard textbooks available that introduce the basic concepts. Some of them have handbook character and are designed for daily use in practice [16.87–91]. Others emphasize the mathematical background and statistical tools [16.92].

It is also noticeable that, at least during the last years, lots of communication on reliability issues is carried out via the internet. Therefore, it is inevitable that we will cite some of the key websites dealing with reliability in the following sections. Some of these commercial [16.93, 94] and noncommercial [16.95] websites offer excellent tutorials and introductions to reliability and it is worthwhile studying them. Recently, a website survey paper was published where some commercial and non-commercial sites were summarized [16.96].

The Bathtub Curve

In order to describe the time dependence of a device's failure behavior, a reliability parameter called the failure rate $\lambda(t)$ rate is used. Simply speaking, this describes the (average) number of failures per time unit. An exact definition will be given in the next section.

In most cases, if $\lambda(t)$ is plotted against time, a typical bathtub shaped curve is observed (Fig. 16.100) [16.87, 97]

The bathtub curve is categorized into three regions:

- Region 1 exhibits a falling failure rate and covers the so-called *early failures* (“infant mortality”). The origin of those failures in most cases is not related to material properties, but rather to the quality of the manufacturing process of the whole device.
- Region 2 is characterized by a constant failure rate and covers *random failures* that are not governed by a single failure mechanism. In this region, the device fails due to miscellaneous interactions with its environment, e.g. peak-like overloads, misuse, high temperatures and others.
- Region 3 is the region where material-related failures start to dominate. Therefore, the somewhat imprecise phrase *wear-out failures* is commonly used for this phase. The failure modes in this region are often initiated by detrimental changes of the devices’ material components, caused by the service loads applied to the device. The mechanisms leading to failures are called *degradation mechanisms*. Those mechanisms lead to a strong increase of the failure rate with time. Typical degradation mechanisms are mechanical fatigue (Chap. 7), corrosion (Chap. 12), wear (Chap. 13), biogenic impact (Chap. 14), and material–environment interactions (Chap. 15).

A very important statement is that the Weibull analysis (Sect. 16.7.2) enables us to judge to which category the investigated product belongs using the failure data analysis.

16.7.1 Statistical Treatment of Reliability

Since reliability is defined as a statistical quantity, statistical tools are needed to describe it. In the following section, the origin of the statistical scatter will be described by means of static and dynamic

Fig. 16.100 The typical bathtub curve (*thick line*), as a superimposition of the three failure rates belonging to independent failure mechanisms dominating in the regions 1–3 (*dashed lines*)

stress – strength interference models. In the following section, reliability functions and reliability parameters describing the time-dependent failure behavior are introduced.

Reliability Functions

For a given time value t , $F(t)$ describes the probability for the event that the device will fail within the time interval between 0 and t .

To describe this quantitatively, we introduce the *lifetime* L of the device. L may be given in unit of time, cycle number, or any other quantity related to the life of the device. Then the failure probability $F(t)$ is defined as the probability P that L is smaller than or equal the

Fig. 16.101 Schematic drawing of all four relevant functions discussed in Sect. 16.7.1. In particular, the relation between the failure density function and the other functions is shown

observation time:

$$F(t) = P(L \leq t) . \quad (16.41)$$

$F(t)$ may also be written as integral over its *failure density function* $f(t)$

$$F(t) = \int_0^t f(t') dt' . \quad (16.42)$$

The failure density function has practical meaning, since distribution functions are commonly given in this expression. As an example, the well known bell-shaped curve is the *density function* of the Gaussian normal distribution, but not the distribution function itself.

Given the failure probability, the probability of survival is expressed as its complement $R(t)$. $R(t)$ is called the *reliability function*, or simply the *reliability*

$$R(t) = 1 - F(t) = 1 - P(L \leq t) = P(L > t) . \quad (16.43)$$

The failure rate, which was introduced earlier in a qualitative manner, can now be defined precisely as

$$\lambda(t) = \frac{f(t)}{R(t)} \quad (16.44)$$

and describes the probability that the device survives until $t + dt$ *under the condition* that it already survived until t .

Figure 16.101 presents all these functions within one schematic diagram.

Lifetime Parameters

In practice, a reliability analysis needs to give an answer to several questions related to the lifetime of a device. Depending on the nature of this question, several lifetime parameters may be of interest.

The mean life. The mean life, in the literature referred to as the *mean time to failure* MTTF for non-repairable systems, is the expected value of the reliability function $R(t)$. According to statistics theory, the expected value is calculated as the integral over the density function:

$$\text{MTTF} = E(L) = \int_0^\infty t f(t) dt = \int_0^\infty R(t) dt \quad (16.45)$$

In many textbooks and handbooks, the MTTF is used as the lifetime characteristic to compare the failure behavior of devices. Since the MTTF can be calculated from a given $f(t)$ independent of the nature of the failures, the MTTF is a general expression of the lifetime.

From a practical standpoint, however, it must be stated that the practical derivation of MTTF in many cases is inconvenient for two reasons:

- there might be no closed solution to the integral in (16.45),
- the failures follow a well-defined underlying statistical model such as Weibull (to be explained in the next section), lognormal, exponential, or other. These models use other life characteristics that are easier to calculate and directly associated with the given statistical model. In general, these lifetime characteristics are not identical to the MTTF. For instance, the Weibull model uses the *characteristic life*, which will also be derived in the next section.

B_γ -life, $\gamma\%$ -percentile. The B_γ -life is the lifetime where a failure probability of $\gamma\%$, the so-called $\gamma\%$ -percentile, is reached. In simple words, at the lifetime B_{10} , 10% of all devices will have failed. The exact definition reads:

$$F(B_\gamma) = \gamma\% \quad \text{or} \quad B_\gamma = F^{-1}(\gamma\%) \quad (16.46)$$

The B_{10} -life (or lower percentiles such as B_1 , $B_{0.1}$, $B_{0.001}$) has a huge importance in reliability engineering, because they allow comparison of the reliability of a device in reliability regions that are important for most products ($F < 10\%$; $R > 90\%$). This issue will be made precise by means of an example in the Sect. 16.7.2 on Weibull analysis.

There are several other lifetime parameters known, such as the *median life* or the *modal life*. These parameters, however, are more or less of theoretical nature and are rarely used in daily practice. For the sake of completeness, and since they sometimes occur in the literature, we give their definitions here.

The median life. The median life L_{Median} is defined as the lifetime where a failure probability of 50% is reached. The mathematical expression reads

$$F(L_{\text{Median}}) = \int_0^{L_{\text{Median}}} f(t) dt = 50\% . \quad (16.47)$$

With (16.46), L_{Median} belongs to the 50%-percentile B_{50} .

The modal life. The modal life L_{Modal} is the lifetime where the most failures occur. This is identical to the

maximum value of the density function $f(t)$ and is defined by

$$df(L_{\text{Modal}})/dt = 0 \quad (16.48)$$

Stress–Strength Interference

The time dependence of the failure probability originates from both the interaction of the statistical scatter of the applied *stress* and the statistical scatter of material properties determining the macroscopic *strength* (Sect. 7.3) of the component under load [16.98]. In this context, *stress* means any physical process acting on the device, for example mechanical stress, voltage, temperature or humidity. *Strength*, on the other hand, means the ability of the device to withstand the stress. Both quantities have the same physical dimension and are here – in accordance to me-

chanical stress and strength – generally described by σ .

- The *strength* σ_S ($S = \text{strength}$) scatters due to scatters of manufacturing quality and due to scatters of the material properties.
- The *stress* σ_L ($L = \text{load}$) scatters due to different users and due to varying use conditions.

Failure takes place as soon as the stress exceeds the strength. The *failure probability* is therefore dependent on the probability that a randomly chosen stress condition exceeds the strength of a randomly chosen device. This probability is dependent on the overlap of the distribution functions, as illustrated in Fig. 16.102a showing the so-called *static stress–strength interference*.

The area under both curves is calculated as [16.99]:

$$F = P(\sigma_L > \sigma_S) = \int_{-\infty}^{\infty} f_L(\sigma) \left[\int_{-\infty}^{\sigma} f_S(\sigma) d\sigma \right] d\sigma \quad (16.49)$$

where f_L and f_S are the density functions of the distributions of the stress and the strength, respectively.

The same argumentation holds for the *dynamic interference model* (Fig. 16.102b). Here, the failure probability is zero at $t = 0$ since the overlap of both distribution functions is negligible. Then, during the time of operation, microstructural changes within the material reduce the mean value of the strength and so F increases significantly with increasing operation time.

The interference model has the great advantage that it describes the probabilistic origin of time-dependent failure probabilities in a plausible manner. However, it is not suitable for determining the reliability of a device quantitatively, because the application of (16.49) requires the exact knowledge of the distribution functions of stress and strength near their tails. This demand is usually improperly fulfilled in practice.

16.7.2 Weibull analysis

One of the main topics in reliability engineering is to analyze a given set of failure data. These data may originate from a reliability test performed in the lab or from a warranty analysis of field data. The Weibull analysis makes use of the famous and widely used Weibull distribution, and has become the major tool in modern industry. Many publications document the importance of this tool [16.89]. It should be mentioned that there exist other distributions which are also important. Especially in the

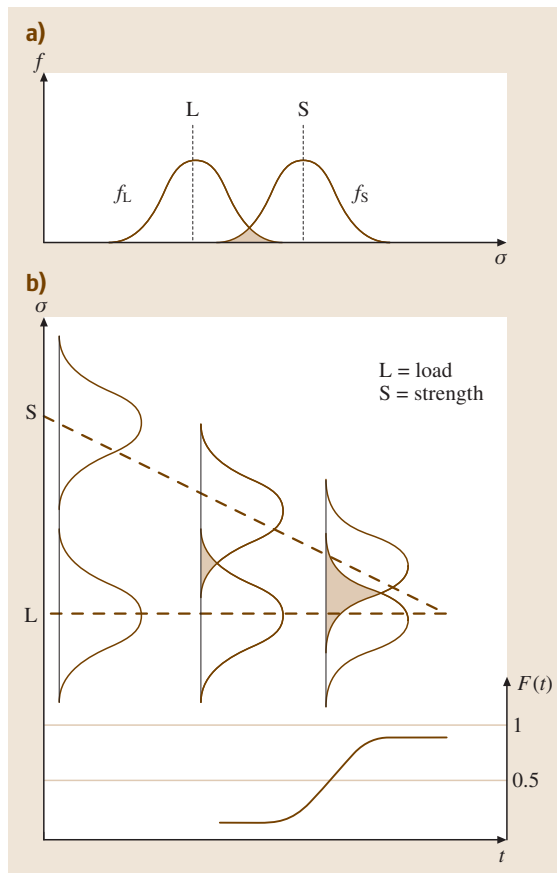

Fig. 16.102 (a) Static, and (b) dynamic interference model. The failure probability of a device depends on the area under the distribution densities for stress and strength

case of degradation and fatigue strength phenomena, the lognormal distribution is important [16.100, 101]. In [16.102], the author compared the pros and cons of both distributions for the analysis of wear-out (region 3 of the bathtub curve) failure data.

The Weibull Distribution Function

The Weibull distribution is a multipurpose distribution, which by varying the independent parameters, can be adjusted to almost every failure behavior. The failure function $F(t)$ and the failure density function $f(t)$ of the Weibull distribution read as follows [16.89, 103]:

$$F(t) = 1 - e^{-\left(\frac{t}{\eta}\right)^\beta}, \quad (16.50)$$

$$f(t) = \frac{\beta}{\eta} \left(\frac{t}{\eta}\right)^{\beta-1} e^{-\left(\frac{t}{\eta}\right)^\beta}. \quad (16.51)$$

The reliability function $R(t) = 1 - F(t)$ is given by

$$R(t) = e^{-\left(\frac{t}{\eta}\right)^\beta}. \quad (16.52)$$

The Weibull distribution has the following parameters:

- The shape parameter β (also called the Weibull parameter or slope),
- The characteristic life η .

(An additional parameter, the failure free time, will be introduced later in this section.)

The most important parameter is the shape parameter β , since the distribution can be adapted to the given failure phenomenon by varying β . In Fig. 16.103, the density function and the failure function are plotted for constant η and different β , showing that the characteristics are different for different β .

A very important result is that the value of the shape parameter corresponds to the three regions of the bathtub curves as follows (Fig. 16.100):

$\beta < 1$ corresponds to region 1 of the bathtub curve, since $\beta < 1$ results in a decreasing function in the failure rate plot.

$\beta = 1$ corresponds to region 2 of the bathtub curve, since $\beta = 1$ results in a horizontal line in the failure rate plot. For $\beta = 1$, the Weibull distribution becomes an *exponential distribution function*, which is an important special case. The fact that the failure probability is independent of time is represented in the term *memory loss*. As an example, electronic devices often show such a time-independent failure behavior.

$\beta > 1$ corresponds to region 3 of the bathtub curve, since $\beta > 1$ results in an increasing failure rate function.

For $\beta > 1$, the density function exhibits a maximum value, and for $\beta \approx 3$ it is similar to the Gaussian bell-shaped curve (compare Fig. 16.103).

Weibull Analysis Procedure

In the previous section, we outlined the importance of determining the Weibull parameters in order to categorize the failure phenomena. In this section, it will be described how the parameters η and β are determined from a given set of failure data.

Two common methods for Weibull analysis are known. The first one is the so-called median rank regression (MRR), the other one is maximum-likelihood estimation (MLE).

Fig. 16.103 Weibull density function (a) and failure probability (b) for different β and $\eta = 3$. From the density function plot, we see that a bell-shaped curve is only reached for $\beta > 1$. In the case $\beta < 1$, no local extrema are present. From the probability plot, we see the peculiarity that the characteristic life is independent of β

Table 16.10 Measured lifetime data L_i and median failure probabilities $F_{50\%}(L_i)$, as well as the $F_{5\%}$ and $F_{95\%}$ -percentiles needed for the confidence bound, which is introduced in Step 7

Sample # i	Lifetime L_i	$F_{50\%}(L_i)$ =((16.53) or Appendix)	$F_{95\%}$ (Appendix)	$F_{5\%}$ (Appendix)
1	L_1	8.3	31.2	0.6
2	L_2	20.1	47.1	4.6
3	L_3	32.1	59.9	11.1
4	L_4	44	71.7	19.3
5	L_5	55.9	80.7	28.9
6	L_6	67.9	88.9	40
7	L_7	79.8	95.4	52.9
8	L_8	91.7	99.4	68.8

The latter is a numerical method that needs intensive computation, while the first one is more instructive and often used. Therefore, we will restrict the discussion to the MRR here.

The median rank Weibull analysis MRR contains the following steps.

Step 1: collecting lifetime data. n samples are tested, yielding n lifetimes L_1, L_2, \dots, L_n . The lifetimes L_i of the specimen are arranged in ascending order in a table (Table 16.10).

Step 2: median rank calculation. This is the procedure that is characteristic of this method. The basic idea is that each sample is assigned a failure probability $F(L_i)$. This is necessary, since from the experiment we only know the lifetime data L_i but not the corresponding failure probabilities. This probability cannot be determined experimentally, but must be found from theoretical considerations. The understanding of its derivation is not essential for proceeding; however, the interested reader may find it in [16.88]. At this point, one hint is helpful: The term *median* must not be mixed up with the *median life* introduced in the first section; since here not the median of the life distribution is meant. Instead, the failure probability $F(L_i)$ itself follows a statistical distribution known as the binomial distribution. Since the binomial distribution cannot be rearranged such that $F(L_i)$ can be calculate directly, some approximation must be introduced.

In the literature, a vast amount of different methods for approximating the failure probability is known, but the formula for median ranks introduced by *Bernard* [16.87, 88] has turned out to be the most often used. This formula reads

$$F_{50\%}(L_i) \approx \frac{i - 0.3}{n + 0.4}.$$

(16.53)

The index 50% indicates that the median of the failure probability distribution is meant.

Fig. 16.104 Schematic drawing of a Weibull plot. The *square data points* show the measured lifetimes and the corresponding median ranks $F(L_i)$. The *darker circles* represent the 5% and 95% confidence bounds. The Weibull parameter β is estimated from the slope of the weibull line, the characteristic life is estimated from the intersection of the regression Weibull line with the 63.2% line. Additionally, we find the B_{10} life as the lifetime where $F = 10\%$ is reached

Instead of calculating the values using (16.53), they can also be looked up in tables for median ranks [16.87]. An excerpt of such a table is given in the appendix to this chapter for different sample sizes up to $n = 12$.

Step 3: probability plotting. The probabilities of failure are plotted against the lifetime or number of survived cycles on so-called Weibull paper, what can be seen in Fig. 16.104 for the example $n = 8$. Weibull paper is commercially available, or can be constructed by the method described in [16.102]. If the data points obey the Weibull distribution, then they yield a straight line with little scatter of the data points. The straight line is also plotted on the Weibull paper, and will serve to determine the parameters β and η .

Step 4: linear regression. Equation (16.50) is rearranged as follows by taking the double logarithm of both sides of the equation:

$$\begin{aligned} F(L_i) &= 1 - \exp(L_i/\eta)^\beta \Rightarrow 1 - F(L_i) = \exp(L_i/\eta)^\beta \\ &\Rightarrow \ln\{-\ln[1 - F(L_i)]\} = \beta \ln(L_i) - \beta \ln \eta. \end{aligned} \quad (16.54)$$

With the general linear equation $y = Ax + B$ we can now identify

$$y_i = \ln\{-\ln[1 - F(L_i)]\}; \quad x_i = \ln L_i \quad (16.55)$$

and

$$A = \beta; \quad B = -\beta \ln \eta. \quad (16.56)$$

These equations allow the determination of the goodness of fit and the Weibull parameters β and η , which is described in the following.

Step 5: estimation of the goodness of fit: the correlation coefficient (CC). In the case of a Weibull-distributed basic population, a straight line is produced in the Weibull plot. If the data do not obey a linear behavior, the basic population may not be Weibull distributed. As a measure for the linearity of the data, the correlation coefficient (CC), which is well known from standard statistic tools [16.104, 105], is commonly used. The CC is defined as

$$CC = \frac{\sigma_{xy}}{\sigma_x \sigma_y}, \quad (16.57)$$

where σ_{xy} is the covariance and σ_x and σ_y are the standard deviations of the x_i and y_i , respectively.

By calculating x_i and y_i from the values $F(L_i)$ and L_i in Table 16.10 by means of (16.55), we can apply the

CC to the obtained data pairs. CC takes a value between 0 and 1, and the higher CC, the better is the fit.

Two problems arise when applying CC:

- It is left to the judgement of the user to decide what correlation coefficient means a good or a poor fit. A possible approach to overcome this problem is shown in [16.106].
- The regression of the y -values versus the x -values is somewhat unsatisfactory and overestimates the goodness of the fit because the y -values are predetermined by the rank calculation. In contrast, the measured lifetime values are in fact the values that show scatter. Therefore, Abernethy [16.89] recommends doing the regression of x versus y .

In standard mathematical calculation software, linear regression is a standard tool and the calculation of the correlation coefficient CC – sometimes also denoted by the symbol R – is also standard.

It should be mentioned that there are some other, more sophisticated and more accurate tests available such as the Chi-squared test and the tests by Kolmogorov–Smirnov and Mann–Scheuer–Fertig (see references in [16.102]), however, for daily practical application, CC appears to be the easiest and quickest method.

Step 6: determination of η and β . From the linear regression performed in Step 4, η and β can easily be calculated by applying (16.56):

$$\beta = A; \quad \eta = \exp(-B/\beta). \quad (16.58)$$

The characteristic life can also be directly determined from the Weibull plot in Fig. 16.104. If we introduce $t = \eta$ in (16.50), we obtain $F(\eta) = 63.2\%$.

Therefore, the Weibull line crosses the $F = 63.2\%$ line at $t = \eta$. This is indicated in Fig. 16.104 by an arrow.

The slope β can be determined graphically only if a special, commercially available Weibull paper is used for the graphical analysis [16.93]. In addition to the paper used in Fig. 16.104, this paper has a second y -axis where β can be found by a method described in [16.88] and [16.93].

Step 7: introducing the confidence interval α . The confidence interval α is a very important parameter. The confidence bound is a demand given from the user of the Weibull analysis, representing his demands on the trustworthiness of the analysis.

In many practical cases, the confidence interval of $\alpha = 90\%$ is demanded. If $\alpha = 90\%$ holds, then the up-

per and lower confidence bounds are the 95% and 5% percentiles. Similar to the 50% percentiles, these values can be found in the tables given in Step 3. These values are added to the two columns $F_{5\%}$ and $F_{95\%}$ in the table. These values can then also be plotted in the Weibull graph (Fig. 16.104).

The meaning of the confidence bounds is as follows. To require a confidence level of, e.g., $\alpha = 90\%$, means that the probability that the true Weibull regression line lies within the confidence bounds is 90%. In Fig. 16.104 this demand can be found by noting that any Weibull line that is compatible with the confidence bounds is a possible solution to our problem.

To avoid frequent misunderstanding, it should be mentioned that the width of the confidence bound does *not* depend on the *scatter* of the measured lifetime data. The width of the confidence bound solely depends on the number of specimen tested. The larger n , the smaller the confidence bound becomes. This is logical, since the significance of the statistical argumentation becomes higher with increasing sample size. For $n > 50$, the influence of α in many cases can be neglected [16.88].

Step 8: estimation of the confidence bounds of β and η . Since the confidence bounds determined in Step 7 lead to more than one possible Weibull line, we also find a range of values for β and η which we need to determine. To do so, one possibility is to determine the Weibull line with maximum and minimum slope still compatible with the confidence bounds (compare Fig. 16.104) and then determine β_{\max} , β_{\min} , η_{\max} , η_{\min} directly. Another possible method is to directly calculate these parameters as described in [16.88, 105].

Three-parameter Weibull Analysis

There is an additional form of the Weibull distribution containing a third parameter, the so-called failure-free time t_0 . In the three-parameter form, the Weibull failure function and density function read

$$F(t) = 1 - e^{-\left(\frac{t-t_0}{\eta-t_0}\right)^\beta}, \quad (16.59)$$

$$f(t) = \frac{\beta}{\eta-t_0} \left(\frac{t-t_0}{\eta-t_0}\right)^{\beta-1} e^{-\left(\frac{t-t_0}{\eta-t_0}\right)^\beta}. \quad (16.60)$$

The failure-free time t_0 is a parameter that, in the case $\beta > 1$, serves to properly describe an *incubation period*, often observed in degradation experiments. Before t_0 no failure is observed. This behavior cannot be described with the same accuracy using the two-parameter Weibull distribution. This becomes necessary if the reliability of complex systems must be calculated from the reliabil-

ity functions of the single components the system is made of. In [16.107] four criterion are given when the introduction of t_0 is indicated:

- you must have 21 or more failures; some experts say 100,
- you must be able to explain why the physics of failure support a guaranteed failure-free zone,
- the two-parameter plot should show curvature,
- and the distribution analysis must favor the three-parameter form. This means that the correlation coefficient becomes larger when trying several $t_0 \neq 0$.

The failure-free time can be estimated by means of graphical methods. A simple and commonly used method is introduced by *Dubey* [16.108] (Fig. 16.105).

After plotting the data to the Weibull graph, the ordinate is distributed into two equidistant sections of length ΔF . Then, the corresponding lifetimes t_1 , t_2 and t_3 are determined as described in the figure. Based on these values, t_0 can be determined by means of the Dubey formula (16.61)

$$t_0 = t_2 - \frac{(t_3 - t_2)(t_2 - t_1)}{(t_3 - t_2) - (t_2 - t_1)}. \quad (16.61)$$

Note that in case of using a three-parameter Weibull distribution ($t_0 \neq 0$) the parameters β and η will also differ from the values obtained from a two-parameter Weibull distribution (if $t_0 = 0$ is assumed). In this case, an appropriate method is to transform the lifetime by means of the relation

$$t' = t - t_0 \quad (16.62)$$

and then plot the data to the Weibull net; t_0 must be either chosen iteratively by trial and error until the best straight line fitting the data is found. As a starting value, the Dubey formula may be used.

From this procedure, the new values for β and η including the 5% and 95% confidence levels may be calculated according to the above described procedure. Note that a confidence interval for the failure-free time t_0 cannot be determined by these methods.

So far, the theoretical justification and the method to determine the failure-free time was discussed. In Sect. 16.7.5, where system reliability issues are discussed, the relevance of the failure-free time t_0 to practical problems will be illustrated in more detail.

Example: comparison of different materials. The following simple example elucidates the meaning of the

Weibull parameters such as β , η and B_{10} life. In daily practice, it is important to judge from the parameters only without having the Weibull plots visualized.

For the construction of a safety-critical component subject to variable mechanical amplitude loading, two different materials A and B were tested in the lab, and the failure data were analyzed by Weibull analysis. The result is shown in Fig. 16.106. How can we judge from the Weibull parameters which material is better suited to this application?

Judging from the characteristic life values, material A must be considered to be superior to material B because $\eta_A > \eta_B$. However, material A also exhibits a broader scatter, which can be seen from the shallower Weibull line, resulting in a lower β value. As we see from the figure, this results in a lower B_{10} life of material A . Since we know that the component is *safety critical*, low failure probabilities are of interest. Therefore, we must compare the materials in the region of small percentiles like B_{10} or even smaller. Judged from the B_{10} lives, material B is superior to material A .

This example teaches the following:

- In most practical cases, B_{10} life or smaller percentiles are used to compare failure data;
- Broader scatter (smaller β) usually results in lower B_{10} and is often a more serious drawback than lower characteristic life.

16.7.3 Reliability Test Strategies

So far, we have assumed that the failure data are already available and that all tested items have failed within the observation period. In this section, we will introduce several methodologies for how the data are created either in practical reliability tests in the lab or from warranty data.

In practice we always have the constraint that the sample size as well as the testing time is limited, or that the data set obtained from a warranty analysis is incomplete.

Censored Tests

A censored test is a test where either not all items fail or where not all failures are taken into account for analysis. Censoring becomes necessary for the following reasons:

- Some failure modes that occur are different from those anticipated and such units are withdrawn from the test;
- We need to make an analysis of the available results before test completion (time constraints);

Fig. 16.105 Estimation of the failure-free time t_0 with the method by Dubey

- A warranty analysis is to be made of all units in the field (non-failed and failed units). The non-failed units are considered to be suspended items.

Different types of censoring may occur in practice. Here we will restrict discussion to the most important. Other types of data are presented in [16.109].

Figure 16.107 shows the following cases:

- a) Some items fail within the observation time (\diamond), some survive (\rightarrow).
- b) Some items fail (\diamond), and some are removed from the test (\bullet). We call these suspended items. A possible reason for suspension is that these items failed due to another failure mechanism than the one of interest.
- c) No item fails. This special case will be dealt with below..

In the following, we discuss how the data are analyzed in the given cases.

Case (a): some items fail within the observation time, some survive. In this case, the Weibull analysis is per-

Fig. 16.106 Weibull analysis performed for samples made of two different materials *A* and *B* in order to decide which material is better suited to the given purpose. Judging from the characteristic lives, we find that $\eta_A > \eta_B$, leading to the assumption that material *A* is better. However, by comparing the B_{10} -lives, we find the opposite is true. In practical applications the region of low failure probabilities is of interest and therefore the comparison of B_{10} life is usually the stronger argument. In our case, material *B* must be considered superior to material *A*

formed as described for complete tests in Sect. 16.7.2. Care must be taken that the n used here is the number of all items, that means, the failures and the survivors (in our example in Fig. 16.107, this means $n = 6$ and not $n = 3$).

This test has special practical meaning since field data are often of this type: a batch of devices has been delivered to customers. After a certain time, some failures are documented, and the rest of the items is still in function. Those data can be analyzed as described.

Case (b): some items fail, and some are removed from the test. The Weibull analysis of those data requires a technique that differs slightly from that presented above. In particular, the rank positions i must be adjusted because assigning the usual positions $i = 1 - n$ to each item, regardless of whether it is neglected in the

Fig. 16.107 Different events during a reliability tests during the testing period: (a) Some items fail (\diamond), some survive (\rightarrow). (b) Some items fail (\diamond), others are suspended from the test (\bullet). (c) All items pass the test (see Sect. 16.7.3)

analysis or not, is not appropriate. Instead, the procedure is the following [16.88]:

- Step 1 Collect data as usual, and assign it a capital F (= failed) or S (= suspended), and list the data in a table in ascending order (Table 16.11)
- Step 2 Calculate the rank positions for the failed items, and add them to the table. Suspended data are neglected. The new rank positions for the failed items are calculated using the following rule [16.110, 111]. This is necessary, because a suspended item causes an uncertainty at which rank position the suspended and the following item are located. We therefore need to calculate a mean rank

Item # j	Lifetime L_j	Event F/S	Increment (4.14) y_i	Rank position (4.13) i	Median rank (4.1) F_i
1	L_1	F	1	1	0.109
2	L_2	F	1	2	0.263
3	L_3	S	1.25	-	-
4	L_4	F	1.25	3.25	0.461
5	L_5	S	1.875	-	-
$n = 6$	L_6	F	1.875	5.125	0.754

Table 16.11 Calculation of the adjusted rank positions if censored items are present (for this example, $n = 6$). By the arrows it is shown how the rank positions of failures following a suspension are calculated

position, which is no longer necessarily a natural number.

The rank of the j -th item i_j is calculated as the sum of the previous rank i_{j-1} and an increment y :

$$i_j = i_{j-1} + y_j \quad (16.63)$$

with the increment y_j being

$$y_j = \frac{n+1-i_{j-1}}{1+n_{>j}} \quad (16.64)$$

with n being the overall (not only the failed) sample size, and $n_{>j}$ being the remaining number of items with index being greater than the actual j .

- Step 3 Calculate the median ranks according to (16.64) and add them to the table.
- Step 4 Perform a Weibull analysis as described in Sect. 16.7.2.

Case (c) all items still in function – Success Run

The success run has become one of the major tools in reliability engineering. This is because it combines the number of test specimen and the testing time. Additionally, the meaning of the confidence interval α for reliability estimation becomes most obvious in this kind of test.

The typical task is the following. We have to guarantee a minimum reliability $R_{i,\min}$ for a device at a given demanded lifetime L_{dem} . To do so, we have a limited number of specimens (e.g. $n = 3$) which we test for a time t_{test} .

If we assume the basic population to be Weibull distributed, then the formula for this test reads as follows:

$$R_{i,\min}(L_{\text{dem}}) = (1 - \alpha) \left[\frac{1}{n \left(\frac{t_{\text{test}}}{L_{\text{dem}}} \right)^\beta} \right] \quad (16.65)$$

For the derivation of this expression see [16.90]. Its meaning is that, if n components survive a reliability test

of duration $t_{\text{test}} > L_{\text{dem}}$, then we can guarantee a minimum reliability $R_{i,\min}$ of the device at the demanded lifetime L_{dem} at a confidence level of α .

In practice, it is often the case that a confidence level and the least guaranteed reliability at the demanded lifetime are given. From (16.63), we can calculate the necessary number of specimen and the corresponding testing time which is necessary to *confirm that the given reliability can be guaranteed*. This important result is seen in Fig. 16.108 where the least guaranteed reliability is plotted as a function of the so-called *lifetime ratio* $t_{\text{test}}/L_{\text{dem}}$ and the sample number.

The main drawback of the test is that the *Weibull parameter β must be known in advance*. It cannot be determined using this method. It must be known from experience, similar studies or from tests under simplified conditions.

Sudden Death Test

The sudden death test is widely used to avoid time-consuming experiments with large numbers of samples. A necessary precondition is that the test facilities allow the testing of all items of a sample simultaneously. The test is therefore preferred if a huge machine park is available but the test time is restricted. Recently, some effort has been undertaken to adapt the testing technique to the constraints of small test place number [16.112].

The basic idea of the sudden death test can be described as follows.

- Step 1 Take a test sample ($n > 20$).
- Step 2 *Subdivide* the test sample into m smaller samples of size k (for example: $n = 20$, $m = 4$, $k = 5$); see Fig. 16.109.
- Step 3 Perform lifetime tests on each item of each sample simultaneously.
- Step 4 If the first item out of each of the samples fails, the test is truncated for all items within this sample and the lifetime is written in a table (Fig. 16.109).

Fig. 16.108 Guaranteed least reliability $R_{i,\min}$ of a device tested in a success run as a function of the lifetime ratio and of the number of samples n . The figure indicates that with smaller sample number the testing time must increase in order to maintain the same reliability level. It is helpful in practice to know the rule of thumb that a reliability of 90% can be guaranteed when three test specimen survive 2–2.5× the demanded lifetime

- Step 5 This procedure (Steps 3 and 4) is executed for each of the m samples.
- Step 6 Afterwards, the m lifetime values obtained from each of the m samples is analyzed accord-

ing to the standard Weibull analysis introduced in Sect. 16.7.2. The median ranks are calculated by replacing the total number of items n by the number of samples m :

$$F(t_i) = (i - 0.3)/(m + 0.4); \quad i = 1 \dots m \tag{16.66}$$

- (See the table in Fig. 16.109).
- Step 7 Plot the data to a Weibull paper (see Fig. 16.110) in order to obtain a Weibull line for the first failures.
- Step 8 Construct the Weibull line of the whole sample (size n) by the following procedure described in Fig. 16.110.

The previous steps were introduced in that detail in order to provide an understanding to the underlying principles. Modern reliability software is able to determine the weibull line and weibull parameters much more comfortable from the failure data directly.

Degradation Tests
Degradation testing is a rather new method that has recently attracted many researchers [16.113, 114]. This kind of testing is possible if there is a parameter that can be measured during the operating time of the device and which indicates the degradation process. The plotting of the parameter versus the lifetime describes the so-called degradation path. As an example, the abrasion of a car tyre can be measured during a test and plotted versus the driven kilometers. From the data points we can extrapolate to longer lifetimes and estimate the time when the abrasion reaches a critical value. The extrapolation data from n devices tested result in n lifetimes that can be analyzed with Weibull as described before. The benefit is that the test can be truncated at a time much smaller than the expected lifetime. Some research is ongoing on how long a device must be tested until the extrapolation becomes good enough [16.115].

Example. A ferroelectric memory chip can distinguish between logic 1 and 0 if the polarization states $P(N)$ after N polarization reversals (cycles) do not fall beyond 80% of the initial value P_0 . $P(N)/P_0 = 80\%$ is therefore the failure criterion of the device. Let us assume a cycling test with four samples was carried out, where $P(N)$ is measured after a discrete number of cycles. In order to save time, the measurements are truncated after 10^8 cycles, although the failure criterion is not reached. From the literature, it is known that $P(N)$ is related to N by $P(N)/P_0 = \exp(-N/N^*) + C$, where N^* and

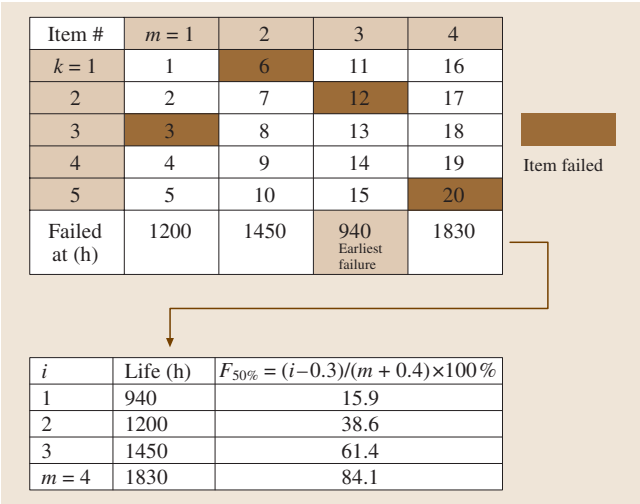

Fig. 16.109 Test scheme for a sudden-death test. The samples are subdivided into m samples of size k . The first failure in each sample truncates the test for the whole sample. The first failures are listed in ascending order in a table, and the failure probabilities are calculated

C are constants [16.116]. This model can be fitted to the data points and extrapolated to higher cycle numbers than 10^8 in order to find the lifetimes L_i where the failure criterion is fulfilled (Fig. 16.111). With L_i given, a Weibull analysis may be performed as already described in Sect. 16.7.2.

16.7.4 Accelerated Lifetime Testing

Accelerated lifetime testing (ALT) is a frequently used method for reducing test time. Many publications deal with the special problems arising from this procedure [16.117].

The basic idea of an accelerated lifetime test is to apply higher stresses to the device than it experiences under real service conditions in order to provoke a reasonable number of failures within a reasonable time. Here, stress means any physical process that influences the lifetime of the device; it may be mechanical stress, electrical voltage, current, temperature, humidity and so on. New questions arise from this procedure:

- By what factor do the higher stresses accelerate the degradation process? How are higher stresses and shortened lifetime physically related?
- how far do higher stresses influence the failure mode? Will higher stresses produce failure modes that would not have occurred under normal conditions?

In ALT it must be assured that the observed failures at higher loading originate from the same failure mechanism that would be expected under use conditions in practise. A proof for this is the following rule:

- Failures that origin from the same failure mechanism show the same shape parameter in the Weibull net, and therefore are shifted parallel to each other. They only differ in their lifetime, which is shorter for higher stresses (Fig. 16.112);
- Only the *lifetime* L of the device, which may be expressed by any parameter related to the distribution (MTTF, η , B_{10} , ...) is affected by the acceleration.

Analysis Procedure

The acceleration is measured by the ratio by which the lifetime is shortened by applying a higher stress. This number is called the acceleration factor.

Let us assume that we can calculate the time to failure L from a model equation $L(S)$, where S is the stress level

Fig. 16.110 Data analysis for a sudden-death test. At first the Weibull line of the first failures of each sample is constructed (1). Then, the earliest failure line is sketched as a *horizontal* line through the earliest failure data point of the overall experiment (2). The 50% point of the Weibull line is then projected down onto the earliest-failure line [dashed arrow, (3)]. The intersection point with the earliest-failure line is the point of the first failure of the overall sample. The complete Weibull line of the complete sample is constructed via parallel translation of the Weibull line [small arrow, (4)]

Fig. 16.111 Degradation test. Four devices were tested and the data were extrapolated to the critical failure value of 80% remaining polarization. The lifetime data can now be analyzed by means of the Weibull analysis

Fig. 16.112 The Weibull line obtained from measurements at higher stress is transferred to the Weibull line that would have been achieved from experiments at use stresses by multiplying the lifetime (here the characteristic life) by an acceleration factor κ . The Weibull parameter β is assumed to remain constant if the failure mode is the same at both stress levels

applied to the item. $L(S)$ is the functional description of the dependency of the lifetime on the given physical quantity.

Now let us assume that we test the device at two different stress levels with $S_{acc} > S_{use}$. (where “acc” stands for acceleration, and “use” means the normal use condition of the device) Then we define the acceleration factor κ as follows:

$$\kappa = \frac{L(S_{use})}{L(S_{acc})} \quad (16.67)$$

The basic rule for how an accelerated reliability test is to be performed can be summarized as follows (Fig. 16.112):

- Step 1 Collect failure data at higher stresses S_{acc} .
- Step 2 Perform a Weibull analysis as described in Sect. 16.7.2.
- Step 3 Calculate the lifetime at normal use conditions by applying a suitable physical model describing

the acceleration. Those acceleration models are described below.

Acceleration Models

Using acceleration models, the mechanistic origin of the acceleration is described. For any accelerated lifetime testing, this is a crucial point at which the validity of the whole test is decided. Two basic problems arise at this point:

- In most cases, the physical model must be known from pre-knowledge on the physical origin of the observed failure. It is not sufficient to adjust model equations to the given failure data;
- Physical models contain parameters (such as the activation energy, for instance; see below) that have to be estimated or known from the literature. In a few cases only can these parameters be calculated from the failure data directly.

In the following Table 16.12, some of the common acceleration test models are discussed in order to show the principle. Here, we restrict the discussion to the Arrhenius, the inverse power law (IPL) and the Coffin–Manson model. These and further models can be found in [16.118].

Advanced Acceleration Techniques

In recent years, some acceleration methods have arisen that differ markedly from the scheme above sketched. In particular, the highly accelerated lifetime testing (HALT) and highly accelerated stress screening (HASS) methods have gained increasing attraction in the near past.

The goal of these methods is to find weaknesses of a product at an early stage of development, e.g. for a prototype, rather than predicting the lifetime of the device.

We will mention these methods in brief here [16.118], and recommend the papers published in [16.119] for further information on this topic.

Step stress profile testing. Using a step stress profile, test specimens are first subjected to a given level of stress for a preset period of time, and are then subjected to a higher level of stress for a subsequent period of time. The process continues at ever-increasing levels of stress, until either all the specimens fail, or the time period at the maximum stress level ends. This approach precipitates failures more rapidly for analysis. However, with this technique it is very difficult to model the acceleration properly and, hence, to predict the item life under normal usage quantitatively.

Table 16.12 Commonly used acceleration models, with their applications, model equations and acceleration factors

Model	Application	Model equation	Acceleration factor
Arrhenius	Failure mechanisms that depend on chemical reactions, diffusion processes or migration processes. It covers many of the non-mechanical (or non-material fatigue) failure modes that cause electronic equipment failure.	$L(T) = A \exp\left(\frac{\Delta H}{kT}\right)$ T : temperature (K) A : constant k : Boltzmann constant ΔH : activation energy of the process (must be known in advance)	$\kappa_T = \frac{L(T_{\text{use}})}{L(T_{\text{acc}})} = \exp\left[\frac{\Delta H}{k}\left(\frac{1}{T_{\text{use}}} - \frac{1}{T_{\text{acc}}}\right)\right]$
Inverse power law (IPL)	Stresses which are non-thermal in nature; in most cases the stress is given to be electrical voltage, e.g., Capacitors often follow the IPL relationship	$L(U) = AU^{-b}$ U : driving voltage of the device A : constant b : characteristic exponent	$\kappa_U = \frac{U_{\text{use}}}{U_{\text{acc}}} = \left(\frac{U_{\text{acc}}}{U_{\text{use}}}\right)^b$
Coffin–Manson	Mechanical failure, material fatigue or material deformation, crack growth in solder and other metals due to repeated temperature cycling as equipment is turned on and off.	$\Delta \varepsilon_p N_f^c = A$ $\Delta \varepsilon_p$: plastic strain amplitude (peak–peak) N_f : number of cycles to fail c : cycling exponent (must be known in advance) A : material constant	$\kappa_{\Delta \varepsilon} = \frac{N_f(\Delta \varepsilon_{\text{use}})}{N_f(\Delta \varepsilon_{\text{acc}})} = \left(\frac{\Delta \varepsilon_{\text{acc}}}{\Delta \varepsilon_{\text{use}}}\right)^{\frac{1}{c}}$

HALT (highly accelerated lifetime testing). HALT is a development test, an enhanced form of step stress testing. It is typically used to identify design weaknesses and manufacturing process problems, and to increase the margin of strength of the design.

HASS (highly accelerated stress screening). HASS is a form of accelerated environmental stress screening. It represents the most intense environment of any seen by the product, but is typically of a very limited duration. HASS is designed to go to the fundamental limits of the technology. This is defined as the stress level at which a small increase in stress causes a large increase in the number of failures. An example of such a fundamental limit might be the softening point of plastics.

16.7.5 System Reliability

In many practical cases, a system is manufactured from several single components. The reliability R_S of the whole system depends on the reliability of the single components R_i .

Serial Systems

In practice, it is very often the case that the system's functionality depends on the component functionality

such that a failure of any component means a failure of the whole device. For example, the system reliability of a car depends on the reliability of the tyre as well as on the engine. From this example, we see that the components do not necessarily need to interact with each other directly.

The underlying system structure can be interpreted as a serial system structure, which is shown in Fig. 16.114a.

For a serial system, the reliability of the system at a given time t is calculated to be the product of the reliabilities of the components, what follows from basic rules for probability calculations:

$$R_{S,\text{serial}}(t) = R_1 R_2 \dots R_n = \prod_i R_i(t) \quad (16.68)$$

or, by using $F_S = 1 - R_S$ and $F_i = 1 - R_i$:

$$F_{S,\text{serial}}(t) = 1 - \prod_i [1 - F_i(t)] \quad (16.69)$$

From these relations, we can draw some important conclusions:

- The more components with given reliabilities, the smaller the system reliability becomes;
- In order to maintain a high reliability of the system, the reliability of the components must be improved;

Fig. 16.113 The reliability of a system as a result of the reliabilities of its components, here for the example $n = 3$ and for a serial system. We see that the system reliability is always lower than the reliability of the weakest part. In this example, the system reliability is dominated either by component A or C, depending on the region of the failure probability. Component B, on the other hand, has minor influence since it is more reliable than the others in the whole region

- The system cannot be better than the worst component.

Example. Let a system have a reliability of 0.9 and let it consist of 10 components. If we, for simplicity, assume that all components have the same reliability R_i , then each component must have a reliability of $R_i = 0.9^{1/10} = 0.989$.

If only nine components have $R_i = 0.989$ and the tenth component has $R_{10} = 0.8$, then the system reliability rapidly decreases to $R_S = 0.989^9 \times 0.8 = 0.72$.

If we increase the number of components from 10 to 20, the demand for the component reliability increases from 0.989 to 0.995: $R_i = 0.9^{1/20} = 0.995$.

This example elucidates the sensitivity of the system reliability to the component reliability and illustrates the high demands we have to apply to component reliability.

The reliabilities of the components as well as the system reliability can be visualized in a Weibull plot. In Fig. 16.113 we see this for the case of a three-component system. The thick line represents the Weibull distribution of the whole system as a result of the multiplication rule introduced above.

From this plot, we find further interesting facts:

- The system Weibull line is always located towards lower lifetimes. (This is identical to the above statement that the system has a lower reliability than the components);
- Due to the sensitivity of the system reliability to the component reliability, it makes a significant difference if we use the two- or three-parameter Weibull distribution for the components. If the two-parameter distribution is used although a three-parameter distribution is *justified*, then the failure probability is overestimated. This leads to an over-dimensioning of the device. Especially in mechanical engineering, where the strength of a device is dependent on the material amount, this plays an important role from an economical and ecological point of view [16.120].

Parallel Systems, Redundancy

If the system contains components that are able to fulfil the same functionality as other components, then the system contains redundancy. In the system structure, those components are represented as parallel structures, as shown in Fig. 16.114b.

In contrast to a serial system, additional redundant components increase the reliability. This is also indicated in the system equations for parallel systems where the failure probabilities $F(t)$, rather than the reliabilities, are multiplied:

$$F_{S, \text{parallel}}(t) = F_1 F_2 \dots F_n = \prod_i F_i(t) \quad (16.70)$$

or, expressed in terms of the reliability functions $R_i(t) = 1 - F_i(t)$:

$$\begin{aligned} R_{S, \text{parallel}}(t) &= 1 - [(1 - R_1)(1 - R_2) \dots (1 - R_n)] \\ &= 1 - \prod_i [1 - R_i(t)] \end{aligned} \quad (16.71)$$

Combined Systems

In practice, it is often the case that within a system some components are in series and others are parallel. In this case, the system reliability can be calculated from the rules of Boolean algebra. A simple example will elucidate the principle.

In Fig. 16.114c we see the functional structure of a system. The system reliability calculates as follows:

$$R_S = R_1 R_2 \underbrace{[1 - (1 - R_3)(1 - R_4)]}_{\text{= parallel subsystem}} R_5 \quad (16.72)$$

Actual Problems and Future Trends in Reliability and System Reliability

In the final section of this chapter, we will summarize and discuss actual problems from daily practice with reliability issues.

1. Lack of component failure data. The main problem in daily practice is that we need failure data of the components for the calculation of system reliabilities following the schemes sketched above. Those failure data – as we have outlined in the previous sections – are not sufficiently represented by giving a lifetime of the device. Instead, we need the failure behavior in the form of the Weibull parameters, containing information about the average life *and* the scatter. As already mentioned, these values are not documented in public data bases. Exceptions are failure rates for electronic devices and structural durability data for metallic components [16.100].
2. Increasing complexity of the systems. At present, some trends are observable: (a) systems are tending to become more complex. (b) mechanical and electrical components are simultaneously included in the functionality of systems, for example *X-by-wire* techniques. Such *mechatronic systems* will be one of the future challenges in reliability engineering, which has also been documented by the increasing number of publications in this field over the last years [16.121].
3. New materials. Additional challenges arise from the fact that mechatronic systems often include new materials that serves as actuators or sensors. This class of materials is called *smart materials*. These active materials, which include ferro- and piezo-

electric ceramics [16.122, 123] and shape-memory alloys [16.124], exhibit failures under long-term operation that are not well understood despite intensive work over the last decades. In particular, it is not understood which failures occurs under which service conditions (electrical, mechanical stress, temperature, . . .), and the failure probability functions under those service conditions are not yet known.

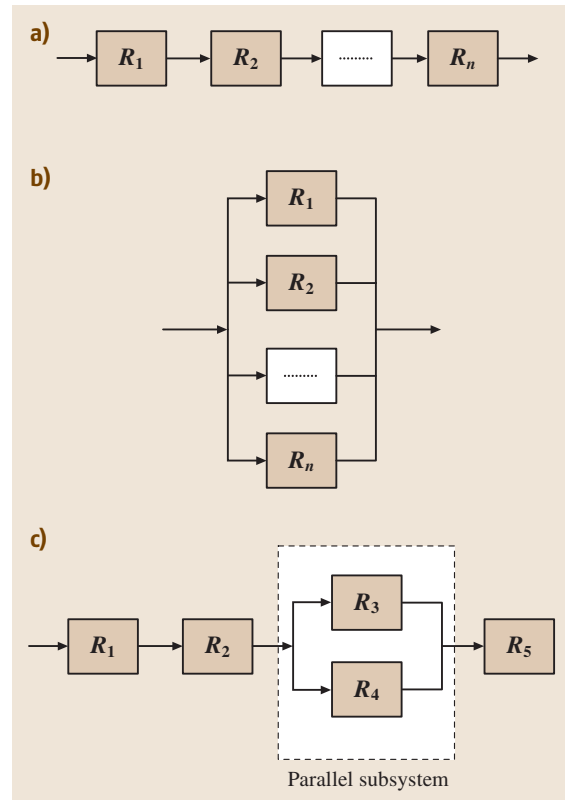

Fig. 16.114 (a) Serial system; (b) Parallel system; (c) Combined system

16.A Appendix

In the following table, the median rank regression for the 5%, 59% and 95% percentiles of the failure probability F [in %] are listed for sample sizes from $n = 3$ up to

$n = 12$. The values are of interest for the Weibull analysis introduced in Sect. 16.7.2.

Molecular Dynamics

This chapter gives an overview of the molecular dynamics (MD) simulation method. In the first section, the basics techniques of MD will be introduced so that the reader is able to start actual calculations. In the following three sections, several applications of MD simulation, some adapted for actual materials and others concerned with idealized model systems, will be presented. In the second section, a simulation study of diffusionless transformations such as the martensitic transformation and solid-state amorphization is presented. Analysis of amorphous and crystalline structures is described in Chap. 5 in this Handbook. MD calculations of the processes involved in the preparation of amorphous alloys by rapid solidification as well as annealing processes in these alloys are discussed in the third section. In the last section, the investigation of atomic diffusion processes in liquid and solid (crystalline and amorphous) phases by MD simulation is explored. Readers may also refer to Chap. 7 concerning atomic diffusion processes in materials.

17.1 Basic Idea of Molecular Dynamics

In this section, the basic formalism of MD simulation will be introduced, and some useful methods invented for MD calculations will then be presented.

17.1.1 Time Evolution of the Equations of Motion

The essential task in MD simulation is to solve the Newtonian equation of motion numerically. Hence, techniques for numerical solution of differential equations will be explained in this section. The main topics are numerical recipes used for this purpose such as the Verlet and the Gear methods.

The basic idea of molecular dynamics is simple: to follow the motion of all atoms in the system by solving

the Newtonian equations of motion:

$$d^2\mathbf{r}_i(t)/dt^2 = \mathbf{F}_i(t)/m_i, \quad i = 1, 2, 3, \dots, N, \quad (17.1)$$

or

$$d^2r_{i\alpha}(t)/dt^2 = -\frac{1}{m_i} \partial\phi/\partial r_{i\alpha}(t), \quad \alpha = 1, 2, 3 \quad (17.2)$$

if the Lagrangian of the system has the following form:

$$L_0 = \frac{1}{2} \sum_i m_i \mathbf{v}_i^2 - \phi(\mathbf{r}_1, \mathbf{r}_2, \dots). \quad (17.3)$$

In the numerical integration of the differential equation (17.1), we should calculate the coordinates of

Fig. 17.1 An illustrative view of the integration steps of a particle trajectory in MD simulation

all particles in the system step by step in time, as depicted in Fig. 17.1. For simplicity, let us use a one-dimensional expression $x(t)$ for the particle coordinates. The basic equation for the purpose of predicting the coordinates $x(t + \Delta t)$ at a future time $t + \Delta t$ is the Taylor expansion:

$$x(t + \Delta t) = x(t) + x'(t)\Delta t + x''(t)(\Delta t)^2/2 + x'''(t)(\Delta t)^3/3! + \dots, \quad (17.4)$$

where the prime denotes the functional derivative. For a practical calculation, we should truncate the Taylor expansion at a finite order of Δt , and also include the information of the Newtonian equation of motion. To achieve the latter, we use the following relation, which holds for the second time derivative of the particle coordinates at any time:

$$x''(t) = F(t)/m. \quad (17.5)$$

Based on this idea, a large number of algorithms have been suggested. We shall explore some of the popular algorithms together with their merits and drawbacks.

Verlet Method

The first example of the popular algorithms is the Verlet method [17.1], which can be derived as follows. Let us write the Taylor series of a forward time step and a backward time step up to third order:

$$x(t + \Delta t) = x(t) + x'(t)\Delta t + x''(t)(\Delta t)^2/2 + x'''(t)(\Delta t)^3/3! + O[(\Delta t)^4], \quad (17.6)$$

$$x(t - \Delta t) = x(t) - x'(t)\Delta t + x''(t)(\Delta t)^2/2 - x'''(t)(\Delta t)^3/3! + O[(\Delta t)^4]. \quad (17.7)$$

By adding the above expansions, the third-order terms cancel and, using the equation of motion (17.5), we

get

$$x(t + \Delta t) = 2x(t) - x(t - \Delta t) + F(t)(\Delta t)^2/m, \quad (17.8)$$

which holds up to third order in the time step Δt . This relation is called the Verlet leap-frog algorithm.

An advantage of this method is its simple form, which allows us to code a program very easily. For example, the coding processes can be:

- Step 1: Specify the initial position $x(t_0)$ and the position at the first step $x(t_0 + \Delta t)$.
- Step 2: Calculate the force $F(t_0 + \Delta t)$ at the first step.
- Step 3: Compute $x(t_0 + 2\Delta t)$ according to (17.8).
- Step 4: Repeat steps 2 and 3 with $t_0 \rightarrow t_0 + \Delta t$.

Throughout the whole calculation processes, we only need to record the two latest positions of the particles in the Verlet method, which saves computer memory space.

The form of (17.8) includes only particle coordinates and no velocity terms. The velocity $v(t)$ can be evaluated by rewriting (17.8) as follows:

$$x(t + \Delta t) = x(t) + v(t)\Delta t + F(t)(\Delta t)^2/2m, \quad (17.9)$$

$$v(t) = [x(t + \Delta t)] - x[(t - \Delta t)]/2\Delta t. \quad (17.10)$$

Although the Verlet method has merit due to its simple form, we encounter a difficulty when the force $F(t)$ depends on the velocity $v(t)$, because the velocity (17.10) can be computed only after calculating the forward-step coordinate $x(t + \Delta t)$, which is itself calculated using the velocity $v(t)$. This is something of a vicious circle. Since the force term rarely includes the velocity for usual atomic interactions, this deficiency is not always a limitation. However, as we shall discuss later, when we try to control the temperature or the pressure of the simulation system by introducing a fictitious variable, we inevitably encounter this problem caused by a velocity-dependent force term.

To avoid this situation, a slightly more complicated prescription, called the predictor–corrector scheme is commonly used, where the coordinates $\tilde{x}(t + \Delta t)$ at a forward step is temporarily calculated, and then subsequently corrected using the force term $F(t + \Delta t)$ calculated at the next time step.

Gear Method

Among the methods using the predictor–corrector scheme, the most popular method is one called the Gear predictor–corrector method [17.2]. The calculation procedure consists of two parts. The first step is called

the predictor step, which is just a Taylor expansion expressed in vector representation for a set of coordinates $x(t)$ and their time derivatives $x'(t)$, $x''(t)$, $x'''(t)$, \dots :

$$\tilde{\mathbf{q}}(t + \Delta t) = G\mathbf{q}(t), \text{ where}$$

$$G = \begin{pmatrix} 1 & 1 & 1 & 1 & \dots \\ 0 & 1 & 2 & 3 & \dots \\ 0 & 0 & 1 & 3 & \dots \\ 0 & 0 & 0 & 1 & \dots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{pmatrix}, \quad \mathbf{q}(t) = \begin{pmatrix} x(t) \\ x'(t)\Delta t \\ x''(t)(\Delta t)^2/2! \\ x'''(t)(\Delta t)^3/3! \\ \vdots \end{pmatrix}.$$

(17.11)

One advantage of the Gear method is that we can choose the order of time step Δt in the Taylor expansion to take into account. If we choose to calculate up to order $(\Delta t)^{p-1}$, or equivalently we choose the coordinate vector $\mathbf{q}(t)$ as a p -component vector, then we call it the p -th order Gear method.

Using the predicted coordinates $\tilde{\mathbf{q}}(t + \Delta t)$, we then calculate the force $F(t + \Delta t)$ in the second, corrector step as follows:

$$\mathbf{q}(t + \Delta t) = \tilde{\mathbf{q}}(t + \Delta t) + A(\Delta t)^2 \times [F(t + \Delta t) - \tilde{x}''(t + \Delta t)]/2,$$

(17.12)

where A is a constant vector called the correction vector.

The forms of the matrix G and vector A depend on the order of the method. Whereas G is uniquely determined by the order p , there is no unique choice for the correction vector A that make the third component A_3 unity and thereby satisfy the equation of motion at $t + \Delta t$. Gear determined [17.2] the vector A so that the numerical errors do not accumulate monotonically. For the fourth-, fifth- and sixth-order algorithms, the prescribed values are listed below:

$$G = \begin{pmatrix} 1 & 1 & 1 & 1 \\ 0 & 1 & 2 & 3 \\ 0 & 0 & 1 & 3 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \quad A = \begin{pmatrix} 1/6 \\ 5/6 \\ 1 \\ 1/3 \end{pmatrix},$$

for $p = 4$,

(17.13)

$$G = \begin{pmatrix} 1 & 1 & 1 & 1 & 1 \\ 0 & 1 & 2 & 3 & 4 \\ 0 & 0 & 1 & 3 & 6 \\ 0 & 0 & 0 & 1 & 4 \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix}, \quad A = \begin{pmatrix} 19/120 \\ 3/4 \\ 1 \\ 1/2 \\ 1/12 \end{pmatrix},$$

for $p = 5$,

(17.14)

$$G = \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 \\ 0 & 1 & 2 & 3 & 4 & 5 \\ 0 & 0 & 1 & 3 & 6 & 10 \\ 0 & 0 & 0 & 1 & 4 & 10 \\ 0 & 0 & 0 & 0 & 1 & 5 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}, \quad A = \begin{pmatrix} 3/20 \\ 251/360 \\ 1 \\ 11/18 \\ 1/6 \\ 1/60 \end{pmatrix},$$

for $p = 6$.

(17.15)

Consequently, the coding process is as follows:

- Step 1: For the p -th order method, specify the initial position $x(t_0)$ and its derivatives $x'(t_0)$, $x''(t_0)$, \dots , and $x^{(p-1)}(t_0)$.
- Step 2: Calculate the predicted coordinates $\tilde{\mathbf{q}}(t_0 + \Delta t)$ at the first step according to (17.11).
- Step 3: Calculate the force $F(t_0 + \Delta t)$ at the first step using $\tilde{\mathbf{q}}(t_0 + \Delta t)$.
- Step 4: Compute the corrected $\mathbf{q}(t_0 + \Delta t)$ according to (17.12).
- Step 5: Repeat steps 2 to 4 with $t_0 \rightarrow t_0 + \Delta t$.

In the course of numerical integration, it is inevitable that numerical errors will accumulate. The size of these errors depends on the numerical integration method used, as well as the time step Δt . To estimate the order of the numerical errors, we calculate the trajectory $x(t)$ of a simple harmonic oscillator of unit mass

$$x''(t) = -x(t), \quad (17.16)$$

and evaluate the deviation from the analytical solution for different integration methods and different time steps.

Figure 17.2 shows the results for the deviation of the numerically integrated trajectory from the exact solution after 100 oscillation periods (200π). As one can see from the slope of a linear approximation to the plots depicted in the figure, the numerical error of the p -th Gear method scales as $(\Delta t)^p$. This behavior is just what one would expect from (17.11), but it is not straightforward, because the number of calculation steps grows as $(\Delta t)^{-p}$ for a constant interval T , although the error for each step is assured to be as low as $(\Delta t)^p$ in the p -th Gear method. In this context, it is interesting that the numerical error of the Verlet method behaves as $(\Delta t)^2$, even though the error at each step is kept as low as $(\Delta t)^4$. In this sense, the Verlet method is considered to be a second-order formalism.

The tendency in Fig. 17.2 tells us that we can keep the numerical errors low if we use the Gear method with a sufficiently small time step compared to a typical time

Fig. 17.2 The relation between the deviation in particle trajectory from the exact solution of the harmonic oscillator after 100 cycles and the calculation time step Δt . The slope k of the linear approximation of each set of plots is also depicted

scale for characteristic motion of the system considered. However, in the case of the simulation of complex systems of many atoms, numerical errors might also originate from other factors such as an artificial cut-off of the interactions or computer roundoff errors in the numerical treatment. So, we cannot definitely conclude that the higher-order Gear methods are superior to the Verlet method. In some practical simulations of a small protein [17.3], the Verlet method does show more accurate energy conservation than the higher-order (fourth to eighth) Gear methods for a considerably large time step, although the calculation time is shorter and the consumed memory space is lower for the Verlet methods. In a practical sense, we should choose these numerical methods depending on available computational resources such as calculation speed and memory storage.

Program Languages and Computational Platforms

To end this section, we consider the program languages in which the calculation code is written and the platforms on which the MD calculations are performed. The program that executes MD calculations on computers are usually written in particular languages. The FORTRAN language is one of the most popular due to its historical use for supercomputers. Of course, other program languages such as the C or JAVA are also good for the coding MD programs.

In terms of the platform for the simulation, any type of computer, for example supercomputers, workstations, personal computers (PCs), or others, can be used for MD simulations. Any type of operating system, such as UNIX, Windows, Macintosh, or Linux, will work, as long as it supports the language used. In particular, since the main part of the MD calculations consists of the computation of forces acting on each particle, which can be calculated independently, the use of computers with vector or parallel processors makes the calculation highly efficient. In addition, the computing power of modern personal computers is sufficient to perform MD simulations at a satisfactory speed. Examples of typical calculation time of MD simulations on a PC will appear in the following section.

17.1.2 Constraints on the Simulation Systems

MD simulation is inevitably restricted by computational power. Therefore, in this section, we shall introduce two remedies for this deficiency: periodic boundary conditions and the bookkeeping method.

Since the typical time scale for atomic motions is of the order of a picosecond (10^{-12}) or less, we should use values of the order of a femtosecond (10^{-15}) for the time step Δt to keep the numerical errors small. Therefore, it takes many more than a million iterations to follow the motion of a single atom for just a microsecond. Moreover, the number of calculations required grows rapidly as the number of atoms N in the system increases. Under these circumstances, we should satisfy ourselves with the calculation of a small system with fewer than a million atoms and a short physical process over less than a few microseconds. Thus there is always a large discrepancy in both length and time scale between the real macroscopic system and the simulation system we can handle. For example, the typical size of a million-atom system is as small as a few tens of nanometers, which means that the simulation system is far from macroscopic.

Periodic Boundary Condition

A popular remedy for the length scale problem is the use of periodic boundary conditions. As shown schematically in Fig. 17.3, we first confine all the atoms to a box, and then copy the box, together with the atoms in the box, identically in three directions. By repeating this procedure, we can fill the whole space with the original

Fig. 17.3 An illustrative view of periodic boundary conditions

configuration and its replicas. Consequently, an atom leaving the box to the right through one boundary can be identified with an atom entering from the left at the opposite boundary. A system constructed in this way can be taken as having infinite size and an infinite number of atoms.

Of course the periodic system cannot be identical to an infinitely large bulk system. Some drawbacks caused by periodic boundary conditions will be discussed in later sections.

Bookkeeping Method

The main part of the calculational cost in solving the equations of motion is due to the calculation of the interactive forces between atoms, because, roughly speaking, the number of combinations of interacting atomic pairs grows as N^2 or faster with the total number of atoms N . If the atomic force has a long-range interaction range, such as the Coulomb interaction, this problem is very serious, and the complicated Ewald method [17.4] is needed to perform calculations effectively. On the other hand, if the interaction is short-range, which is the case for most metallic systems, a simple prescription called the bookkeeping method effectively saves us a lot of calculation time.

The bookkeeping concept is simple: we keep a book, in which a table of the neighboring atoms is written down for all atoms in the system, and is regularly updated with a proper period $\Delta t N_{\text{book}}$. More concretely, we first calculate the members within a distance $r_{\text{book}} = r_c + r_{\text{margin}}$ of each atom, where r_c is the interaction range, and write them down in the book, as illustrated schematically in

Fig. 17.4. Then we need only consider interactions between the atom and its neighbors, as written in the book, in the following N_{book} numerical integration steps. After every N_{book} integration steps, we update the list of neighbors in the book by calculating the distances between all atomic pairs. The period N_{book} for updating the book should be determined according to $N_{\text{book}} v \Delta t = r_{\text{margin}}$, where v is the average velocity of the atoms.

As previously mentioned, the calculation time required for the force calculation grows like N^2 in a pairwise-interacting system, if we calculate the interaction for all pairs of atoms. On the other hand, when we use the bookkeeping method, the time required only grows linearly with N , because the average number of atoms neighboring each particle is almost constant and does not depend on N .

Figure 17.5 shows the relation between the calculation time needed for 100 integration steps and the total number of atoms N in a simulation cell. In this calculation, we choose a system consisting of pairwise-interacting atoms and use $r_{\text{book}} = 1.32r_c$ and $N_{\text{book}} = 50$. The calculation program was coded in the FORTRAN language and executed on a PC with a single processor. In Fig. 17.5, we have shown the slope k of the linear approximation to each data set in log-log plots. Note that the calculation time for the simulation *with* bookkeeping scales almost linearly, while that of the simulation *without* bookkeeping scales almost quadratically, which leads to a difference of nearly a thousand times in the calculation time for $N = 20\,000$ atoms.

Fig. 17.4 An illustrative view of the regions related with the bookkeeping method

Fig. 17.5 The relation between the calculation time for 100 MD steps and the total number N of atoms in the simulation system with and without bookkeeping

17.1.3 Control of Temperature and Pressure

To compare the simulation results with experimental results, we must control the thermodynamical conditions such as the temperature and the pressure of the simulation system. The techniques for controlling the temperature and the pressure of the simulation system will be introduced in this section: the momentum-scaling method and the Nose–Hoover thermostat for temperature control, and the Andersen and Parrinello–Rahman methods for pressure control.

Before introducing the control methods, we note that the use of the control methods discussed below includes a subtle point; the standard way of temperature or pressure control for the simulation system lies outside the description of the Newtonian equations of motion. Consequently, the deterministic nature of the MD simulation will be lost and there is a risk that the simulation results might depend on the control method we use. Therefore, care should be taken when using such control methods in MD simulations.

Momentum-Scaling Method

To control the temperature of the simulation system, several methods have been presented. One of the simplest methods is the momentum-scaling method [17.5,6]. The temperature T of the system is defined by the average kinetic energy of all the atoms as

$$\frac{3}{2}k_B T = \frac{1}{2} \sum_i m_i v_i^2, \quad (17.17)$$

where k_B is the Boltzmann constant. Accordingly, when we want the system temperature to be T_0 , we rescale the kinetic momenta of all atoms by a factor of $\sqrt{T_0/T}$.

By executing this rescaling procedure repeatedly, the system temperature will approach the desired temperature. Even though this method appears too naive and basic, it has been verified [17.7] that the thermodynamical quantities will approach their equilibrium values after iterated equilibration processes using momentum rescaling if the number of atoms N is sufficiently large.

One of advantages of this method is that the coding procedure is simple. For example, supposed that the rescaling of the momenta is to be carried out every N_{rescale} steps, we would calculate the temperature T of the system according to (17.17), and insert the momentum-scaling transformation for all atoms as

$$p_i \rightarrow \sqrt{T_0/T} p_i. \quad (17.18)$$

after every N_{rescale} integration steps.

In Fig. 17.6, we have depicted two examples of the time evolution of the system temperature T in a simulation in which the temperature is controlled by the momentum-scaling method. Starting from an equilibrated state at $T = 200$ K, we have changed the temperature to 400 K at $t = 1000$ steps, and then to 300 K at $t = 6000$ steps. The upper graph shows the case with $N_{\text{rescale}} = 10$, while the lower graph shows the

Fig. 17.6 Time evolution of the effective temperature T of the simulation system calculated from the total kinetic energy of the atoms

case with $N_{\text{rescale}} = 100$, where the convergence to the desired temperature is slower. In both cases, the temperature of the system is well controlled to the desired value except for accompanying small fluctuations.

Stochastic Method

There is another temperature-control method called the stochastic method [17.8]. In this method, we pick an atom at random and exchange its velocity with a value taken at random from a Maxwell–Boltzmann distribution with the desired temperature T_0 . By executing this prescription repeatedly every N_{exch} steps, the system should approach thermal equilibrium. However, it is difficult to determine a proper value for the interval N_{exch} . An interval that is too short will generate a jiggling behavior of atoms within a small configuration space, while an interval that is too long will result in a very long calculation time to obtain the thermal equilibration at the desired temperature. In addition, there is another shortcoming to the stochastic method, which might bring about an unwanted steady state in the simulation system. Therefore, one should consult [17.9] if using this method.

Nose–Hoover Thermostat

In contrast to the stochastic nature of the previous method, there is a sophisticated temperature-control method with a deterministic nature, called the Nose–Hoover thermostat method [17.10, 11]. In this method, a fictitious variable S , which plays the role of a temperature controller, is introduced into the mechanics of the simulation system. The variable S serves as a sort of friction of atoms, and its value depends on the difference between the system temperature T and the desired temperature T_0 . The equations of motion of the extended system are the following:

$$d^2 \mathbf{r}_i / dt^2 = -\frac{1}{m_i} \partial \phi / \partial \mathbf{r}_i - \frac{\dot{S}}{S} \mathbf{v}_i, \quad (17.19)$$

$$d^2 S / dt^2 = \frac{S}{Q} \left(\sum_i m_i \mathbf{v}_i^2 - 3Nk_B T_0 \right) + \frac{\dot{S}^2}{S}, \quad (17.20)$$

where Q is the fictitious mass of the variable S . The dotted symbols denote their time derivatives.

The role of the variable S can be seen more clearly if we introduce a variable $\zeta = \ln(\dot{S}/S)$ and rewrite (17.19) and (17.20) as

$$d^2 \mathbf{r}_i / dt^2 = -1/m_i \partial \phi / \partial \mathbf{r}_i - \zeta \mathbf{v}_i, \quad (17.21)$$

$$d\zeta / dt = \frac{2}{Q} \left(\frac{1}{2} \sum_i m_i \mathbf{v}_i^2 - \frac{3}{2} Nk_B T_0 \right). \quad (17.22)$$

We can see that the second term on the right-hand side of (17.21), which is proportional to atom velocities, serves as a sort of friction term, whose value depends on the difference between the system temperature T and the desired temperature T_0 . It has also been verified [17.7] that this extended system gives the same partition function as that of the original system in the thermal equilibrium limit.

If we consider the fictitious variable S as the coordinate of an additional atom, which has a peculiar equation of motion (17.20), then a coding procedure can be executed similarly. However, since (17.19–17.22) contain velocity dependent terms, a simple leap-frog method does not work straightforwardly. In this case, use of a predictor-corrector method is appropriate. For example, using the Gear method, the coding procedure is the following: [Here we shall use one dimensional expression $x_i(t)$ for the atom coordinates for simplicity.]

- Step 1: For the p -th order method, specify the initial position $x_i(t_0)$ and its derivatives $x'_i(t_0)$, $x''_i(t_0)$, \dots , and $x_i^{(p-1)}(t_0)$ and assign them to $q_i(t_0)$ for $i = 1$ to N .
- Step 2: Consider $S(t)$ as coordinates of the $(N+1)$ -th atom, specify the initial value for $S(t_0)$ and its derivatives $S'(t_0)$, $S''(t_0)$, \dots , and $S^{(p-1)}(t_0)$, and assign them to $q_{N+1}(t_0)$.
- Step 3: Calculate the predicted coordinates $\tilde{q}_i(t_0 + \Delta t)$ for $i = 1$ to $N+1$ at the first step according to (17.11).
- Step 4: Calculate the force $F_i(t_0 + \Delta t)$ at the first step for $i = 1$ to N according to (17.19) by using $\tilde{q}_i(t_0 + \Delta t)$.
- Step 5: Calculate the force $F_{N+1}(t_0 + \Delta t)$ at the first step according to (17.20) by using $\tilde{q}_i(t_0 + \Delta t)$.
- Step 6: Compute the corrected $q(t_0 + \Delta t)$ according to (17.12) for $i = 1$ to $N+1$.
- Step 7: Repeat steps 3 to 6 with $t_0 \rightarrow t_0 + \Delta t$.

Here one point should be noted about the methods in which fictitious variables are introduced, such as the Nose–Hoover thermostat. Once the ‘motion’ of the fictitious variables has settled down, the fictitious variable does not harm the simulation system. On the other hand, for example, if we try to increase the system temperature by a large amount, the value of the fictitious variable starts to change very rapidly, so the temperature of the system will rise to the target value. However, when the

system temperature reaches the desired value, the motion of the fictitious variables goes on due to their inertia, which results in the temperature continuing to rise until the motion of the variable stops. This type of overshooting behavior is an inevitable result of methods with fictitious variables. We shall see an example of such undesirable behavior in the case of pressure control in the following.

Boundary Box Scaling

If the simulation system has a fixed boundary, we cannot control the pressure of the system. Therefore, pressure control methods are always accompanied by changes of the boundary conditions. Suppose that the simulation system is contained in a boundary box of volume V , the internal pressure of the system can be calculated using the virial formula:

$$P_{\alpha\beta}^{\text{int}} = \frac{1}{3V} \sum_i (m_i v_{i\alpha} v_{i\beta} - q_{i\alpha} \partial\phi / \partial q_{i\beta}), \quad (17.23)$$

where the Greek symbols take the Cartesian values 1, 2, or 3. So a simple method is to enlarge the size of the simulation cell if we want to decrease the pressure, and vice versa. In more concrete words, if the boundary box has a pallerelpiped shape spanned by the three vectors $(\mathbf{a} \ \mathbf{b} \ \mathbf{c}) = \mathbf{h}$, where $h_{\alpha\beta}$ is a 3×3 tensor, we can control the pressure P^{int} of the system by varying the cell shape according to

$$h_{\alpha\beta} \rightarrow h_{\alpha\beta} \left[1 - \varepsilon (P_{0\alpha\beta} - P_{\alpha\beta}^{\text{int}}) \right], \quad (17.24)$$

where P_0 is the desired pressure and ε is an appropriate small parameter. This method is similar to the momentum-scaling method in some sense.

Andersen Method

As in the case of temperature control, there are some more sophisticated methods for the pressure control in which a fictitious variable is introduced in order to control the system pressure. In this case, the simulation cell itself is taken as a fictitious dynamical variable just like the Nose–Hoover thermostat S . The total Lagrangian L is defined as:

$$L = L_0 + L_{\text{cell}}, \quad (17.25)$$

$$L_0 = \frac{1}{2} \sum_i m_i \dot{\mathbf{r}}_i^2 - \phi(\mathbf{r}_1, \mathbf{r}_2, \dots), \quad (17.26)$$

$$L_{\text{cell}} = K_{\text{cell}} - P^{\text{ext}} V, \quad (17.27)$$

where K_{cell} is the ‘kinetic’ term of the simulation cell, which depends on the method, P^{ext} is the external stress, and $V = \det \mathbf{h}$ is the cell volume.

Several forms of K_{cell} have been proposed. In Andersen’s scheme [17.8], the shape of the cell is restricted to be cubic, that is, $h_{\alpha\beta} = V^{1/3} \delta_{\alpha\beta}$. The dynamics are described by

$$K_{\text{cell}}^{\text{A}} = \frac{1}{2} M \dot{V}^2, \quad (17.28)$$

where the dotted variables denote their time derivatives and M is the effective ‘mass’ of the cubic cell. In this case, the equations of motion are the followings:

$$d\mathbf{r}_i / dt = \mathbf{p}_i / m_i + \frac{1}{3} V^{-1} \dot{V} \mathbf{r}_i, \quad (17.29)$$

$$d\mathbf{p}_i / dt = -\partial\phi / \partial \mathbf{r}_i - \frac{1}{3} V^{-1} \dot{V} \mathbf{p}_i, \quad (17.30)$$

$$d^2 V / dt^2 = \frac{1}{M} \left[\frac{1}{3V} \sum_i (m_i \mathbf{p}_i^2 - \mathbf{r}_i \cdot \partial\phi / \partial \mathbf{r}_i) - P^{\text{ext}} \right], \quad (17.31)$$

where the third equation means that the cell motion is triggered by the deviation of the internal stress from the external stress.

By introducing scaled coordinates s_i parameterized as $\mathbf{r}_i = L \mathbf{s}_i$ by the edge length $L = V^{1/3}$ of the cubic cell, (17.29–17.31) can be rewritten as

$$d^2 s_i / dt^2 = -\frac{L^{-1}}{m_i} \partial\phi / \partial \mathbf{r}_i - 2L^{-1} \dot{L} \dot{\mathbf{s}}_i, \quad (17.32)$$

$$d^2 L / dt^2 = \frac{L^{-2}}{3M} \left[\frac{1}{3V} \sum_i (m_i (L \dot{\mathbf{s}}_i)^2 - \mathbf{r}_i \cdot \partial\phi / \partial \mathbf{r}_i) - P^{\text{ext}} \right] - 2L^{-1} \dot{L}^2. \quad (17.33)$$

These expressions are more easy to handle for coding in many cases.

Parrinello–Rahman Method

In the Parrinello–Rahman method [17.12], which is a generalization of Andersen’s method, the shape of the simulation cell is allowed to deform more flexibly. The periodic box has a pallerelpiped shape spanned by the three vectors $(\mathbf{a} \ \mathbf{b} \ \mathbf{c}) = \mathbf{h}$, as shown in Fig. 17.7. The kinetic part is written as

$$K_{\text{cell}}^{\text{PR}} = \frac{1}{2} M \text{tr}(\dot{\mathbf{h}} \dot{\mathbf{h}}^{\text{T}}), \quad (17.34)$$

where ${}^{\text{T}}\mathbf{h}$ denotes the transpose of \mathbf{h} and the dotted variables denote their time derivatives again. The equations

Fig. 17.7 Illustrative images of a deformation of the periodic boundary cell in the Andersen and the Parrinello–Rahman scheme

of motion can then be written down by using scaled coordinates s_i parameterized as $\mathbf{r}_i = h\mathbf{s}_i$ in the following forms:

$$ds_i/dt = h^{-1} \mathbf{p}_i/m_i, \quad (17.35)$$

$$d\mathbf{p}_i/dt = -\partial\phi/\partial\mathbf{r}_i - {}^t h^{-1} \dot{h} \mathbf{p}_i, \quad (17.36)$$

$$d^2 h/dt^2 = \frac{V}{M} (\Pi - P^{\text{ext}}) {}^t h^{-1}, \quad (17.37)$$

where

$$(\Pi - P^{\text{ext}})_{\alpha\beta} = \frac{1}{V} \sum_i [m_i (h\dot{\mathbf{s}}_i)_\alpha (h\dot{\mathbf{s}}_i)_\beta - r_{i\alpha} \partial\phi/\partial r_{i\beta}] - P_{\alpha\beta}^{\text{ext}} \quad (17.38)$$

is the deviation of the internal from the external stress tensor.

As schematically illustrated in Fig. 17.7, the dynamical variable fictitiously introduced into the simulation system is the volume V in the Andersen method, while its counterpart is the shape tensor h in the Parrinello–Rahman method; in both of these methods the periodic simulation cell can change its shape according to the dynamical variable V or h . In both Andersen’s method and the Parrinello–Rahman method, the coding procedure is carried out by taking the fictitious parameters V or h as additional ‘atoms’ just like in the Nose–Hoover thermostat method. In addition, since (17.29–17.33) and (17.35–17.38) contain velocity-dependent terms, use of a predictor–corrector method

is appropriate. For example, to code the Andersen’s constant-pressure method by using the Gear algorithm, the outline is the following: (Here we shall also use one-dimensional expression $x_i(t)$ for the atom coordinates and $s_i(t) = L(t)^{-1}x_i(t)$ for the scaled coordinates for simplicity.)

- Step 1: For the p -th order method, specify the initial (scaled) position $s_i(t_0)$ and its derivatives $s'_i(t_0), s''_i(t_0), \dots$ and $s_i^{(p-1)}(t_0)$ and assign them to $\mathbf{q}_i(t_0)$ for $i = 1$ to N .
- Step 2: Consider $L(t)$ (or $V(t)$) as coordinates of the $(N+1)$ -th atom, specify the initial value for $L(t_0)$ (or $V(t_0)$) and its derivatives, and assign to $\mathbf{q}_{N+1}(t_0)$.
- Step 3: Calculate the predicted coordinates $\tilde{\mathbf{q}}_i(t_0 + \Delta t)$ for $i = 1$ to $N+1$ at the first step according to (17.11).
- Step 4: Calculate the force $F_i(t_0 + \Delta t)$ at the first step for $i = 1$ to N according to (17.32) by using $\tilde{\mathbf{q}}_i(t_0 + \Delta t)$.
- Step 5: Calculate the force $F_{N+1}(t_0 + \Delta t)$ at the first step according to (17.33) by using $\tilde{\mathbf{q}}_i(t_0 + \Delta t)$.
- Step 6: Compute the corrected $\mathbf{q}_i(t_0 + \Delta t)$ according to (17.12) for $i = 1$ to $N+1$.
- Step 7: Repeat step 3 to 6 with $t_0 \rightarrow t_0 + \Delta t$.

As noted above, there is a risk that the fictitious variables introduced to control temperature or pressure might harm the real dynamics of the atoms. In this regard, we shall see how the fictitious variables control the system pressure in the constant-pressure formalism. In Fig. 17.8, an example of the time evolution of the internal pressure $P = (P_{11}^{\text{int}} + P_{22}^{\text{int}} + P_{33}^{\text{int}})/3$ of a simulation system is shown. The system consists of 4000 atoms with face-centered cubic (fcc) structure interacting via a Lennard–Jones potential, which will be explained in the following section. By using the Parrinello–Rahman method, the external pressure is changed from 0 GPa to 1 GPa at MD time step = 2000. Overshooting behavior is found just after the moment at which the pressure is changed until the pressure settles down around the desired value. This overshooting deviation reaches nearly 1 GPa. A similar behavior could be also found in the time evolution of the temperature for the Nose–Hoover thermostat method.

Even after the internal pressure has come to its equilibrium value there remains a small fluctuation of the pressure due to the thermal motion of the simulation cell, as found in Fig. 17.8. This type of breathing behavior inevitably exists in formulations using fictitious variables, and its properties strongly

Fig. 17.8 Time evolution of the internal pressure P of the simulation system

Fig. 17.9 'Breathing' behavior of the internal pressure P of the simulation system

depend on the 'mass' of the fictitious variable. For the same simulation system as shown in Fig. 17.8, we can calculate the breathing behavior of the internal pressure P due to the thermal fluctuation in the cases of different two masses M^* and $10M^*$ of the Parrinello–Rahman cell. (The mass M^* will be defined soon.) The results are shown in Fig. 17.9, where we can see the frequency of the breathing strongly depends on the mass M of the simulation cell.

In general, a large mass gives a small overshoot but a slow convergence, while a small mass gives a large overshoot but a rapid convergence. In any case, the dynamics of the atoms in the simulation is inevitably affected by the motion of the fictitious variables [17.13]. In this context, Parrinello suggested [17.14] that the mass of the simulation cell should be determined such that the periods of the MD cell oscillation and that of sound waves are of the same order. The suggested value is $M^* = 3 \sum m_i / 4\pi^2$, where m_i are the atom masses.

NPT Ensemble

By combining the temperature-control and pressure-control methods, we can perform the simulation of an *NPT* ensemble, which is most appropriate for comparison with experimental results under ordinary conditions. For example, if we take the Nose–Hoover thermostat method for temperature control and the Andersen method for pressure control, the equation of motions of the total system are the following:

$$d^2 s_i / dt^2 = -\frac{L^{-1}}{m_i} \partial \phi / \partial \mathbf{r}_i - (S^{-1} \dot{S} + 2L^{-1} \dot{L}) \dot{s}_i, \quad (17.39)$$

$$d^2 S / dt^2 = -\frac{S}{Q} \left[\sum_i m_i (L \dot{s}_i)^2 - 3Nk_B T_0 \right] + S^{-1} \dot{S}^2, \quad (17.40)$$

$$d^2 L / dt^2 = \frac{L^{-2}}{3M} \left[\frac{1}{3V} \sum_i \left[m_i (L \dot{s}_i)^2 - \mathbf{r}_i \cdot \partial \phi / \partial \mathbf{r}_i \right] - p^{\text{ext}} \right] + S^{-1} \dot{L} - 2L^{-1} \dot{L}^2, \quad (17.41)$$

where S is the Nose–Hoover thermostat variable with a mass Q , L is the edge length of the cubic simulation cell with a mass M in Andersen's method, and s_i are rescaled coordinates defined through $\mathbf{r}_i = L \mathbf{s}_i$. A coding procedure using the p -th order Gear method would be along the following lines:

- Step 1: Specify the initial position $s_i(t_0)$ and its derivatives $s_i'(t_0)$ to $s_i^{(p-1)}(t_0)$ and assign them to $\mathbf{q}_i(t_0)$ for $i = 1$ to N .
- Step 2: Consider $S(t)$ and $L(t)$ as coordinates of the $(N+1)$ -th and the $(N+2)$ -th atom, specify the initial values for $S(t_0)$ and $L(t_0)$ and their derivatives, and assign each to $\mathbf{q}_{N+1}(t_0)$ and $\mathbf{q}_{N+2}(t_0)$, respectively.
- Step 3: Calculate the predicted coordinates $\tilde{\mathbf{q}}_i(t_0 + \Delta t)$ for $i = 1$ to $N+2$ at the first step according to (17.11).
- Step 4: Calculate the force $F_i(t_0 + \Delta t)$ at the first step for $i = 1$ to N according to (17.39) by using $\tilde{\mathbf{q}}_i(t_0 + \Delta t)$.
- Step 5: Calculate the force $F_{N+1}(t_0 + \Delta t)$ and $F_{N+2}(t_0 + \Delta t)$ at the first step according to (17.40) and (17.41) by using $\tilde{\mathbf{q}}_i(t_0 + \Delta t)$.
- Step 6: Compute the corrected $\mathbf{q}_i(t_0 + \Delta t)$ according to (17.12) for $i = 1$ to $N+2$.
- Step 7: Repeat steps 3 to 6 with $t_0 \rightarrow t_0 + \Delta t$.

We can also perform a simulation of the *NPT* ensemble by combining the momentum-scaling method for temperature control and the Parrinello–Rahman method for pressure control. A coding procedure using the p -th order Gear method is similar to the preceding case:

- Step 1: Specify the initial position $s_i(t_0)$ and its derivatives $s'_i(t_0)$ to $s_i^{(p-1)}(t_0)$ and assign them to $q_i(t_0)$ for $i = 1$ to N .
- Step 2: Specify the initial values for $h_{\alpha\beta}(t_0)$, that is, the shape of the simulation cell, and their derivatives, consider $h_{\alpha\beta}(t)$ as coordinates of the $(N+1)$ -th to the $(N+9)$ -th atom, and assign each to $q_{N+1}(t_0)$ to $q_{N+9}(t_0)$.
- Step 3: Calculate the predicted coordinates $\tilde{q}_i(t_0 + \Delta t)$ for $i = 1$ to $N+9$ at the first step according to (17.11).
- Step 4: Calculate the force $F_i(t_0 + \Delta t)$ at the first step for $i = 1$ to N according to (17.35) and (17.36) by using $\tilde{q}_i(t_0 + \Delta t)$.
- Step 5: Calculate the force $F_{N+i}(t_0 + \Delta t)$ at the first step for $i = 1$ to 9 according to (17.37) by using $\tilde{q}_i(t_0 + \Delta t)$.
- Step 6: Compute the corrected $q_i(t_0 + \Delta t)$ according to (17.12) for $i = 1$ to $N+9$.
- Step 7: Repeat steps 3 to 6 with $t_0 \rightarrow t_0 + \Delta t$.
- Step 8: Rescale the atomic momenta $p_i(t)$ for $i = 1$ to N according to (17.18) after every N_{rescale} steps.

17.1.4 Interaction Potentials

The time evolution of the simulation system completely depends on the forces interacting between atoms, which are usually derived from interaction potentials. Possible forms of the interaction potentials popularly used in simulations will be presented in this section. Among them, the Lennard–Jones two-body potential and the embedded-atom method (EAM) many-body potential, both of which are used repeatedly throughout this chapter, will be given special attention.

The functional form $\phi(r_1, r_2, \dots)$ of the potential function plays a crucial role in MD simulation, not only in the physical aspects but also in the technical aspects for coding. In this respect, the potential forms can be classified into two following categories: two-body potentials and many-body potentials. The former can be expressed as a sum of functions of atomic distances as:

$$\phi(r_1, r_2, \dots) = \sum_{(i,j)} \phi_{ij}(|r_i - r_j|). \quad (17.42)$$

Lennard–Jones Potential

One of the simplest and commonly used two-body potentials is the m – n Lennard–Jones (LJ) potential, in which the pairwise interaction between elements A and B separated by distance r is written as

$$\phi^{AB}(r) = e_0^{AB} \left[\left(r_0^{AB} / r \right)^m - m/n \left(r_0^{AB} / r \right)^n \right]. \quad (17.43)$$

Here the parameters m and n can be adjusted according to the elements in the system and are taken to be integers in many cases. For example, $(m, n) = (12, 6)$ is used for rare gasses, while $(m, n) = (8, 4)$ has been proved [17.15] to be adequate to describe metallic systems. The potential has its minimum, $-e_0^{AB}$, at the distance r_0^{AB} . Therefore, we can consider these two parameters as the chemical bond strength and the atomic size, respectively.

EAM Potential

It is well known that two-body potentials cannot reproduce the Cauchy discrepancy between the elastic constants and the correct vacancy formation energy. A straightforward remedy for the problem is to use many-body potentials. Among them, one of the most popular many-body potentials used for metallic systems is called the embedded-atom method (EAM) [17.16], which is based on the effective medium theory. In this framework, the potential energy is written as

$$\phi = \sum_i F^A(\rho_i) + \sum_{(i,j)} \varphi_{ij}^{AB}(r_{ij}). \quad (17.44)$$

Here the first term $F^A(\rho_i)$ corresponds to the energy required to embed atom i into the electron density ρ_i , while the second term φ_{ij}^{AB} corresponds to the core–to-core repulsion energy between atom i and atom j separated by the distance r_{ij} expressed in a pairwise functional. The suffices A and B denote the species of the atoms. The former term incorporates the many-body effect through the electron density assumed to be a linear superposition:

$$\rho_i = \sum_{(i,j)} f_i^A(r_{ij}), \quad (17.45)$$

where $f_i^A(r_{ij})$ is the contribution to the electron density ρ_i at atom i due to atom j at the distance r_{ij} .

The functional forms of $f(r)$ and $\varphi(r)$ are determined so as to reproduce the static properties such as the cohesive energy, lattice constants, elastic constants, and the vacancy formation energy. For example, simple

exponential forms such as

$$f^A(r) = f_0^A \exp(-\beta_A r/r_0^{AA}), \quad (17.46)$$

$$\varphi^{AB}(r) = \varphi_0^{AB} \exp(-\gamma_A r/r_0^{AB}), \quad (17.47)$$

are often used, where f_0^A , φ_0^{AB} , β_A and γ_A are parameters, and r_0^{AB} is the equilibrium nearest-neighbor distance.

On the other hand, the standard way to determine the embedding function $F^A(\rho_i)$ is rather more complicated. In the original scheme suggested by Foiles [17.17], the Rose equation of state is used to determine the form of $F^A(\rho_i)$. The Rose equation of state is given from the empirical experimental data and shows the dependence of the cohesive energy of a cubic crystal on the nearest-neighbor distance r as

$$E^A(r) = -E_c^A [1 + \alpha_A (r/r_0^{AA} - 1)] e^{-\alpha_A (r/r_0^{AA} - 1)}, \quad (17.48)$$

where E_c^A is the cohesive energy with the equilibrium lattice parameter and the parameter α_A is defined as

$$\alpha_A = 3\sqrt{\Omega_0^A B_0^A / E_c^A}, \quad (17.49)$$

using the equilibrium atomic volume Ω_0^A and the bulk modulus B_0^A of the equilibrium state. By using the expression (17.44), the embedding function is calculated as

$$F^A(\rho) = E^A(r) - \frac{1}{2} \sum_j \varphi_{ij}^{AA}(r_{ij}), \quad (17.50)$$

where the calculation is performed for a cubic lattice with the nearest-neighbor distance r , and r would be varied around its equilibrium value r_0^{AA} to obtain the value of $F^A(\rho)$ around the equilibrium electron density ρ_0 .

From a practical point of view, the value of the electron density ρ does not significantly deviate from its equilibrium value ρ_0 . Therefore, a polynomial approximation around ρ_0 is sufficient for calculations except for cases with highly defective structure, such as a surface structure:

$$F^A(\rho) = \sum_i F_i^A (\rho - \rho_0)^i, \quad i = 0, 1, 2, \dots, \quad (17.51)$$

where the coefficients F_i^A are determined so as to reproduce the experimental properties.

According to the tight-binding theory, another functional form $F(\rho)$ has also been suggested. Up to the

second-moment approximation, the functional form of the embedding function is evaluated as

$$F(\rho) = F_0^{\text{FS}} \sqrt{\rho/\rho_0}. \quad (17.52)$$

This type of potential is called the Finnis–Sinclair potential [17.18] and has been widely used in simulations of metallic systems.

Cutoff Procedure

Since the functional forms found in (17.43–17.47) have an infinite interaction range, we usually make a cutoff termination to the potential functions to decrease the calculational cost in MD simulations. For each function to be modified, we set both the starting distance r_s where the termination starts and the cutoff distance r_c where the modified function vanishes.

The two typical terminating processes are as follows. One is to exchange the potential function with a cutoff function $g_c(r)$ for $r > r_s$, which is continuous at r_s to the potential function up to the second derivative, and vanishes for $r > r_c$. For the choice of $g_c(r)$, a polynomial form is often taken:

$$g_c(r) = \sum_i c_i (r - r_c)^i, \quad \text{for } r_s < r < r_c \quad (17.53)$$

where the parameters c_i are determined to satisfy continuity at r_s to the potential function up to the second derivative, and $i = 2, 3, 4, 5, \dots$. For example, a modified LJ potential with terminating at the third-order polynomial starting at its inflection point is called the LJ-spline potential. For the case $(m, n) = (8, 4)$, which we shall use in the following sections, the parameters in (17.53) are uniquely determined as $c_2 = -(10\,240/3159)(5/9)^{(1/2)} r_0^{-2}$, $c_3 = -(655\,360/369\,603)(5/9)^{(3/4)} r_0^{-3}$, and the terminating position $r_c = (103/64)r_s \sim 1.864r_0$ by requiring continuity to the potential function up to the second derivative at the inflection point $r_s = (9/5)^{(1/4)} r_0 \approx 1.158r_0$. For a smoother cutoff at r_c , the fourth-order function ($i = 3, 4$) would be used.

The other approach is to multiply by a switching function $g_s(r)$ that satisfies the properties $g_s(r_s) = 1$, $g'_s(r_s) = g''_s(r_s) = 0$, and $g_s(r_c) = g'_s(r_c) = g''_s(r_c) = 0$ to the potential function on the interval $[r_s, r_c]$. For example, if we take a polynomial function

$$g_s(r) = \sum_i d_i (r - r_c)^i, \quad \text{for } r_s < r < r_c \quad (17.54)$$

of fifth order, that is, $i = 3, 4, 5$, then the coefficients in (17.54) are determined as $d_3 = 10(r_s - r_c)^{-3}$,

$d_4 = -15(r_s - r_c)^{-4}$, and $d_5 = 6(r_s - r_c)^{-5}$. An exponential form such as

$$g_s(r) = \exp \left\{ (r - r_s)^3 / [(r - r_s)^2 - (r_s - r_c)^2] \right\}, \quad (17.55)$$

can be also used for the switching function.

17.1.5 Physical Observables

The method of extracting physical observables will be explained in this subsection. Various observables can be calculated by the MD simulations, including volume, energy, pressure, elastic moduli, diffusivity, viscosity, radial distribution function, etc. Here only formulas for evaluating the observables are shown in this section, while the examples applied to the actual MD simulations will appear in later sections.

Thermodynamical Properties

In the course of the MD simulation, thermodynamical properties such as the total volume V and the internal energy E are always calculated, so they are easy to monitor. The internal pressure P of the simulation system can also be monitored by using (17.23). In ordinary MD simulations, we consider a long-time average of the thermodynamical properties as an ensemble average:

$$\langle O \rangle_{\text{ensemble}} = \langle O \rangle_{\text{time}}. \quad (17.56)$$

In the actual estimation of these observables, we usually take an average over 100–10 000 time steps, among which the longer time averages reduce the effect of thermal fluctuations and statistical errors. Other thermodynamical properties, such as the specific heat or the thermal expansion rate, can be estimated from the change of E and V with T or P .

Structural Properties

The radial distribution function provides a lot of information about atomistic structure. It can be directly calculated from the atomic coordinates $\mathbf{r}_i(t)$. In many cases, by taking a time average of the pair distribution

$$\sum_{\langle i, j \rangle} \left[\mathbf{r}_i(t) - \mathbf{r}_j(t) \right]^2, \quad (17.57)$$

we can greatly reduce the effect of thermal vibrations.

Microscopic structural properties such as the number of atomic pairs or local symmetry properties around each atom also yield important information [17.19]. One of the popular methods used to investigate the microscopic structure is Voronoi polyhedra analysis. Some examples will be given in Sect. 17.3.2.

Dynamical Properties

Among the dynamical and transport properties, the diffusivity is easy to estimate because we know the position of all atoms. That is, we can estimate the self-diffusion coefficient D from the linear part in the time evolution of the mean square displacement of the atoms as

$$\frac{1}{N} \sum_i \left\langle \left[\mathbf{r}_i(t_0) - \mathbf{r}_i(t_0 + t) \right]^2 \right\rangle = \frac{1}{6} D t + \text{const.}, \quad (17.58)$$

where the time average $\langle \dots \rangle$ starts from the initial time t_0 . The diffusivity D can be also calculated from the zero mode of the velocity autocorrelation function

$$\frac{1}{N} \sum_i \langle \mathbf{v}_i(t_0) \cdot \mathbf{v}_i(t_0 + t) \rangle \quad (17.59)$$

as

$$D = \frac{1}{3} \int_0^\infty dt \frac{1}{N} \sum_i \langle \mathbf{v}_i(t_0) \cdot \mathbf{v}_i(t_0 + t) \rangle / \langle \mathbf{v}_i(t_0)^2 \rangle. \quad (17.60)$$

In the same manner, the viscosity $\eta_{\alpha\beta}$ can be estimated from the stress autocorrelation function as

$$\eta_{\alpha\beta} = \frac{1}{k_B T} \int_0^\infty dt \langle V(t_0) \rangle \langle P_{\alpha\beta}(t_0) P_{\alpha\beta}(t_0 + t) \rangle / \langle P_{\alpha\beta}(t_0)^2 \rangle, \quad (17.61)$$

where the stress tensor $P_{\alpha\beta}$ is found from (17.23), and the Greek symbols take the Cartesian values 1, 2, or 3.

Elastic moduli can be calculated [17.20] from a thermodynamical fluctuation formula. From a long-time average of the fluctuation of the stress tensor $P_{\alpha\beta}$, the adiabatic elastic coefficients $C_{\alpha\beta;\gamma\delta}$ can be calculated as

$$\begin{aligned} C_{\alpha\beta;\gamma\delta} = & -\frac{\langle V \rangle}{k_B T} \left(\langle P_{\alpha\beta} P_{\gamma\delta} \rangle - \langle P_{\alpha\beta} \rangle \langle P_{\gamma\delta} \rangle \right) \\ & + \frac{N k_B T}{\langle V \rangle} (\delta_{\alpha\delta} \delta_{\beta\gamma} + \delta_{\alpha\gamma} \delta_{\beta\delta}) \\ & + \frac{1}{\langle V \rangle} \left\langle \sum_{\langle i, j \rangle} r_{ij}^{-2} \left(\partial^2 \phi / \partial r_{ij}^2 - r_{ij}^{-1} \partial \phi / \partial r_{ij} \right) \right. \\ & \left. \times r_{ij\alpha} r_{ij\beta} r_{ij\gamma} r_{ij\delta} \right\rangle, \end{aligned} \quad (17.62)$$

where $\delta_{\alpha\beta}$ is the Kronecker delta, and k_B is the Boltzmann constant.

The vibration modes of atomic motion can also be calculated from the velocity autocorrelation (17.59); examples will appear in Sect. 17.3.2.

17.2 Diffusionless Transformation

In MD simulations, we can only handle short-time phenomena of the order of nanoseconds. Therefore, it is difficult to simulate processes or transformations that rely upon long-range diffusion of atoms. In this section, as examples of diffusionless transformations, we shall pick the martensitic transformation and solid-state amorphization, and investigate the microscopic mechanism underlying these transformations by using the MD simulation.

17.2.1 Martensitic Transformation

The martensitic transformation, which is a typical diffusionless transformations, will be studied from an atomistic point of view using MD simulation in this section. The martensitic transformation of ordered alloys as well as that from fcc iron into a body-centered cubic (bcc) structure will be investigated. The difference between the martensitic transformation in nanoclusters and the bulk will be also discussed.

For a typical system in which a martensitic transformation takes place, we consider here a 1:1 alloy system where the higher-temperature phase is the B2 phase, like the Au–Cd or Ti–Ni system. In most alloy systems where the B2 phase is found as a stable phase, the atomic size difference would play an important role in making the B2 structure stable. Therefore, for a simple model for binary alloys, the interaction between atoms is assumed to be described by the 8–4 Lennard–Jones potential ϕ^{AB} :

$$\phi^{AB}(r) = e_0^{AB} \left[\left(r_0^{AB} / r \right)^8 - 2 \left(r_0^{AB} / r \right)^4 \right]. \quad (17.63)$$

Here the set of parameters e_0^{AB} and r_0^{AB} are determined [17.21] to reproduce the experimental data on molar volumes, cohesive energy and heat of formation of Ti, Ni and B2 phase of the Ti–Ni alloy.

The fitted values of the parameters used in the present simulation are listed in Table 17.1, where atom 1 corresponds to the Ti atom and atom 2 to Ni; the length

Table 17.1 Parameters for the LJ potential in (17.63)

r_0^{11}	1.0000
r_0^{22}	0.8494
r_0^{12}	0.8947
e_0^{11}	1.13375
e_0^{22}	1.03387
e_0^{12}	1.24900

scale is expressed in units of the diameter of atom 1, while the energy scale is expressed in 0.5 eV. As a cut-off, a terminating process using third-order polynomial functions, which starts at the inflection point of the 8–4 LJ potential function (17.63), is taken, as discussed in Sect. 17.1.4. For simplicity, we suppose that atoms 1 and 2 have the same atomic mass m . Throughout this section, all units are normalized by the atomic mass m , the diameter r_0^{11} of atom 1, and the energy unit 0.5 eV in Table 17.1.

For an MD simulation in the NPT ensemble of this binary system, we adopt the momentum-scaling method for temperature control and the Parrinello–Rahman method for pressure control. The period N_{rescale} of the momentum scaling is taken to be 10. The book-keeping radius r_{book} is set at $r_c + 0.6$ and the period N_{book} for updating the ‘book’ ranges from 25 to 100 according to the temperature. The time integration is performed by the fifth Gear algorithm with a time step of $\Delta t = 0.005$ in the normalized units.

As an initial configuration, a $16 \times 16 \times 16$ B2 lattice with an equilibrium lattice parameter $a = 0.9365$ is prepared; snapshots are illustrated in Fig. 17.10. The same number $N/2 = 4096$ atoms of elements 1 and 2 are arranged on the lattice points alternatively, and small velocities randomly taken from the Boltzmann distribution at a temperature $T = 0.001$ (≈ 5.5 K) are assigned to all atoms. After annealing at $T = 0.001$ for 10^5 time integration steps, the system remains in the B2 structure. This means that the B2 structure is at least a metastable phase at low temperature.

After the annealing process at $T = 0.001$, a heating procedure is performed in a stepwise way, as

Fig. 17.10a,b Snapshots of a B2 structure: (a) a perspective view and (b) a top view from the z -direction. The *light gray spheres* and the *dark gray spheres* denote the elements 1 and 2, respectively

shown in Fig. 17.11. The size of each heating step is $0.01 (= 0.005 \text{ eV/atom} \approx 55 \text{ K})$ and every step is followed by a 10 000 integration step equilibration period. The physical values, such as the atomic volume and energy, are determined by averages over the last 1000 steps of the equilibration period. To minimize the artificial effect induced by the momentum-scaling process, we execute the scaling procedure only if the effective temperature (17.17) of the system deviates from the desired value by more than 2%. Consequently, the scaling procedures are concentrated in the first 1000 steps of the equilibration period.

Here one point should be noted about the rate of temperature change in an MD simulation. In the stepwise heating shown in Fig. 17.11, the average heating rate is 2.0×10^{-4} in the normalized units. This corresponds to an extraordinarily high rate, around 10^{12} K/s , although this rate is so low that it takes a considerable calculation time of the order of hours. We shall encounter this type

Fig. 17.11 A snapshot of the time evolution of the system temperature T calculated from the total kinetic energy of atoms in a stepwise heating procedure

Fig. 17.12 The temperature dependence of the axis length of the simulation cell in the heating process starting from a B2 structure

of discrepancy between the time scale in the simulation and the actual calculation time in every stage of MD simulations.

To take the statistical and thermal nature into account, several heating runs are carried out from different initial perturbations. Before the crystal starts to melt, the crystal structure experiences some structural transformations. By monitoring the shape of the periodic simulation cell, we can see how the transformation evolves.

The time evolution of the shape of the simulation cell in the heating procedure starting from a B2 phase is shown in Fig. 17.12, where the cell axis lengths are shown as functions on the temperature. The B2 phase immediately transforms into a tetragonal phase with a symmetry $L_x = L_y \neq L_z$ at $T = 0.02$, and then transforms into an orthorhombic phase with $L_x \neq L_y \neq L_z$ at $T = 0.06$. We call the former phase $L1'_0$ and the latter phase $L1''_0$, because both phases are understood as slight modifications of an fcc-based close-packed structure $L1_0$ with a long-period modulation. Snapshots of the $L1'_0$ phase and the $L1''_0$ phase are shown in Fig. 17.13 and 17.14, respectively. Upon further heating, the sys-

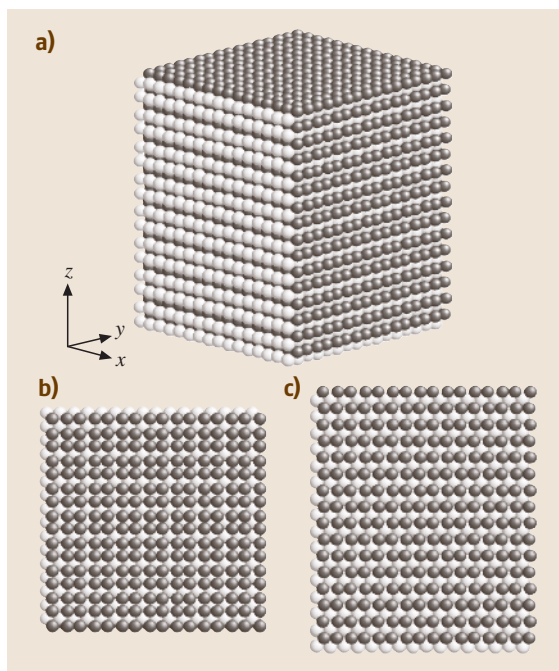

Fig. 17.13a–c Snapshots of an $L10'$ structure: (a) perspective view, (b) a top view from the z -direction, and (c) a side view from the x -direction. The atoms are shown using the same colors as in Fig. 17.10

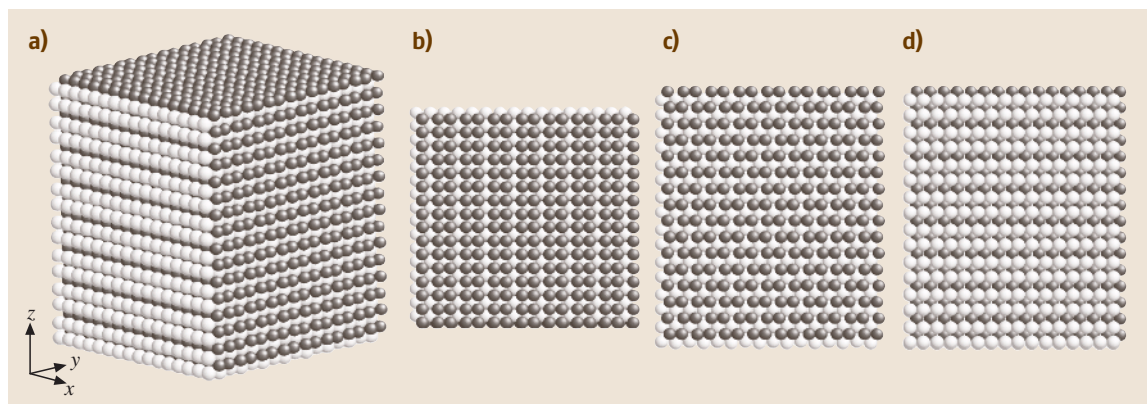

Fig. 17.14a–d Snapshots of an $L10''$ structure: (a) a perspective view, (b) a top view from the z -direction, (c) a side view from the x -direction, and (d) a side view from the y -direction. The atoms are shown using the same colors as in Fig. 17.10

tem transforms back into the B2 phase at $T = 0.46$, and finally, the B2 crystal melts into the liquid phase at $T = 0.66$.

To understand the phase evolution in the heating process shown above, we shall estimate the enthalpy of each phase found in the simulation. Once we know the atomic configuration of the phase, we can calculate the enthalpy at 0 K of each structure using an energy-minimization process, which is equivalent to an MD calculation at 0 K, if the corresponding structure has a marginal stability at 0 K. The calculated energy levels at 0 K for the B2, the $L1_0'$, and the $L1_0''$ phase are shown in Fig. 17.15. This suggests that the $L1_0''$ phase is the ground state and the B2 phase is a fragile metastable state at 0 K. Therefore, the B2-to- $L1_0'$ transition at $T = 0.02$ is considered to be a simple transition from an unstable state to the ground state, while the $L1_0'$ -to- $L1_0''$ transition at $T = 0.06$ and the $L1_0'$ -to-B2 transition at

$T = 0.46$ are understood as the phase transitions to the higher enthalpy states driven by the entropy contribution to the free energies.

The character of the transition between the B2 and the $L1_0''$ phase can be seen from the temperature dependence of the potential energy. If we stop the heating process at a temperature between $T = 0.46$ and 0.65 before melting and cool down the system, we can observe the transition from the B2 phase to the $L1_0''$ phase. Figure 17.16 shows the change of the potential energy per atom in a heating process (triangles) and a cooling process (circles) at a rate of 2.0×10^{-4} . We can see a hysteresis behavior, which means that there is some extent of superheating (supercooling) in the heating (cooling) process with such a high heating (cooling) rate.

For traditional reasons, the transition temperature M_s of a martensitic transformation is defined by the transition from the high-temperature phase into the low-temperature phase, and the transition temperature from the low-temperature phase into the high-temperature phase is called the reverse transformation temperature A_s . Following this convention, Fig. 17.16 tells us that the martensitic temperature M_s of the B2-to- $L1_0''$ transformation is 0.39 and the reverse martensitic temperature A_s of the $L1_0''$ -to-B2 transformation temperature is 0.46 at this cooling/heating rate. It also suggests that the equilibrium temperature T_0 between the $L1_0''$ phase and the B2 phase should be around 0.43. It should also be noted that the potential energy jumps up at the $L1_0''$ -to-B2 transition, which means that this is certainly an entropy-driven transformation.

In general, it is likely that the higher-temperature phase has a structure with higher symmetry. In this

Fig. 17.15 Energy levels of (meta-)stable structures found at 0 K

Fig. 17.16 Change of the potential energy per atom with temperature in a heating and a cooling process

context, it is natural that the highest-temperature phase B2 has a cubic symmetry, $L_x = L_y = L_z$. However, it is somewhat strange that the lowest-temperature phase $L1'_0$ has a tetragonal symmetry $L_x = L_y \neq L_z$, while the middle-temperature phase $L1''_0$ only has orthogonal symmetry $L_x \neq L_y \neq L_z$. This can be understood if we look into the translational symmetry. As shown in Figs. 17.13 and 17.14, the lower-temperature phases $L1'_0$ and $L1''_0$ show a breakdown of translational symmetry due to the presence of a periodic modulation of the position of atoms, which makes the translational period of the corresponding direction twice as long as that of the B2 phase. For the $L1'_0$ phase, this type of breakdown of translational symmetry is found in the x - and z -directions, while it is found in all three directions for the $L1''_0$ phase. Therefore, in this sense, the translational symmetry reduces step by step from the B2 phase to the $L1'_0$ phase.

Although the LJ potential parameters used here are determined by the static properties of the Ti–Ni system, the structure of low-temperature phases ($L1'_0$ and $L1''_0$) found in the simulation is different from that experimentally observed in the system, which is a hexagonal phase called B19'. We have also calculated the energy of hexagonal based structure starting from the B19 structure, and found a metastable structure that is a sort of modulation of B19, tentatively called B19''. However, the energy of the B19'' phase is higher than those of $L1'_0$ and $L1''_0$, although it is lower than that of B2, as shown schematically in Fig. 17.15.

In spite of these drawbacks of this LJ potential, this model system has interesting features found in many martensitic transformations, that is, the existence of the martensites with long-period modulation, a series of martensites at low temperatures, and the hysteresis be-

havior in the upward/downward transformation. It is quite amazing that such a simple two-body potential can reproduce a variety of aspects common to martensitic transformations. Therefore, in the next section, we shall use this model to investigate how the transformation properties would change in nanoclusters.

17.2.2 Transformations in Nanoclusters

Some physical properties become different from those in the bulk in nanosized clusters. In this section, we shall investigate how the phase-transformation behavior changes in such nanoclusters by performing the MD simulation for the model for B2 alloy clusters and iron clusters with a special focus on the martensitic transformation.

In general, physical properties change in small clusters. For example, the melting temperature goes down in nanosized clusters of pure metals [17.22]. Even the stable phases change dramatically in nanoclusters of alloys [17.23]. On the other hand, due to the finiteness of the total number of atoms in the system, nanoclusters are appropriate targets for MD simulation. Therefore, we shall investigate how the transformation properties would change for nanoclusters by using the simple model of martensitic transformation discussed in the previous section as well as a pure-iron system described by a simple EAM potential.

Transformation in B2 Alloy Clusters

A spherical nanocluster specimen with a B2 structure is prepared at a temperature around A_s for the bulk system, as depicted in Fig. 17.17a). The temperature-control method and the bookkeeping method are the same as in the bulk case discussed in the preceding section, while there is no need for boundary condi-

Fig. 17.17a,b Snapshots of nanoclusters with $N = 4279$ atoms: (a) a B2 cluster and (b) an $L10''$ cluster. The atoms are shown using the same colors as in Fig. 17.10

tions for a free single cluster, or equivalently, a fixed boundary condition is imposed. By lowering the temperature, we can observe a martensitic transformation into the $L1_0''$ structure as we found in the bulk case with periodic boundary conditions. A snapshot of the $L1_0''$ cluster of the low-temperature phase is also depicted in Fig. 17.17b). When we observe a martensite at low temperatures, we raise the temperature to observe a reverse transformation as well as melting of the cluster. By performing such simulation processes for the various sizes of nanoclusters, we can detect [17.24] the dependencies of the martensitic transformation temperature M_s , the reverse transformation temperature A_s , and the melting temperature T_m on the cluster size.

The calculated cluster-size dependencies of the transformation temperatures M_s (closed triangles), A_s (open triangles), and the melting temperature T_m (closed circles) are shown in Fig. 17.18, where the temperature is expressed in the same units as in Fig. 17.16. Throughout the simulations the cooling and the heating rate is 2.0×10^{-4} . All transformation temperatures decrease on decreasing the cluster size. In particular, the dependence of both A_s and M_s on the cluster size shows good agreement with the experimental data on Au–Cd alloy nanoclusters [17.25]. These results indicate that the decrease of the martensitic temperature is caused not by the increase of the activation barrier of the transformation, but by the decrease of the equilibrium temperature T_0 between the B2 phase and the martensite in this model. Moreover, since both the martensitic transformation and the melting are entropy-driven transformations, these results also suggest that the origin of the peculiar trans-

Fig. 17.18 The size dependence of the melting temperature T_m and the martensitic temperatures M_s and A_s of the B2 nanoclusters, together with those for the bulk B2 phase on the right edge of the graph

formation behavior of nanoclusters should be mainly due to the fact that the thermal vibrational state of atoms changes in nanoclusters due to the drastic increase of the population of atoms belonging to the free surface.

Transformations in Iron Clusters

As pointed out above, the transformation properties of nanoclusters are closely related to the existence of a large portion of surface atoms in nanoclusters. In this context, we shall investigate the effect of the surface by using another model for iron clusters.

For an iron potential, we use a simple EAM potential developed by Johnson and Oh [17.26]. In their model, the electron-density function $f(r)$ and the two-body potential $\varphi(r)$ have the following forms:

$$f_i^A(r) = f_0^A (r_0^A/r)^{-\beta}, \quad (17.64)$$

$$\varphi^A(r) = \sum_{i=0}^3 \varphi_i^A (r/r_0^A - 1)^i, \quad (17.65)$$

together with terminating procedures using third-order polynomials starting at $r_s = 1.20253r_0^{\text{Fe}}$ and vanishing at $r_c = 1.39385r_0^{\text{Fe}}$ for both functions $f(r)$ and $\varphi(r)$. To include the strong core–core repulsion in the two-body term, Johnson and Oh introduced the ‘stiffening’ modification

$$\varphi_a^A(r) = \varphi^A(r) + k_a [\varphi^A(r) - \varphi^A(r_0^A)] (r/r_0^A - 1)^2, \quad (17.66)$$

which is valid for $r < r_0^{\text{Fe}}$.

The embedding function $F(\rho)$ has the analytic form

$$F(\rho) = F_0 [1 - \ln(\rho/\rho_0)^n] (\rho/\rho_0)^n, \quad (17.67)$$

where ρ_0 is the equilibrium electron density of the bcc phase with equilibrium lattice parameter $2/\sqrt{3}r_0^{\text{Fe}}$, and F_0 and n are fitting parameters.

The potential parameters found in (17.64–17.67) are listed in Table 17.2, and are determined [17.26] by the available experimental data of the atomic volume, the cohesive energy, the bulk modulus, the Voigt average shear modulus, the anisotropy ratio, and the unrelaxed vacancy-formation energy for bcc iron.

Table 17.2 Parameters for the EAM potential (17.64–17.67)

r_0^{Fe} (Å)	2.4824	ϕ_0 (eV)	−0.2651
f_0 (Å ^{−3})	1.0000	ϕ_1 (eV)	−0.8791
β	6.0000	ϕ_2 (eV)	9.2102
F_0 (eV)	−2.5400	ϕ_3 (eV)	−13.3088
n	0.3681	k_a	12.0630

Due to the lack of explicit magnetic contribution to the potential energy in this simple scheme, this potential cannot reproduce the phase stability between *fcc* iron and *bcc* iron at a given temperature. Instead, this potential stabilizes the *bcc* structure at any temperature for the bulk as well as clusters [17.27]. Therefore, if we start the simulation from a metastable *fcc* phase, we can observe the *fcc*-to-*bcc* martensitic transformation if there is enough thermal excitation to overcome the activation barrier from the *fcc* to *bcc* structure, but the opposite transformation cannot be observed. However, we can investigate an atomistic mechanism at the beginning stage of the *fcc*-*bcc* martensitic transformation by using this model.

In this case, we first prepare *fcc* clusters with various sizes ranging from $N = 400$ to 10 000 atoms at very low temperatures (≈ 10 K). The system temperature is controlled by the momentum-scaling method. After an annealing and relaxing period of 10 000 time steps with $\Delta t = 0.005$ ps, all clusters retain their initial *fcc* structure, independent of their size. This means that there is some potential barrier in the transformation path between the *fcc* phase and the *bcc* phase for nanoclusters. Then the clusters are heated up to melt at a heating rate of around 5 K/ps.

In the heating process, an *fcc*-to-*bcc* transition is observed [17.27] for the clusters with $N < 8000$ and the transformation temperature increases as the cluster size increases, while no explicit phase transformation is observed before melting in the larger clusters. In contrast to the previous case for the B2 alloy clusters, these results suggest that the cluster-size dependence of the *fcc*-to-*bcc* martensitic transformation temperature originates from the change in the height of the activation barrier.

In this sense, the activation barrier is expected to have a close relation to the surface structures of the

nanoclusters. Hence the initial stage of the *fcc*-to-*bcc* transformation is analyzed with special attention to the motion of surface atoms. As shown in Fig. 17.19, the transformation starts from the surface of the nanocluster and proceeds into the interior of the cluster. By analyzing the atomic correspondence between the initial configuration of an *fcc* cluster and the final configuration of a *bcc* cluster, a uniaxial transformation called the Bain transformation takes place in this case. Moreover, further simulation study reveals [17.27] that a vortex-like collective motion is activated on the surface of the clusters according to the temperature, and the collision between two collective modes induces atomic collective motion similar to the Bain transformation, and stimulates the creation of an embryonic martensitic transformation on the surface.

17.2.3 Solid-State Amorphization

Under extreme conditions, such as severe plastic deformations or irradiation damage, some alloy systems show a crystal-to-amorphous transition. This solid-state amorphization is considered as a sort of diffusionless transformation. The physics behind the mechanism of the solid-state amorphization will be investigated by MD simulation for a model system in this section.

It is well known that the atomic size ratio between the constituent elements plays an important role in the amorphous formation of alloys [17.28]. Therefore, to investigate the mechanism of solid-state amorphization, we shall examine a binary system where the interaction is described by the 8-4 LJ potential (17.63) as a model for binary alloys, since we can easily vary the atomic size ratio by changing the parameter r_0^{AB} .

Here we deal with the binary system composed of elements 1 and 2, and, without loss of generality, assume

Fig. 17.19 Snapshots of a transformation procedure of a Fe nano-cluster from *fcc* to *bcc*. The Bain transformation starts from the *upper-right surface* and proceeds into the *lower-left*, in which the (1 0 0) plane of *fcc* changes into the (1 1 0) plane of *bcc*

$r_0^{11} = 1$ and $r_0^{22} \leq 1$. The atomic distance between different elements is defined as $r_0^{12} = (r_0^{11} + r_0^{22})/2$. To focus on the atomic size effect, we make a further simplification that all chemical bonding parameters are identical, that is, $e_0^{11} = e_0^{22} = e_0^{12} = 1$. The atomic masses of both elements are also supposed to be the same unit mass. Consequently, the binary system is characterized by only two variable parameters: the atomic size ratio r_0^{22} of element 2 to element 1, and the concentration x_2 of element 2. All physical quantities are expressed in the above units in this section.

The crystal-to-amorphous transformation processes are simulated in the following procedures. We first prepare an **fcc** solid solution at nearly zero temperature by randomly assigning the solute atoms to the **fcc** lattice sites. After an annealing and relaxation period, we then slowly heat up the system at a rate of 2.0×10^{-4} . In a system that has high glass-forming ability for alloys, the stability of the solid-solution phase against the amorphous phase would be lost, and solid-state amorphization, that is, the transition from the solid solution to an amorphous phase, should be observed if the system acquires enough thermal excitation to overcome an activation barrier.

MD calculations for a 4000-atom system with periodic boundary conditions have been performed [17.29]. The pressure of the system is kept to zero by using the Parrinello–Rahman method. The temperature of the system is set to the desired value by the momentum-scaling method. Figure 17.20 shows the potential energy evolution in a heating process from an **fcc** solid solution of the system where the atomic size ratio r_0^{22} is 0.82 and the composition x_2 of the smaller elements 2 is 0.50. The **fcc** solid solution (or strictly speaking, face-centred

Fig. 17.20 Potential energy dependence on the temperature in a heating process from the **fcc** solid solution of the $(r_2, x_2) = (0.82, 0.50)$ system

tetragonal or fct phase) first evolves into **bcc** solid solution (body-centred tetragonal or bct phase) at $T_1 = 0.28$, and then into an amorphous phase at $T_2 = 0.32$, and finally into the liquid phase at $T_3 = 0.35$. The snapshots of each phase found in this heating process are shown in Fig. 17.21, where the light gray spheres and the dark gray spheres denote the elements 1 and 2, respectively. Note that there is only a small jump in the potential energy at the phase transition at T_1 and T_2 , while drastic structural changes are found between the different phases, as shown in Fig. 17.21.

Similar calculations were performed while varying the atomic size ratio r_0^{22} at $x_2 = 0.25, 0.50$, and 0.75 . At each concentration, we observe the transition from solid solutions to amorphous phases if r_0^{22} is less than some corresponding critical ratio r_c^{SS} , while no amorphiza-

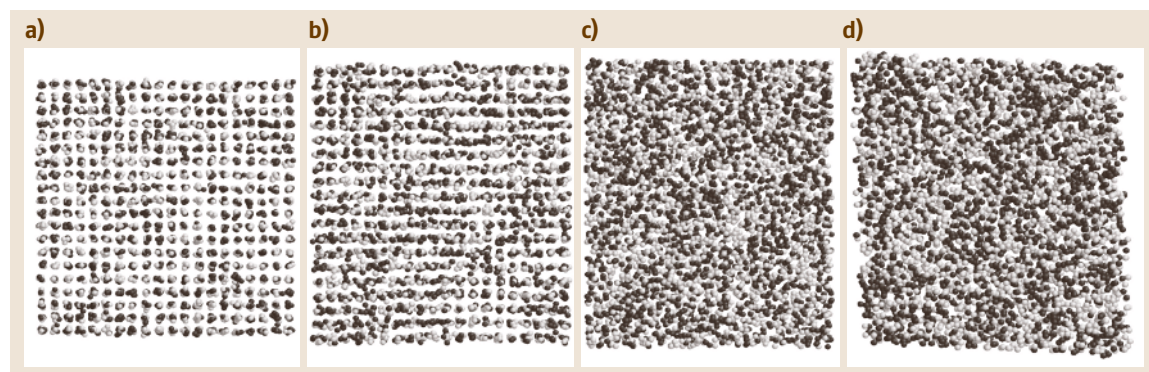

Fig. 17.21a–d Snapshots of the phases appearing in the heating process shown in Fig. 17.20: (a) an **fcc** solid solution (fct) phase ($T = 0.25$), (b) a **bcc** solid solution phase (bct) phase ($T = 0.29$), (c) a glassy phase ($T = 0.33$), (d) a liquid phase ($T = 0.39$). The light gray spheres and the dark gray spheres denote the elements 1 and 2, respectively

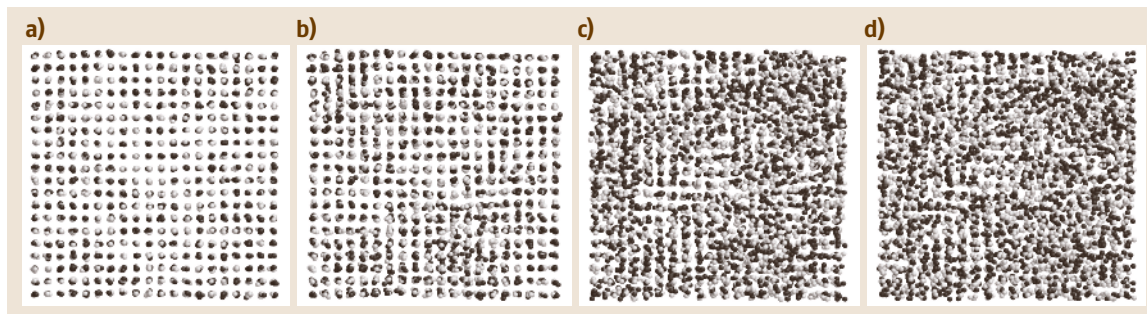

Fig. 17.22a–d Snapshots of atomic configuration of the prepared samples arranged on the fcc lattice sites and annealed at $T = 0.001$ in several systems with different atomic size ratio r_0^{22} : (a) the $(r_0^{22}, x_2) = (0.82, 0.50)$ system, (b) the $(r_0^{22}, x_2) = (0.81, 0.50)$ system, (c) the $(r_0^{22}, x_2) = (0.80, 0.50)$ system, and (d) the $(r_0^{22}, x_2) = (0.79, 0.50)$ system. The colors of the atoms are the same as in Fig. 17.21

tion but melting accompanying with a potential energy jump is observed if r_0^{22} is larger than r_c^{SS} . Especially, if r_0^{22} is considerably below r_c^{SS} , we find a solid-state amorphization in the preparation stage of the initial fcc configuration at nearly zero temperature, as shown in Fig. 17.22 for the $x_2 = 0.50$ case.

Thus, for a given atomic size ratio, we can roughly estimate the composition range where the solid-state amorphization would be observed in the heating and annealing processes in the simulation. The results are shown by the shaded region in Fig. 17.23. This suggests that a large atomic size ratio produces a high glass-forming ability into the binary alloy systems. The same tendency in the glass-forming ability for a binary system was reported in a similar MD study using the 12–6 LJ potential [17.30]. We also note that the effect of the atomic size ratio on the glass-forming ability has a slightly asymmetric nature, that is, the glass-forming tendency is

Fig. 17.23 The atomic size dependence of the composition range in which solid-state amorphization is observed

higher at $x_2 = 0.75$ than at $x_2 = 0.25$ ($x_1 = 0.75$). This feature can be found in the atomic size effect on the glass-forming ability under rapid solidification, which is one of the topics to be discussed in the next section.

17.3 Rapid Solidification

The rapid solidification procedure is also a short-time process that can be handled by MD simulation. In this area, there are a lot of interesting topics, such as the physics of glass transition, the local structure and vibrational state of glassy materials, the preparation of amorphous alloys, and nanocrystallization found in the annealing process of amorphous phases. In this section, we shall tackle these problems in the MD framework.

17.3.1 Glass-Formation by Liquid Quenching

In this section, rapid solidification processes from the melt are simulated for Ti–Al binary alloy systems. The

glass-forming condition is discussed in relation to the experimental observations.

One of the most popular preparation methods of amorphous alloys is the rapid solidification process from the melt. In ordinary rapid solidification processes, the cooling rate is in the range $1\text{--}10^5$ K/s, which is hard to handle by MD simulation. However, the Ti–Al binary system has such poor glass-forming ability that the amorphous phase can be obtained only by sputtering deposition [17.31]. The effective cooling rate in vapor deposition experiments might reach the order of 10^{10} K/s or more, which is tractable even in MD simulations. In this sense, the Ti–Al system is ad-

equate for MD studies on amorphous formation and its crystallization.

In addition, Ti–Al alloys have both technical and theoretical interest, because their excellent mechanical properties strongly depend on their composition and the microstructure. The microstructure can be controlled by heat treatment through a metastable state such as the amorphous phase. Hence it is important to understand the microscopic mechanism involved in the formation and crystallization of the amorphous phases.

We use an EAM potential for Ti and Al developed by Oh and Johnson [17.32]. In their scheme, the electron-density function $f(r)$ and the two-body potential $\varphi(r)$ for the pure metal A are supposed to have the exponential forms

$$f^A(r) = f_0^A \exp[-\beta_A(r/r_0^{AA} - 1)], \quad (17.68)$$

$$\varphi^{AA}(r) = \varphi_0^A \exp[-\gamma_A(r/r_0^{AA} - 1)], \quad (17.69)$$

where f_0^A , φ_0^A , β_A and γ_A are parameters, and r_0^{AA} is the equilibrium nearest-neighbor distance. The embedding function $F^A(\rho)$ is determined by the Rose function $E^A(r)$ according to the procedure discussed in Sect. 17.1.4 by using the modified form of the Rose function

$$E^A(r) = -E_c^A [1 + \alpha_A(r/r_0^{AA} - 1)] \{ (r/r_0^{AA})^{-m_A} - m_A(r/r_0^{AA})^{-1} + m_A \} e^{-\alpha_A(r/r_0^{AA} - 1)}, \quad (17.70)$$

$$(17.71)$$

and (17.49) and (17.50). The potential parameters found in (17.68–17.70) are listed in Table 17.3; these are determined [17.32] by the available experimental data of the atomic volume, the cohesive energy, the bulk modulus, the Voigt average shear modulus, the anisotropy ratio, and the unrelaxed vacancy formation energy for fcc Al and hexagonal close-packed (hcp) Ti.

Table 17.3 Parameters of the EAM potential for the Ti–Al system

r_0^{TiTi} (Å)	2.9511	r_0^{AlAl} (Å)	2.8635
f_0^{Ti} (Å ⁻³)	0.4	f_0^{Al} (Å ⁻³)	1.0
β_{Ti}	6.0000	β_{Al}	5.000
$\phi_{\text{Ti}}^{\text{Ti}}$ (eV)	0.51132	ϕ_0^{Al} (eV)	0.09539
χ_{Ti}	8.9971	χ_{Al}	11.5
E_c^{Ti} (eV)	4.85	E_c^{Al} (eV)	3.58
α_{Ti}	4.743	α_{Al}	4.594
m_{Ti}	2.4	m_{Ti}	2.37

The Ti–Al cross potential is created by using Johnson's method [17.33], in which the cross potential between the elements A and B can be written by using the functions from the pure A – A and the pure B – B potential as

$$\varphi^{AB}(r) = \frac{1}{2} \left[\frac{f^B(r)}{f^A(r)} \varphi^{AA}(r) + \frac{f^A(r)}{f^B(r)} \varphi^{BB}(r) \right]. \quad (17.72)$$

The only fitting parameter in (17.72) is the ratio f_0^A/f_0^B . We have determined the ratio $f_0^{\text{Ti}}/f_0^{\text{Al}}$ to reproduce the experimental value of the heat of solution [17.34]. The fitted value is also listed in Table 17.3.

Here one point should be noted about the EAM potential above. The potential is prescribed so as to reproduce the static properties of hcp Ti and fcc Al such as the cohesive energy, the lattice constant and the elastic constants. But it cannot reproduce correctly the formation energy of the intermetallics in the Ti–Al system such as Ti₃Al, TiAl, and TiAl₃.

Since we have a particular interest in the effect of the difference of the potential used in the simulation on the simulation results, the 8–4 LJ potential is also used in another series of simulations. The parameters used in the simulations are listed in Table 17.4, which are fitted [17.35] so as to reproduce a Ti-rich portion of the phase boundaries in the Ti–Al system in the cluster variation method (CVM) framework.

To perform the MD simulation of NPT ensembles, we use the momentum-scaling method every 10 steps and the Parrinello–Rahman method to keep the internal pressure zero. The flexible mobility of the simulation cell in the Parrinello–Rahman scheme has the advantage of minimizing the restriction due to the periodic boundary conditions, which is especially important in crystallization processes. The equation of motion is numerically integrated using the fifth Gear algorithm with a time integration step of 0.004 ps.

Table 17.4 Parameters of the LJ potential for the Ti–Al system

r_0^{TiTi} (Å)	2.922
r_0^{AlAl} (Å)	2.864
r_0^{TiAl} (Å)	3.029
e_0^{TiTi} (eV)	0.812
e_0^{AlAl} (eV)	0.559
e_0^{TiAl} (eV)	0.812

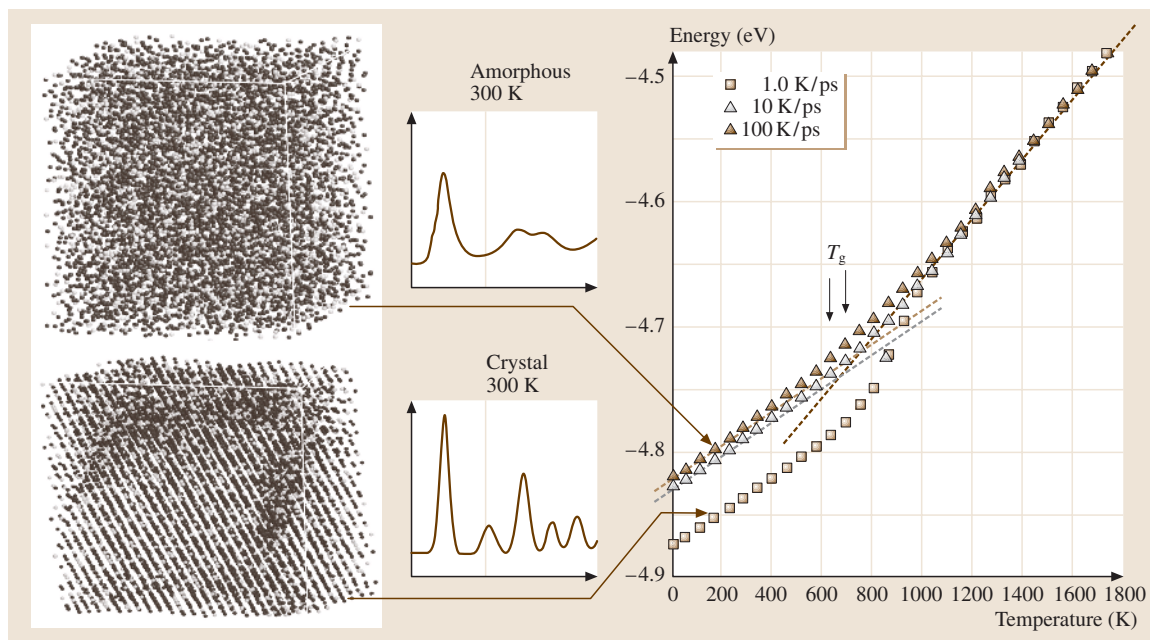

Fig. 17.24 The temperature dependence of the internal energy of the Ti-25 at %Al system in the cooling processes: the squares, the open triangles, and the closed triangles correspond to the case with the cooling rate of 1.0 K/ps, 10 K/ps, and 100 K/ps, respectively. The left graphs are snapshots of atomic configuration and the pair distribution functions of an amorphous phase (upper) and a crystalline phase (lower) at 300 K

The MD simulation of the rapid solidification process in the Ti–Al systems of various compositions is carried out in the following way. In the first stage, to make a liquid phase of Ti–Al alloys, we prepare an fcc solid-solution as an initial configuration in a similar manner discussed in Sect. 17.2.3. By annealing it at a high temperature (≈ 2000 K) above the melting point, the initial structure immediately melts. Since the atomic diffusion rate is high in the liquid phases, an isothermal annealing period of 2×10^5 steps (≈ 0.8 ns) is considered to be enough to acquire a sample of the equilibrium liquid state at a given composition.

In the next stage, we choose a liquid phase obtained by the aforementioned prescription as a starting configuration. Then we cool the system down to 10 K in a stepwise manner with various rates ranging from 10^{11} K/s to 10^{15} K/s. Whether we obtain a crystalline phase or an amorphous phase at the end of the cooling process depends on both the cooling rate and the composition. If we have an amorphous phase, we then raise the temperature of the system up to melting, or, if necessary, keep it at some temperature for isothermal annealing. In the course of the heating or annealing pro-

cedure, a structural relaxation process in the amorphous phase and, in some cases, a crystallization process from the amorphous state could be observed.

Some typical evolutions of the internal energy during cooling processes for the Ti-25 at %Al system of 4096 atoms are shown in Fig. 17.24, where the squares, the open triangles, and the closed triangles correspond to the cooling rate with 1.0 K/ps, 10 K/ps, and 100 K/ps. The sudden drop of the internal energy at around $T = 900$ K in the slowest cooling case corresponds to a liquid-to-crystal transition. On the other hand, the discontinuity in the slope in the two faster cooling cases corresponds to a glass transition, using which we can define the glass transition temperature T_g , as denoted in Fig. 17.24. The left graphs in Fig. 17.24 are snapshots of atomic configurations of an amorphous phase (upper) and a crystalline phase (lower) at 300 K together with the pair distribution functions of the corresponding phase, which reflects a typical feature in each phase, that is, a split-shaped second peak in the amorphous phase and a shell structure in the crystalline phase.

In glass transitions it is a general feature [17.36] that a lower cooling rate gives a lower T_g . This tendency is also observed in the simulation. By comparing the

Fig. 17.25 The temperature dependence of the internal energy of the Ti-25 at %Al system with 4096 atoms in a heating process from an amorphous phase. The heating rate is 1.0 K/ps

Fig. 17.27 The solidified phases after the cooling process mapped onto the cooling rate versus composition plane. The *squares* and the *circles* correspond to the crystalline and amorphous phases, respectively

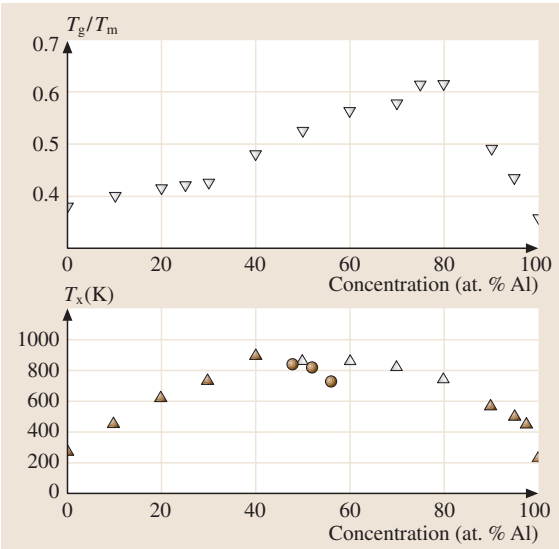

Fig. 17.26 The composition dependence of the glass-transition temperature (*upper column*) and the crystallization temperature (*lower column*) observed in the Ti–Al system. The glass-transition temperature is rescaled by the melting point at each composition. The crystallization temperatures taken from the heating procedure with the rate of 1.0 K/ps are denoted by the closed triangles, those from a long time annealing are denoted by the *open triangles*, and those from the experimental observation [17.37] are denoted by the *closed circles*

results between the case with the cooling rate 10 K/ps and that with the rate 100 K/ps in Fig. 17.24, we find that the lower cooling rate gives the lower energy amorphous state and, consequently, gives the lower T_g . The dependence of T_g on the cooling rate is approximately estimated as that cooling rate that is 10 times higher gives a 50 K increase in T_g .

Figure 17.25 shows an example of the time evolution of the internal energy in a heating procedure from an amorphous phase for the Ti-25 at %Al case. The drop at around 800 K corresponds to amorphous-to-crystal transition, while the subsequent jump at 1900 K corresponds to melting. Thus we can define the crystallization temperature T_x and the melting point T_m of this composition.

By performing this procedure for different compositions, we can obtain [17.38] the composition dependence of the glass-transition temperature T_g and the crystallization temperature T_x in the Ti–Al system. The results are shown in Fig. 17.26. Since T_g as well as T_x depends on the cooling/heating rate, the plotted data are rescaled values corresponding to a constant rate of 1.0 K/ps. In the upper graph, the compositional dependence of the glass-transition temperature T_g are plotted, where the value of T_g is normalized by the observed melting point T_m at each composition. In the lower graph, the composition dependence of the crystallization temperature T_x taken from the heating procedure with constant rate are denoted by the closed triangle,

while those from long-time annealing are denoted by the open triangle, and those from experimental observations [17.37] are denoted by the closed circles. We find an agreement between the simulation results and the experimental observations.

We can also map the obtained phase after quenching onto the cooling rate–composition plane in Fig. 17.27, where the open triangles denote crystalline phases, while the closed circles denote amorphous phases. By using these plots, we can estimate the amorphous-forming composition range at a given cooling rate.

The results are shown in Fig. 17.28, where the upper two results are from the sputtering deposit experiments [17.31], the middle two are from the MD simulations with the EAM potentials, and the lower two are from the MD simulations with the LJ potentials. Considering that the effective cooling rate in the sputtering deposition experiments is the order of 10^8 – 10^{12} K/s, the MD simulations with EAM potentials show better agreement with the experiments than those with the LJ potentials.

As mentioned before, there is a risk that the periodic boundary condition might harm the dynamics of the simulation system. Hence we investigate the effect of the system size on the critical cooling rate by varying N from 218 to 8000 atoms for the pure Al system. In Fig. 17.29, we have mapped the final phases on the cooling rate–system size plane using the same symbols as used in Fig. 17.27. This shows that the effect is significant in small systems with less than 1000 atoms. The similar effect of size on the thermodynamical observables such as the melting point, the crystallization temperature, and the glass-transition temperature, are also calculated and plotted in Fig. 17.30, where the effect appears smaller than on the critical cooling rate, but with a similar nature. So, we conclude that we need at least a few thousand atoms in simulations using periodic boundary conditions to reduce the effect of the boundary conditions.

17.3.2 Annealing of Amorphous Alloys

The annealing procedure of the Ti–Al amorphous alloys is simulated in this subsection. The atomistic mechanism of the structural relaxation in amorphous alloys as well as that of crystallization is investigated by MD simulation with special attention to the local atomic structure of the amorphous phases and the vibrational modes characteristic of the amorphous states.

In amorphous alloys, neither the local atomistic structure nor the mechanism of the structural relaxation is clearly understood. To clarify these problems, the

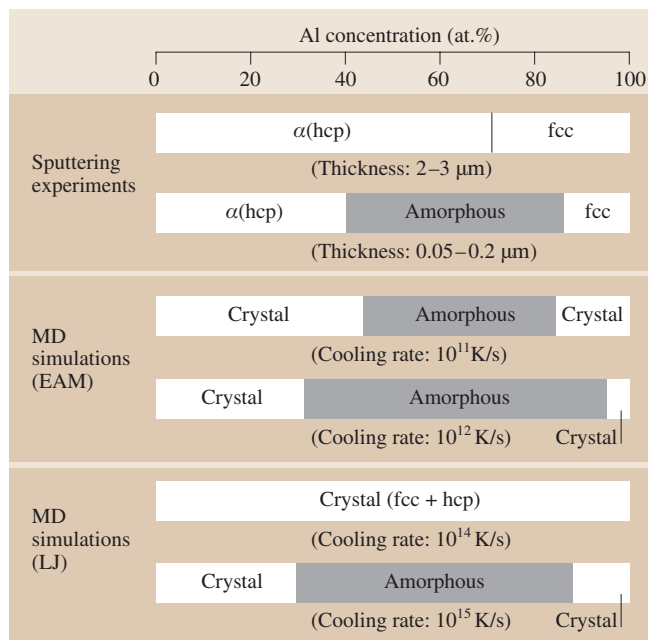

Fig. 17.28 Glass-forming ranges of the Ti–Al system given by experiments and simulations. The upper two are given from the sputtering deposition experiments [17.31], the middle two are given from the MD simulations with the EAM potentials, and the lower two are given from MD simulations with the LJ potentials, respectively. The crystal structure found in the simulations is fcc, hcp, or their mixture in any case

Fig. 17.29 The system-size dependence of the critical cooling rate when varying the total number N of atoms in the simulation for the pure Al system. The quenched phases are denoted by the same symbols as used in Fig. 17.27

Fig. 17.30 The system-size dependence of the melting point T_m , the crystallization temperature T_x , and the glass-transition temperature T_g when varying the total number N of atoms in the simulation for the pure Al system

structural change at the atomistic level will be investigated in the relaxation and crystallization process of amorphous phases in the Ti–Al binary system by using the MD simulation discussed in the previous subsection. To analyze the local structure in the amorphous phases obtained in the simulations, we shall introduce some local order parameters, which will shed light on the basic feature of the atomistic structure of the amorphous phases from different angles.

Icosahedral Symmetry

From experimental observations [17.39] and MD simulations [17.19], it has been established that icosahedral structures are the basic building blocks of the amorphous state in monatomic systems. Since the atomic size difference between Ti and Al is small (a few %), Ti–Al amorphous alloys might include such icosahedral structures.

Fig. 17.31 Icosahedral clusters found in Ti–Al amorphous alloys obtained in the simulations. The *brown* spheres and the *white* spheres denote the Ti atoms and the Al atoms, respectively

Fig. 17.32 The medium-range structure in a Ti-50 at%Al amorphous alloy with 8000 atoms after the classification of the atoms according to the symmetry of the surrounding atoms. The *dark gray*, *light gray*, and *white spheres* denote the atoms with icosahedral symmetry, the atoms with crystalline symmetry, and the other atoms with somewhat distorted surroundings, respectively

hedral structures. Indeed, we can find [17.34] many types of icosahedral clusters in the Ti–Al amorphous phases obtained by the simulations, as depicted in Fig. 17.31. Therefore, we shall investigate the local atomic structure while paying particular attention to this icosahedral symmetry to analyze the microstructure of the phases emerging in the heating and annealing processes.

For this purpose, the Voronoi tessellation technique [17.19] is useful to analyze the local symmetry of atomic configuration around each atom. Dividing the whole configuration space by the bisecting planes for all atomic pairs, we can assign the Voronoi polyhedron or the Wigner–Seitz cell to each atom. The shape of the Voronoi polyhedron reflects the local structure around the corresponding atom. Thus we can assign [17.19] the environmental character to the atoms from the distribution of the faces of the corresponding Voronoi polyhedron.

By evaluating the shape of the Voronoi polyhedra, we can classify the atoms into three groups accord-

ing to their surrounding structure [17.38]: atoms with an environment of icosahedral symmetry, atoms with an environment of crystalline symmetry, and other atoms with somewhat distorted surroundings. Figure 17.32 shows the above classification applied to a Ti-50 at %Al amorphous alloy with 8000 atoms, where the icosahedral-like atoms, the crystal-like atoms, and the other atoms are depicted by the dark gray, light gray, and white spheres, respectively. The remarkable feature is that there is a region with crystalline symmetry even in the amorphous phase and it forms a medium-range ordered structure on the nanometer scale together with a region with icosahedral symmetry. The geometrical origin of the medium scale is understood as follows.

The essence of glass-formation is the competition between the locally stable state (icosahedral cluster) and the globally stable state (crystalline ordering) and the domination of the former. However, the icosahedral clusters have fivefold symmetry so they cannot fill up all space by themselves and there is some limit of order at the nanometer scale for such icosahedral packing. That is why the inhomogeneity on a medium scale exists in the amorphous states.

Thus we can take the fraction X_{ico} of the atoms with icosahedral symmetry and the fraction X_{cry} of the atoms with crystalline symmetry as order parameters which reflect the local symmetry.

In a similar sense, we use the fraction X_{penta} of the pentagons in the total Voronoi faces as an order parameter, since all the faces of the Voronoi polyhedron with icosahedral packing consist of pentagons, while those with bcc, fcc, or hcp crystal consist of squares and hexagons.

DRP Structure

Historically, the first model of atomistic structure for amorphous alloys is the dense random packing (DRP) model [17.40]. In the DRP model, the basic structure is the closest packing of hard spheres and the basic unit is the tetrahedron made of four mutually contacting spheres. Since such closest packing is almost ideally realized in the icosahedral clusters, the abundance of the icosahedral clusters in the amorphous phase reflects the existence of the DRP structure and hence the tetrahedral packing in its basis. Therefore, by counting the number of tetrahedra made of four mutually neighboring atoms in the amorphous alloys, we can use the number N_{tetra} of tetrahedral clusters per atom as an order parameter to characterize the order of the DRP structure.

Free Volume

Next we introduce the notion of free volume following the idea of *Cohen* and *Grest* [17.41]. The atoms surrounded by enough free volume can move by the length of the order of atomic distance, while those having little space around them can only make oscillatory moves around their equilibrium positions. Those atoms having enough free volume are called liquid-like atoms. In the free volume theory, the glass-to-liquid transition can be understood as a percolation of free volume or the liquid-like atoms. In this context, we take a simple definition for the free volume as follows.

Firstly we define the nearest neighbors of an atom by the atoms within a distance of 1.4 times of its atomic size, which corresponds to the first minimum in the radial distribution. Then we define an atom as having enough free volume if it has fewer than 12 neighbors. Under this definition, atoms surrounded by a crystal packing such as fcc, hcp, or bcc are not atoms with free volume, and neither do atoms surrounded by the icosahedral structure. On the other hand, even in a crystal, the atoms neighboring a defect structure such as a vacancy are atoms with free volume. Thus we have another parameter X_{free} which is the fraction of atoms with enough free volume.

Fig. 17.33 shows the time evolution of the above order parameters in the annealing process of amorphous alloys. The left column corresponds to a Ti-25 at %Al amorphous alloy annealed at 520 K and the right column corresponds to a Ti-50 at %Al amorphous alloy annealed at 810 K. The common feature is the decrease in the atomic volume and the energy, as well as that in the free volume. On the other hand, the striking difference is in the evolution of X_{penta} and X_{cry} , that is, an increase in X_{penta} and X_{ico} together with an decrease in X_{cry} are observed in the right column, while a decrease in X_{penta} and X_{ico} together with an increase in X_{cry} are observed in the left column. This indicates that a more stable amorphous phase with less free volume would form in the annealing procedure for the system with the composition 50 at %Al, while embryos of crystalline phases would form in the annealing period for the system with the composition 25 at %Al. Consequently, in the relaxation period, the microscopic process proceeds differently depending on the Al concentration of the system. At the midway composition, where the glass-forming ability is high, less free volume and hence more stable amorphous phase forms, while the early stages of crystallization take place at low Ti or low Al

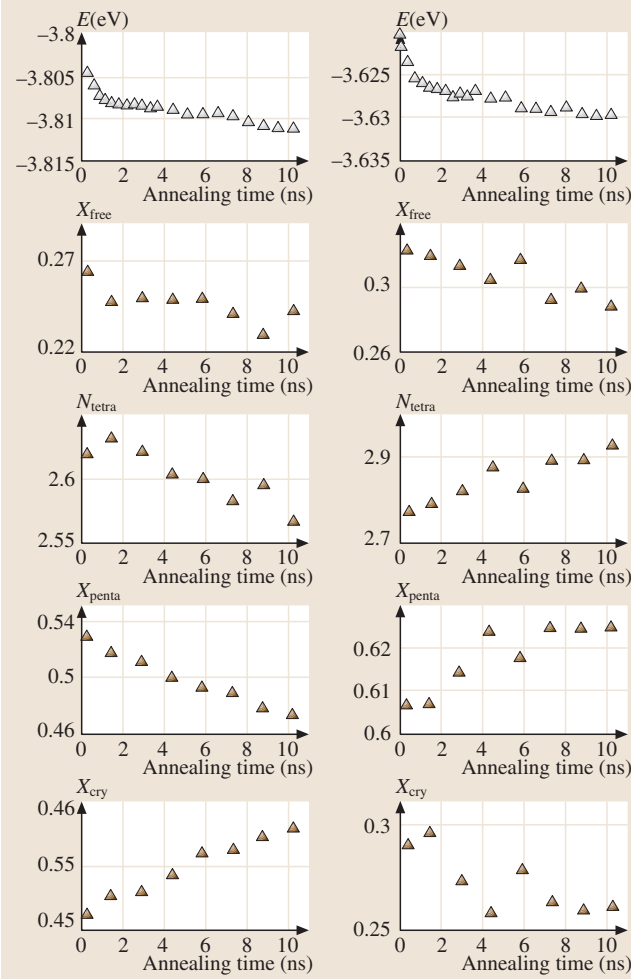

Fig. 17.33 The time evolution of the internal energy E and the structure parameters, X_{free} , N_{tetra} , X_{penta} , and X_{cry} . The left column corresponds to the Ti-25 at %Al system with 8000 atoms annealed at 520 K, while the right column corresponds to the Ti-50 at %Al system of the same size annealed at 810 K

concentration where the glass-forming ability is rather low.

Next we investigate how the above parameters that show local structures change in crystallization processes. Figure 17.34 shows the time evolution of the internal energy E , the fraction X_{penta} of the pentagons, the fraction X_{cry} of atoms with crystalline symmetry, the fraction X_{free} of free volume atoms, and the number N_{tetra} of tetragonal clusters in the annealing process at 580 K of a Ti-25 at %Al amorphous alloy with 8000 atoms. The drastic change in

the parameters at $t = 11$ ns apparently corresponds to the amorphous-to-crystal transition. This can also be seen from the snapshots of atomic configuration of a) the as-quenched state (annealing time $t = 0$ ns), b) a relaxed amorphous state ($t = 10.3$ ns), c) a partially crystallized state ($t = 11.4$ ns), and d) a fully crystallized state ($t = 15$ ns), which are depicted in the right of Fig. 17.34. By using this type of analysis, we can depict a time-temperature-transformation (TTT) curve of the simulation system, as shown in Fig. 17.35, where the tentative TTT-curve of the Ti-25 at %Al amorphous alloy is shown by the bold line.

Finally we proceed to investigate the vibration modes in the amorphous state. The vibrational state of thermal atomic motion is closely related to the local atomic structure. In this sense, an excess of vibration states experimentally observed [17.42] in many types of amorphous phases is thought to play an important role. This is called the boson peak and seems to be a universal feature of amorphous states. However, its structural origin is not clearly understood yet. Indeed, some pioneering MD studies have shown that these modes are closely related to the local atomistic structure [17.43] and a cooperative motion on the nanometer scale [17.44]. Hence we here try to uncover the microscopic origin of the boson peak by investigating the atomic vibrational state in the Ti-Al amorphous phases during the annealing procedure. The investigation of the microscopic origin of the boson peak helps us to understand the physics of the glass transition and the amorphous state itself.

As mentioned in Sect. 17.1.5, we can calculate the power spectrum $f(\omega)$ of the atomic vibration energy from the velocity autocorrelation function of the atoms as:

$$f(\omega) = \frac{2}{\pi} \int_0^{\infty} dt \cos \omega t \langle \mathbf{v}(0) \mathbf{v}(t) \rangle / \langle \mathbf{v}^2 \rangle, \quad (17.73)$$

where the brackets means the average over all atoms. In Fig. 17.36, the calculated vibration energy spectrum of three different phases of Ti-25 at %Al alloys in the annealing process at 580 K shown in Fig. 17.34, are depicted, where the full line, dashed line, and dotted line correspond to the as-quenched amorphous state (annealing time $t = 0$ ns), a relaxed amorphous state ($t = 10.3$ ns), and a crystallized state ($t = 15$ ns), respectively. We can easily see the excess of states in both the low- and high-frequency

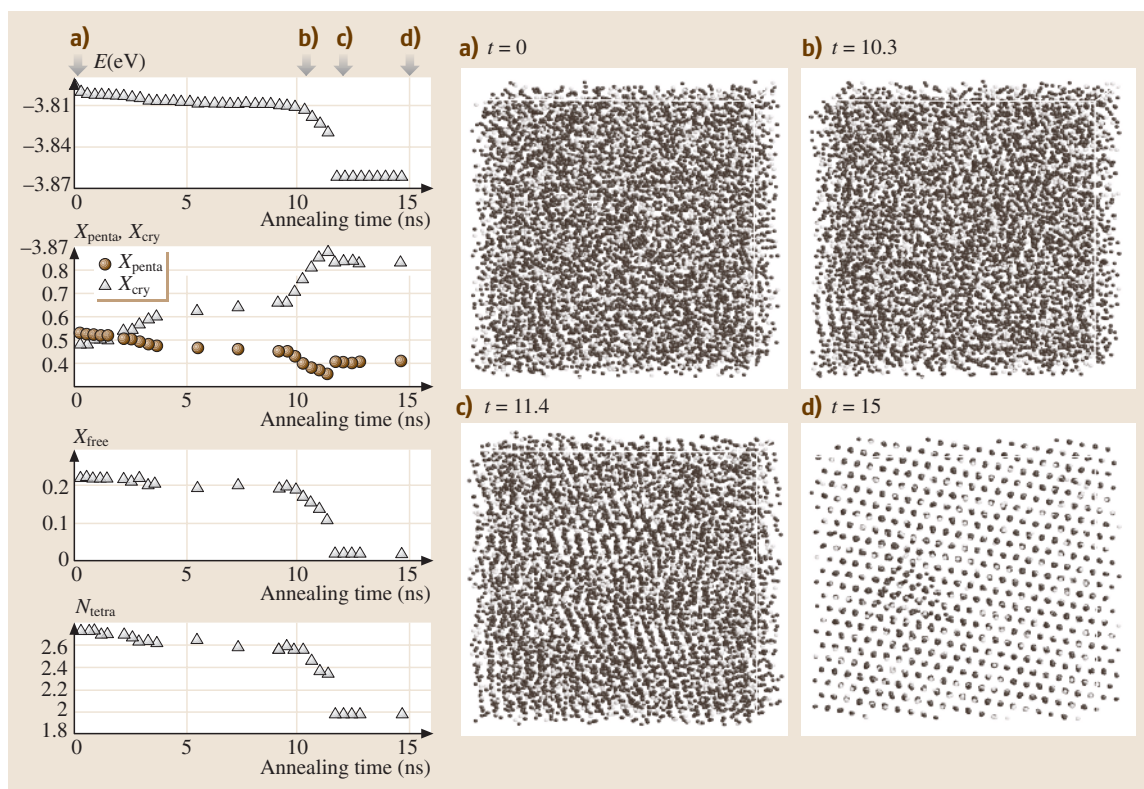

Fig. 17.34a–d The time evolution of the internal energy E , the fraction X_{penta} of the pentagons, the fraction X_{cry} of atoms with crystalline symmetry, the fraction X_{free} of free volume atoms, and the number N_{tetra} of tetragonal clusters in the annealing process at 580 K of the Ti-25 at%Al amorphous alloy with 8000 atoms. The right graphs are snapshots of atomic configuration at the annealing times (a) $t = 0$ ns, (b) $t = 10.3$ ns, (c) $t = 11.4$ ns, and (d) $t = 15$ ns

tail in the amorphous states and that the amount of the excess decreases with time of annealing. Especially, the excess in the low-frequency tail that

corresponds to the boson peak is shown in the inset of Fig. 17.36.

To clarify the microscopic origin of the boson peak, we next investigate the differences between the contributions made to the excess of vibration modes by different local structures. For this purpose, the classification into three regions based on the atomic local symmetry illustrated in Fig. 17.32 is used, and the contribution to the vibrational spectrum from each region is calculated. The results calculated at 10 K for a Ti-50 at%Al amorphous alloy with 8000 atoms are shown in Fig. 17.37, where the solid line, dashed line, and dotted line correspond to the icosahedral-like atoms, the

Fig. 17.35 The calculated TTT curve of an annealed Ti-25at%Al amorphous alloy (bold line). The dotted lines denote the histories of the heat treatments performed in the simulations and the triangles denote the points where crystallization is observed

Fig. 17.36 The time evolution of the vibration spectrum in the annealing process at 580 K of the Ti-25 at %Al amorphous alloy with 8000 atoms. The *solid line*, the *dashed line*, and the *dotted line* correspond to the as-quenched amorphous phase, the relaxed amorphous phase after 10 ns annealing, and the crystallized phase after 15 ns annealing, respectively. The *inset* denotes the low frequency tails

crystalline-like atoms, and the other atoms, respectively, and the inset shows the lower frequency tails. This means that the contribution to the boson peak from atoms with more free volume and fewer neighbors is the largest, while that from the icosahedral atoms is next, and that from crystalline atoms is the smallest. This is consistent with the fact that the decrease in the boson peak during the annealing process is accompanied by a decrease in free volume. But the quantitative difference is so small that we could only discern it in the inset of Fig. 17.37.

17.3.3 Glass-Forming Ability of Alloy Systems

In order to acquire the high glass-forming ability of alloy systems, there are well-known empirical rules [17.28]: large atomic size difference and negative heat of mixing between the alloying elements. In this section, the microscopic origin of these rules is explored by using MD calculations for a model system in which the atomic size ratio and the heat of mixing between the constitute elements can be varied independently.

Here we again choose a binary system where the interaction is described by the 8–4 LJ poten-

Fig. 17.37 The contribution to the vibration spectrum from the atoms with different local structures calculated at 10 K for a Ti-50 at %Al amorphous alloy with 8000 atoms. The *solid line*, the *dashed line*, and the *dotted line* correspond to atoms with icosahedral symmetry, atoms with crystalline symmetry, and other atoms with distorted surrounding, respectively. The *inset* denotes the low-frequency tails

tial as a model for binary alloys, which is discussed in Sect. 17.2.3. There are two reasons for using this model. The first is that we can independently vary the atomic size ratio and the heat of mixing by changing the parameter r_0^{AB} and e_0^{AB} , respectively. The second reason can be found in Fig. 17.28, which shows the calculated amorphous-forming range in the Ti–Al system both for the EAM potential and the LJ potential. Quantitatively, the results from the LJ potential are poorer than those from the EAM potential compared to the experimental observations, but qualitatively, the predicted composition range that has maximum glass-forming ability is almost the same for both potentials. In addition, the predicted critical cooling rate for the LJ potential is a thousand times higher than that for the EAM potential, which means the necessary calculation time is much lower for the LJ potential. In this sense, the MD simulation using the LJ potential is a counterpart of the acceleration experiment, if we are only interested in the glass-forming range.

The model system used in the simulation is almost the same as that used in Sect. 17.2.3, except that we assume that $e_0^{11} = e_0^{22} = 1$ and that the heat of mixing is controlled by varying the interaction parameter e_0^{12} . That is, $e_0^{12} < 1$ means a positive heat of mixing, while

$e_0^{12} > 1$ means a negative heat of mixing. All physical quantities are expressed in the above units in this section. Note that the unit of cooling rate is around 5×10^{15} K/s for typical alloy systems.

To simulate rapid solidification processes, we first prepare a liquid phase in the same manner as mentioned in Sect. 17.3.1, and then rapidly quench the system to solidify. Depending on the cooling rate as well as the atomic size ratio and the heat of mixing of the system, we have a crystalline phase or an amorphous phase. By varying the cooling rate, we can estimate the critical cooling rate needed for amorphization by melt quenching. Alternatively, by varying the atomic size ratio r_0^{22} , the chemical interaction e_0^{12} , and the concentration x_2 of the solute element, we can calculate the glass-forming range by melt quenching under a constant cooling rate.

First we show the pure geometrical effect on the glass-forming ability. In Fig. 17.38a, the shaded regions denote the glass-forming ranges in the rapid solidification on the (x_2, r_0^{22}) plane at fixed chemical interaction of $e_0^{12} = 1$. The darker shading corresponds to the lower cooling rate. For the midway compositions, the glass-forming ability is extremely high if the atomic size ratio is less than 0.9.

We note that the glass-forming ranges are not symmetric in composition and are slightly shifted to higher solute concentration. This suggests that the glass-forming ability should be higher when the adding element has a larger atomic size than the main constituent than when the adding element has a smaller size, assuming that the solute element is added in the same amount.

To investigate the chemical effect on the glass-forming ability for melt quenching, we next fix the atomic size ratio at $r_0^{22} = 1$ and vary the chemical bond strengths between $0.5 < e_0^{12} < 1.5$. In this case, however, we cannot observe any obvious change in the critical cooling rate compared to the system with $e_0^{12} = 1$.

Then we turn to the system with a fixed atomic size ratio of 0.95 and vary e_0^{12} . Figure 17.38b shows the glass-forming range in this case, where the heat of mixing ΔH is defined as $\Delta H = (e_0^{11} + e_0^{22})/2 - e_0^{12}$. The larger negative ΔH gives a greater glass-forming ability, although no amorphization is observed in the cases at low cooling rates less than 1×10^{-4} .

The above results show the following two features: 1) The effect of the chemical factor on the glass-forming ability is rather smaller than that of the geometrical factor and it becomes significant if it is

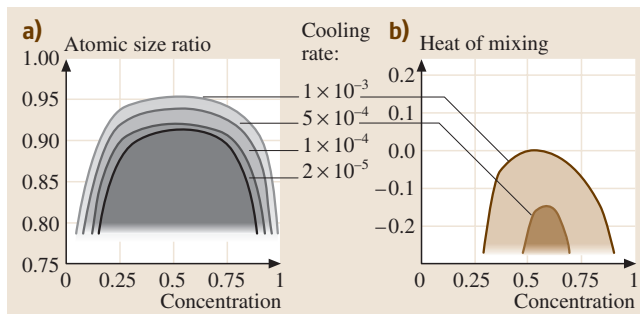

Fig. 17.38a,b Composition ranges in which amorphous phases are formed by melt quenching in the model binary systems. **(a)** Glass-forming ranges under the variation of r_0^{22} with $e_0^{12} = 1$; **(b)** glass-forming ranges under the variation of e_0^{12} with $r_0^{22} = 0.95$. The darker shading corresponds to the lower cooling rate

Fig. 17.39 An amorphous phase (left) and a nanocrystalline phase prepared by rapid solidification

combined with the geometrical effect. 2) Both the geometrical and the chemical factor act asymmetrically, in other words, the glass-forming ability is different whether we add the larger atomic size element to the main constituent element or add the smaller one.

Finally, we show an interesting possibility for control of the nanostructure of rapidly solidified phases. Figure 17.39 shows snapshots of an amorphous phase (left) and a nanocrystalline phase (right) obtained by rapid solidification processes with different conditions. That is, they are obtained in different binary systems with different atomic size ratios under different cooling rates. These snapshots indicate that, to choose the parameters such as the atomic size ratio properly, we could control the grain size of nanocrystalline phases by rapid solidification, as well as we could control the formation of the glassy phases.

17.4 Diffusion

In this section, we shall focus on atomic diffusion. The atomistic mechanism for diffusion is investigated by the MD simulation in a number of cases: the diffusion via vacancies or interstitials in crystalline phases including ordered phases, and the diffusion in the liquid and the glassy phases.

17.4.1 Diffusion in Crystalline Phases

In this section, the atomic diffusion process in crystalline phases is investigated by MD simulation. The atomic-level processes are clarified in the cases of diffusion via vacancies and that via interstitials. The difference between the diffusion properties in pure metallic systems and those in ordered alloy systems is discussed.

To investigate diffusion properties in crystalline phases, here we choose the alloy model discussed in Sect. 17.2.1 where the atomic interactions are described by the 8–4 LJ potential. Therefore, all units used in this section are the same as those found in Sect. 17.2.1. The advantage of using this model is that we can find three ordered phases in this system, that is, the $L1'_0$ and the $L1''_0$ (fcc-based) phases at low temperatures, and the B2 (bcc-based) phase at high temperatures. So we can compare the diffusion properties of the ordered alloys with those of pure metals.

The atomic diffusion in crystalline phases is mainly due to vacancies and interstitials. In MD simulations, the atomic diffusivity can easily be calculated from the atomic mean square displacement as in (17.58), while diffusion experiments are always accompanied with many difficulties. We introduce a single vacancy

Fig. 17.40 Time evolution of average mean square displacement of atoms in an fcc phase introduced one vacancy into $N = 4000$ atoms at $T = 0.6$

into an fcc crystalline phase consisting of $N = 4000$ atoms of element 1 at $T = 0.60$. Figure 17.40 shows a time evolution of the atomic mean square displacement in the fcc phase introduced a single vacancy. The slope of the time dependence denoted by the dotted line in Fig. 17.40 corresponds to the atomic diffusivity D , while the intersection point of the dotted line with the vertical axis corresponds to the average value of thermal vibration. Note that the temperature $T = 0.6$ amounts to 90% of the melting temperature of the fcc structure of elements 1, and the drawback of the MD calculation of the diffusivity is that we can barely estimate the diffusivity at low temperatures far away from the melting point within the available calculation time.

According to the prescription discussed above, we can estimate the diffusivity via vacancies in the fcc phase of element 1 as well as the alloy phases of the element 1 and the element 2, that is, the B2 phase and the $L1''_0$ phase by introducing a pair of vacancies of the element 1 and 2 into a perfect crystalline phase. The results are shown in Fig. 17.41. The temperature dependence of the atomic diffusivity in each phase are denoted by closed circles (fcc), open triangles (B2), and closed triangles ($L1''_0$). In the calculation, a pair of vacancies is introduced into an $N = 4000$ system for the fcc phase, and into an $N = 3456$ system for the ordered phases. The values T^{-1} on the horizontal axis are normalized by the melting temperature of each phase, except the $L1''_0$

Fig. 17.41 The temperature dependencies of the diffusivity in a B2 phase (open triangles), an $L1''_0$ phase (closed triangles), and an fcc phase (closed circles) with the vacancy concentration ≈ 0.0005 and that of diffusivity in an fcc phase with the same interstitial concentration (open squares)

Fig. 17.42 Trajectories of largely moved atoms in an **fcc** phase with two vacancies at $T = 0.30$. The *balls* denote the final positions of atoms and the *sticks* connect them to the initial positions

phase, which is normalized by the melting temperature of the B2 phase.

Although the calculated values include a considerable amount of statistical errors, especially at low temperatures, we can recognize the following properties. Comparing the diffusivity in the B2 phase with that in the $L1'_0$ phase, the atomic diffusion is suppressed in the latter phase, mainly because the $L1'_0$ phase has a structure based on a close-packed structure. Comparing the diffusivity in the **fcc** phase with that in the $L1'_0$ phase, both of which are based on close-packed structure, the atomic diffusion is also suppressed in the latter phase, which suggests that the atomic diffusion would be suppressed in ordered alloys. We have also calculated the diffusivity in the **fcc** phase by introducing a pair of interstitials into an $N = 4000$ system; the results are plotted in Fig. 17.41. The results indicate that diffusion via interstitials has a much higher rate and lower activation energy than that via vacancies.

In the MD simulations, we can easily pick up the atoms that contribute the diffusion. In Fig. 17.42, we have depicted the trajectories of atoms which have moved a distance larger than half of the nearest neighbor distance within 10^5 time steps in an **fcc** phase of element 1 having introduced a pair of vacancies at

Fig. 17.43 Trajectories of largely moved atoms in an **fcc** phase with two interstitials at $T = 0.25$. The *balls* denote the final positions of atoms and the *sticks* connect them to the initial positions

$T = 0.30$, where the balls denote the final positions of such atoms and the sticks connect them to their initial positions. Two strings of atom trajectories can be identified, one of which looks broken into three parts due to the periodic boundary conditions. These two strings correspond to two vacancies introduced into a perfect **fcc** crystal.

In Fig. 17.43, similar trajectories of atoms that have moved significant distances after 10^5 time steps are depicted for an **fcc** phase, having introduced a pair of interstitials at $T = 0.25$. The two figures look similar, but there are two differences between them. One is the history of the string of the sequence of the moving atoms has been made. Each string looks like a row of tadpoles and has two ends: one end is the 'head' of the leading tadpole, and the other end is the 'tail' of the tadpole at the opposite end of row. So we call the former the head of the string and the latter the tail of the string. For the case of diffusion via vacancies, the atomic 'jump' starts from the head of the string and ends with the tail of the string, while the direction of the time sequence is opposite for the case of diffusion via interstitials. The second difference is in the distance of each atomic jump. For the case of diffusion via vacancies, the distance of each atomic jump is nearly always the nearest-neighbor distance, while that for the case of the diffusion via interstitials is less than the nearest-neighbor distance. These

characteristics of atomic diffusion will be revisited in the next section, where the diffusion in liquid and glassy phases are discussed.

17.4.2 Diffusion in Liquid and Glassy Phases

The diffusion mechanism in the liquid phase or the glassy phase is not clearly understood. So, in this section, we try to clarify the mechanism in those phases by MD simulation for a model system. The qualitative change in diffusion property during the liquid quench process found in the simulations is discussed in relation to conventional theories of glass transitions.

The physics behind the glass transition is a long-standing problem in materials science. The discovery [17.45, 46] of bulk metallic glasses has given us a good opportunity to investigate the glass transition in a nearly ideal situation because of the broad stable supercooled liquid region in the system. Indeed, experimental observations [17.28, 47–49] of atomic transport phenomena such as diffusivity and viscosity in metallic glasses have gradually revealed the dynamical nature of the glass transition. Especially, recent nuclear magnetic resonance (NMR) measurements [17.50] have shed light on the microscopic transport mechanism in both supercooled liquid and glassy phases. Moreover, many tasks using MD simulations also give [17.51–54] us useful information about the intrinsic nature of the glass transition from an atomic point of view. In this context, we shall describe a series of MD simulations while focusing on transport phenomena such as atomic diffusion in both liquid and glassy states by using the same model of binary alloys as discussed in Sect. 17.3.3.

MD calculations for an idealized alloy system interacting via the 8–4 LJ potential are performed under periodic boundary conditions. The pressure of the system is kept at zero by using the Parinello–Rahman method and the temperature of the system is controlled by the momentum-scaling method. In order to investigate transport properties in supercooled liquid and glassy phases, we need to prevent nucleation of the crystalline phase during the observation. In other words, we should select the potential parameters such that the system should have a high glass-forming ability, or equivalently, a stable supercooled liquid region. The glass-forming ability of the system under rapid solidification has been investigated in Sect. 17.3.3 by another series of MD simulations and it was shown that a large atomic size difference plays a decisive role. Hence we take the atomic size ratio as $r_0^{22} = 0.8$ and vary the concentra-

tion x_2 of the element 2. For simplicity, we assume an equi-chemical interaction, $e_{11} = e_{22} = e_{12} = 1$. We also assume the interaction distance between different elements is $r_{12} = (r_{11} + r_{22})/2$. All physical quantities are expressed in this units in this section as in Sect. 17.3.3.

The melting temperature T_m of the pure system is around 0.67 in these reduced units. We prepare the binary mixture with $x_2 = 0.2, 0.5$, and 0.7 at $T = 0.8$ and slowly cool the system down. The cooling rate 1×10^{-4} corresponds to about 10^{-11} K/s for a typical metallic system. The liquid-to-glass transition is observed in every case and the nucleation of crystalline phases has not been observed in any case. The glass-transition temperature T_g is determined by the discontinuity of the specific heat, as discussed in Sect. 17.3.1. The atomic self-diffusion coefficients D are calculated by the mean square displacement, as shown in the preceding section.

Figure 17.44 shows the time evolution of the total diffusion coefficient D in the equimolar ($x_2 = 0.5$) system in a cooling procedure. The temperature dependence goes down remarkably beyond some critical temperature T_c and then changes to another behavior below the glass-transition temperature T_g , as indicated in the figure. According to the temperature dependence of the diffusivities, we can classify the phases during the liquid-to-glass transition into three stages. That is, ordinary liquid or weakly supercooled liquid phases (region I), strongly supercooled liquid phases (region II), and

Fig. 17.44 Three stages of the temperature dependence of atomic diffusivity during rapid solidification of a binary system with an atomic size ratio of 1:0.8 and a concentration of 50%

glassy phases (region III), as shown schematically in Fig. 17.44.

The transition from region I to II looks a transition from viscous flow to restricted diffusion caused by structural arrest or infinitely slow relaxation processes, while the transition from II to III is understood as the so-called glass transition because it coincides with the T_g determined calorimetrically. In other words, T_c corresponds to the beginning of the structural arrest or structural slowing down and T_g corresponds to the completion of the structural arrest or structural freezing. Note that the latter change of the diffusion rate at T_g has been detected in experimental observations [17.48–50] for metallic glasses.

On the other hand, the former change has not been experimentally observed yet. The Arrhenius behavior of the temperature dependence in region II suggests that the atomic diffusion needs some activation processes such as cooperative motion. The activation energies estimated from the Arrhenius plots are 6.0 in region II and 1.6 in region III in the LJ units. These correspond to 3.0 eV and 0.8 eV for a typical metallic system, respectively, both of which are consistent with the experimental results [17.28, 49].

We have also plotted the temperature dependence of the diffusivity in a crystalline phase in Fig. 17.44 by the closed triangles, which are obtained during a solidifica-

tion process of the pure system with $x_2 = 0$. Compared to the diffusivity in glassy phases, this indicates that the atomic mobility would be much higher in glassy phases than in crystalline phases.

For the systems with other compositions ($x_2 = 0.2$ and 0.7), we can also recognize three regions I–III in both cases, although T_c as well as T_g depends on the solute composition. Therefore, the three-stage feature of diffusivity found in the simulations seems to be a universal character in glass transitions.

To investigate the microscopic nature of atomic diffusion processes in the supercooled liquid and glassy phases, we calculate the atom trajectories, as discussed in the previous section. We first pick the atoms that have moved more than half of the nearest neighbor distance in a time period and then draw lines from the initial to the final position of such atoms. Figure 17.45 shows the trajectories of such atoms in a glassy phase at $T = 0.15$ of the equimolar system in the interval of 10^5 time steps. Many chain-like trajectories are observed. Although these chain-like trajectories look very similar to those found in crystalline phases depicted in Fig. 17.42 and 17.43, the time analysis reveals the following different features in these motions.

Firstly, the motion of atoms in the same chain occurs almost simultaneously (within a few picoseconds), while the sequence of motions found in crystalline phases takes place in a ‘one after another’ way and ranges over a longer period. This indicates that collective motion should exist in the glassy phases. Another feature is that this collective motion is not exactly simultaneous, but seems to start from the tail and end with the head of the chain, as in diffusion via interstitials.

Similar analyses have been done for the liquid phases (regions I and II). We also found the chain-like cooperative motion in the supercooled liquid phases. However, the atomic motion in the liquid phases is complicated and other types of collective motion seem to exist, so more extended analysis is needed; this is one direction for future work.

We have found that three independent regimes exist during the liquid-to-glass transition, which show the different diffusion characteristics: ordinary (or weakly undercooled) liquid phases (region I), strongly supercooled liquid phase (region II), and glassy phase (region III). We believe that this will be a universal feature in glass-transition phenomena. For bulk metallic glasses, the transition from II to III has been observed [17.28], while that from I to II has not yet. However, for ionic glasses, a sign of transition from I to II has been observed in the relaxation property by

Fig. 17.45 Trajectories of chain-like collective motions in a glassy phase at $T = 0.15$. The *balls* denote the final positions of atoms and the *sticks* connect them to the initial positions

neutron scattering experiments [17.55]. The landscape theory [17.56] as well as the free-volume theory [17.57] and the mode-coupling theory [17.58] might provide a key to understanding the nature of this three-stage behavior. From this viewpoint, this peculiar behavior in atomic transport might have its microscopic origin

in atomic cooperative motions or the redistribution of atomic free-volumes. Since MD simulation is a convenient method to clarify the microscopic nature of atomic transport phenomena, it is well worth trying to continue MD study for the glass transition along this line.

17.5 Summary

Due to the increasing power of modern computers, computer simulations will become the third class of investigation method along side the experimental and theoretical method. Among these simulation methods, MD simulation is a powerful tool to investigate the microscopic mechanism in various types of phenomena, since all information about the atoms in the simulation system can be available. A main drawback of this method is the limit in both length scale and time scale due to a lack of sufficient computational power. Even under such limitations, we can apply this method to the investigations of various types of phenomena in materials, as discussed in this chapter:

- Martensitic transformation in bulk and nano-clusters
- Solid-state amorphization
- Glass-formation by rapid solidification
- Structural relaxation and crystallization of amorphous alloys
- Atomic diffusion in crystalline phases, glassy phases, and liquid phases.

Of course, there will be an infinite number of other applications for MD simulation in materials science. Therefore, it is very promising to cultivate this method in this field.

18. Continuum Constitutive Modeling

Constitutive models play an important role when characterizing structural materials in order to evaluate their thermomechanical behavior. The experimental characterization of materials (using techniques discussed in Part C of this Handbook) involves measuring and controlling macroscopic variables such as force, displacement and temperature. Concise models are also of great use when characterizing the continuous media used to create structural materials, because phenomenological modeling can be carried out regardless of the internal material structure. This continuum modeling usually successfully describes the behavior of various classes of material under complex boundary conditions.

This chapter presents phenomenological constitutive models from both macroscopic and microscopic viewpoints:

- Starting from viscoplasticity models, model performance is reviewed in order to predict the mechanical response under creep–plasticity interaction conditions, taking into account internal state variables.
- Material anisotropy is discussed; mathematical modeling of initial anisotropy and induced anisotropy based on the representation theorem for higher order isotropic tensors is presented.
- Thermomechanical coupling phenomena involving phase transformations predominate

in engineering applications of heat treatment and material processing. A continuum model is presented that takes into account the way structural rearrangement evolves in materials.

- Finally, microscopic analysis based on crystal plasticity, which relates the resolved shear stress to crystal slip, is applied to describe the inhomogeneous deformation process in polycrystalline materials.

In the context of Part E of this Handbook, which deals with various methods of modeling and simulation, the subject of this chapter – *continuum modeling* – sits

between the *molecular modeling* methods explored in the previous chapter and the *finite element modeling* methods discussed in the next chapter.

18.1 Phenomenological Viscoplasticity

18.1.1 General Models of Viscoplasticity

Materials exhibit a wide variety of phenomena in their thermal and mechanical behavior. If we consider struc-

tural materials specifically, they are usually composed of large numbers of crystals and they show clear yield points that occur when the stress exceeds a certain limit. The mechanical behavior after yield is termed as the

Fig. 18.1 Schematic illustration of unified inelasticity model based on excess stress hypothesis

“plasticity” regime and is believed to be independent of time. However, the materials even exhibit permanent deformation below the yield point, particularly at elevated temperature. This deformation is called “creep” and it is believed that different mechanisms apply to this low-stress creep compared to those that occur during metal plasticity. On the other hand, when the stress is high, materials exhibit complicated behavior arising from a mixture of the two components (plasticity and creep).

The equations used to investigate the thermomechanical behavior of materials are derived from (a) conservation laws for mass, linear momentum, angular momentum and energy, (b) kinematic relationships relating displacement to strain, and (c) constitutive equations. Among these, the constitutive equations reflect the specific response of a material from mechanical and thermal viewpoints, while the other equations are independent of the material under consideration and so they all are common to any kind of boundary value problems. The linear elasticity model is a typical example of a constitutive equation, where the Young’s modulus and Poisson’s ratio (or in another form, Lamé’s constants) specify the mechanical response of the material. The Fourier law of heat conduction is another one, where the heat flux is proportional to the gradient of temperature. The coefficient in the Fourier law simply corresponds to the elasticity constant. For convenience we limit our discussion to isothermal processes in this section; nonisothermal problems are discussed in Sect. 18.3 (including heat treatment processes).

Viscoplasticity models have been proposed in order to deal with rate-dependent behavior. Among these, the so-called “superposition model” is the model that simply combines the conventional plastic strain ε_{ij}^p with the creep strain ε_{ij}^c as

$$\varepsilon_{ij} = \varepsilon_{ij}^e + \varepsilon_{ij}^p + \varepsilon_{ij}^c. \quad (18.1)$$

Here we tacitly assume the independence of the elastic strain ε_{ij}^e . In contrast, the “unified constitutive model” gives the rate-dependent viscoplastic (or inelastic) strain ε_{ij}^{vp} ($= \varepsilon_{ij}^p + \varepsilon_{ij}^c$) regardless of the plasticity and creep. The latter formulation is sometimes advantageous because it can be hard to distinguish between plasticity and creep deformation. We employ the Cartesian coordinate system throughout this section and denote the strain tensor $\boldsymbol{\varepsilon}$ by ε_{ij} ; the index notation merely indicates the components of the tensors within a particular Cartesian coordinate system. We also write equations in direct notation where it does not cause confusion.

The phenomenological modeling and the thermodynamic considerations of unified constitutive models were first discussed by *Malvern* [18.1] and *Perzyna* [18.2] in the early 1960s, and more sophisticated models have since been proposed that include internal state variables, which allow us to predict the creep-plasticity interaction and cyclic hardening/softening behavior. A modern treatment of unified constitutive models can be found in monographs by *Miller* [18.3] and *Krausz* [18.4], and these models are applied to finite element codes in order to analyze the structural responses of real machine components.

When modeling a unified inelastic constitutive equation, the following assumptions are widely employed: the stress–strain curve is static independent of the time scale used, the stress is explicitly dependent on the evolution of the viscoplastic strain rate, and the normality rule applies to the flow potential F . A schematic illustration is shown in Fig. 18.1, where kinematic back stress is introduced at the center of the yield surface. The viscoplastic strain rate is expressed as

$$\dot{\varepsilon}_{ij}^{vp} = \Phi(\boldsymbol{\sigma}, \boldsymbol{\alpha}) \frac{\partial F}{\partial \sigma_{ij}} \quad (18.2)$$

where the function Φ describes the magnitude of the strain rate, while the second term describes the direction of the strain rate. The function Φ is chosen such that the steady creep rate can be expressed in terms of the stress $\boldsymbol{\sigma}$ and the internal state variables $\boldsymbol{\alpha}$ (scalar or tensor). The internal state variables (or simply the “internal variables”) are introduced from a phenomenological point of view in such a way that the model reflects hardening and/or softening behavior depending on the prior deformation history of the material. They may correspond to a physical property such as back stress or drag stress in some cases, while the dislocation density can also be chosen as an internal variable in other cases.

Based on the previous discussion and the illustration in Fig. 18.1, a typical evolution law for viscoplastic

strain can be derived as follows [18.5]. Many materials obey a power law for creep and kinematic hardening can be idealized using the back stress α . Introducing the static yield stress r as the threshold for the onset of yield, we can write the viscoplastic strain rate as

$$\dot{\varepsilon}_{ij}^{\text{vp}} = \left\langle \frac{F(\sigma - \alpha) - r}{D} \right\rangle^n \frac{\partial F}{\partial \sigma_{ij}} \quad (18.3)$$

where F stands for the effective stress given by

$$F = \left[\frac{3}{2} (\sigma'_{ij} - \alpha'_{ij}) (\sigma'_{ij} - \alpha'_{ij}) \right]^{1/2}. \quad (18.4)$$

Here the prime (') denotes the deviatoric part. If we neglect the back stress and yield stress, (18.3) is identical to the well-known creep equation obtained by following the Norton rule. In contrast, the solution of (18.3) for uniaxial stress leads to

$$\sigma = r + D (\dot{\varepsilon}^{\text{vp}})^{1/n} + \alpha. \quad (18.5)$$

When a large value is employed for the power factor n , the second term of the right-hand side becomes negligible and so we obtain an almost rate-independent stress–strain curve. Consequently, this constitutive model is expected to cover a wide range of stress–strain responses, from steady creep to rate-independent plastic behavior.

Internal state variables play a key role when modeling the unified inelasticity model, through which complicated loading histories can be predicted. The internal state variables reflect macroscopic and/or microscopic changes in internal structures [18.6]. The back stress, for example, can be measured in such a way that the Bauschinger effect is produced by the variation, while the back stress cannot be controlled during the deformation process. Therefore, the evolution laws may involve the external variables χ , their rates, and the internal state variables α themselves:

$$\dot{\alpha} = A(\chi, \alpha) : \dot{\chi} + B(\chi, \alpha). \quad (18.6)$$

Any evolution equation in a constitutive model follows the above principle. Identifying specific parameters is, however, another issue. Material parameters are usually specified using stress–strain diagrams, by trial and error.

18.1.2 Inelasticity Models

Some of typical inelastic constitutive models are summarized here. We assume that the total strain rate is decomposed into an elastic part and an inelastic part. The

elastic part is expressed by Hooke's law, and the temperature and other effects are neglected for simplicity.

(a) The Conventional Superposition Model

This type of constitutive model has been widely used and is still often used in real structural analysis due to its simplicity. The model employs the same basic assumed decomposition of strain as (18.1), and the plasticity and creep models are introduced independently. For example, an isotropic plasticity model can be written in terms of the von Mises yield criterion as

$$F = \frac{1}{2} (\sigma'_{ij} - \alpha'_{ij}) (\sigma'_{ij} - \alpha'_{ij}) - \frac{1}{3} \bar{\sigma}_y^2 = 0 \quad (18.7)$$

where the evolution of the back stress α follows Prager's law,

$$\dot{\alpha}'_{ij} = C \frac{2}{3} \dot{\varepsilon}_{ij}^{\text{p}}. \quad (18.8)$$

Here a , b and c are material parameters. For the creep model, Norton's law is introduced with the form

$$\dot{\varepsilon}_{ij}^{\text{c}} = \frac{3}{2} M A \sigma^{N-1} t^{M-1} \sigma'_{ij} \quad (18.9)$$

where A , N , and M are material parameters and t is the time. Other types of plasticity and creep laws are also available using this model.

(b) The Chaboche Model [18.5]

Chaboche proposed a unified constitutive model with the type of power law used in (18.3) through (18.5). The key point of the model is the decomposition of back stress. In the original model, three kinds of back stress (namely $\alpha^{(1)}$, $\alpha^{(2)}$ and $\alpha^{(3)}$) are introduced via

$$\alpha = \sum_{k=1}^3 \alpha^{(k)}. \quad (18.10)$$

It is also assumed that the static yield stress r is decomposed into a constant part r_0 and a development R . Taking the nonlinear hardening laws into account, the evolutions are given by

$$\dot{\alpha}^{(1)} = c_1 \left[a_1 \frac{2}{3} \dot{\varepsilon}^{\text{vp}} - \bar{\varepsilon}^{\text{vp}} \alpha'^{(1)} \right] - h \bar{\alpha}^{(18.1)m-1} \alpha^{(1)}, \quad (18.11a)$$

$$\dot{\alpha}^{(2)} = c_2 \left[a_2 \frac{2}{3} \dot{\varepsilon}^{\text{vp}} - \bar{\varepsilon}^{\text{vp}} \alpha'^{(2)} \right], \quad (18.11b)$$

$$\dot{\alpha}^{(3)} = c_3 \frac{2}{3} \dot{\varepsilon}^{\text{vp}}, \quad (18.11c)$$

$$\dot{R} = b(Q - R) \bar{\varepsilon}^{\text{vp}} - \gamma R^q. \quad (18.12)$$

Here $\bar{\epsilon}^{vp}$ is the equivalent viscoplastic strain rate and $\bar{\alpha}$ the effective back stress. There are many material parameters here and they need to be identified from conventional test data.

(c) The Miller Model [18.7]

Miller applied Garofalo's macroscopic creep equation to a unified constitutive model. The function Φ in (18.2) is expressed as

$$\Phi = B\theta \left\{ \sinh \left[\left(\frac{F(\sigma - \alpha)}{\sqrt{D_0 + D}} \right)^{1.5} \right] \right\}^n. \quad (18.13)$$

Here B , θ , n and D_s are constants. The temperature dependence is expected to depend on the parameter θ the most. Since the function $\sinh(\cdot)$ shows a steep change with variations in F , the model describes quasi-rate-independent yielding without a static yield stress component. The evolution equations for back stress α and drag stress D should suitably be defined.

(d) The Krempl Model [18.8]

This model can be regarded as an extension of viscoelasticity based on a generalized form of the Maxwell and Voigt models. Using nonlinear functions for the coefficients of viscoelasticity, a simple form can be written as

$$m[\sigma - g[\epsilon]] \dot{\epsilon} + g[\epsilon] = \sigma + k[\sigma - g[\epsilon]] \dot{\sigma}. \quad (18.14)$$

The function $g[\epsilon]$ describes a static stress-strain diagram. Since the following relationship holds

$$E = \frac{m[\sigma - g[\epsilon]]}{k[\sigma - g[\epsilon]]} \quad (18.15)$$

around the stress origin (E stands for the elasticity constant), the total strain rate is expressed as

$$\dot{\epsilon} = \frac{\dot{\sigma}}{E} + \frac{\sigma - g[\epsilon]}{E k[\sigma - g[\epsilon]]}. \quad (18.16)$$

If we regard the second term as the viscoplastic strain rate, choosing $g[\epsilon]$ and $k[\sigma - g[\epsilon]]$ appropriately enables us to describe real nonlinear stress-strain responses. The substantial part contributing to the viscoplastic strain rate $\sigma - g[\epsilon]$ is called the “over-stress”.

(e) The Bodner Model [18.9]

This model was developed in order to cover a wide range of deformations at high strain rate. The flow rule of the viscoplastic strain rate is subject to the isotropic Levy–Mises condition. The second invariant of the viscoplastic

strain rate D_2 , which is the evolution, is defined by

$$D_2^2 = D_0^2 \exp \left[- \left(\frac{Z^2}{3} \right)^n \left(\frac{n+1}{n} \right) / J_2^n \right]. \quad (18.17)$$

Here D_0 and n are material constants and J_2 is the second invariant of the deviatoric part of the stress; Z is the internal state variable related to the visoplastic work W_p via

$$Z = Z_1 + (Z_0 - Z_1) \exp(-m W_p) \quad (18.18a)$$

$$m = m_0 + m_1 \exp(-\alpha W_p) \quad (18.18b)$$

Z_0 , Z_1 , m_0 , m_1 and α are material parameters. Estrin [18.10] refined this model, taking into account metallurgical considerations, and applied it to various deformation histories involving plasticity and creep.

(f) The Endochronic Model [18.11]

Valanis assumes the existence of an intrinsic time measure ζ particular to each material using

$$d\zeta^2 = \alpha^2 d\xi^2 + \beta^2 dt^2. \quad (18.19)$$

Here ξ is a parameter related to the strain accumulation, while t means the real time scale. This means that ξ reflects a combined history of deformation and time. He further assumes an intrinsic time scale $z(\zeta)$, which increases monotonically with ζ . Let z be, for example, expressed as

$$z = \frac{1}{\beta} \log_e (1 + \beta \zeta). \quad (18.20)$$

Using proper functions for $\mu(\zeta)$ and $K(\zeta)$, the stress deviator and the mean stress are integrated over the intrinsic time as

$$s = 2 \int_{z_0}^z \mu(z - z') \frac{\partial \epsilon}{\partial z'} dz', \quad (18.21a)$$

$$\sigma_m = \int_{z_0}^z K(z - z') \frac{\partial \epsilon}{\partial z'} dz'. \quad (18.21b)$$

It should be noted that these material functions imply tangent moduli not under the real time scale, but under the intrinsic time scale.

18.1.3 Model Performance

As described in the previous section, a large number of inelasticity models have been proposed [18.12–15]. One is based on a macroscopic creep law, another one

Fig. 18.2 Accumulation of ratcheting strain under various stress levels

reflects the physical deformation mechanism. In order to clarify the performance of each model, benchmark tests [18.16–18] have been carried out by the Subcommittee on Inelastic Analysis and Life Prediction under the support of the Committee on High Temperature Strength of Materials, The Society of Materials Science, Japan. A few examples are demonstrated here. The test material employed was 2.1/4Cr–1Mo ferrite steel, and the experiments were performed at an elevated temperature of 600 °C.

Metallic materials reveal a dependence of the mechanical behavior on rate at elevated temperatures, due to creep deformation, and the test material showed remarkable rate dependence at this temperature. Each model was used to predict the strain accumulated when the tensile stress is loaded at different rates and various holding times are used. Figure 18.2 shows the accumulation of strain for various stress rates and stress levels [18.17]. Since the strain always increases and accumulates with the number of cycles, this accumulation is called ratcheting. As shown in the figure, at least ten models are compared. It should be noted that different results are predicted, even by the same model, when the set of material parameters used is changed. This means that the specification of material parameters is not unique for a model and that even small differences in basic test data for monotonic tension, cyclic loading and monotonic creep seriously influence the ratcheting behavior. It has been reported that the responses under

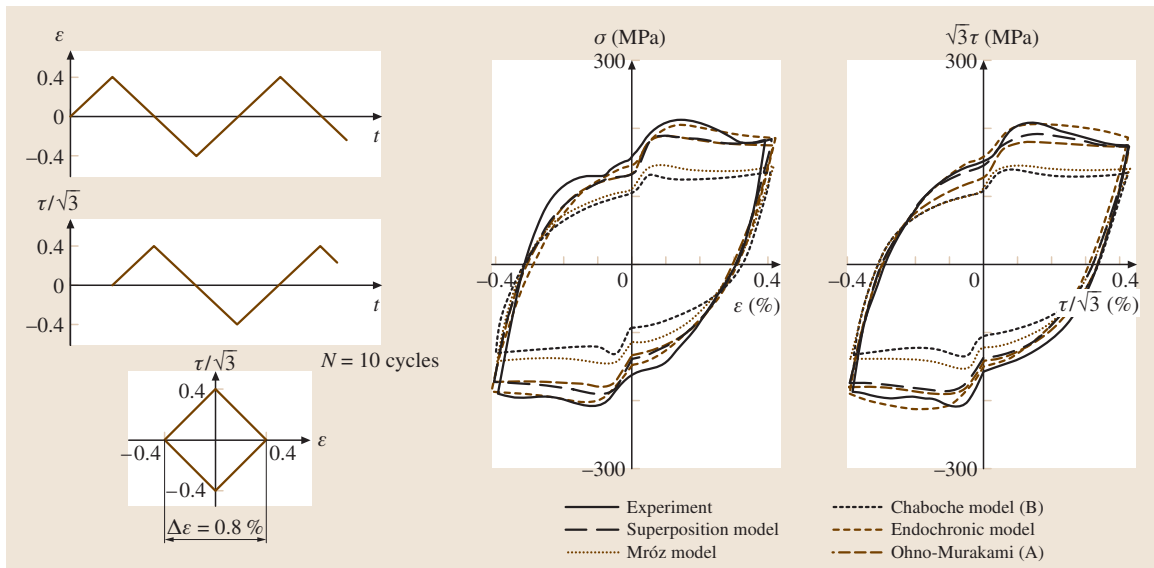

Fig. 18.3 Stress–strain responses under an out-of-phase strain path with square form

controlled stress tests generally exhibit large amounts of scatter.

The next example is stress response under combined states of tension and torsion, where a thin-walled tubular specimen is employed to realize the multiaxial stress. An out-of-phase strain path with a square pattern is imposed on the specimen, as shown on the left-hand side of Fig. 18.3 [18.18]. The stress components show a complicated trajectory due to the out-of-phase strain path. Where the strain trajectory has a corner, the stress trajectory suddenly changes in order to follow the normality

rule, and the magnitude of the stress is generally larger than the normal stress under uniaxial loading. Most of the constitutive models follow the exact trajectory, and the performance of the model is due to the modeling of additional hardening under nonproportional loading. Since all of the parameters used in constitutive models are taken from conventional test data obtained under conditions of uniaxial stress, this particular hardening behavior cannot be predicted in principle. Multiaxiality should preferably be introduced in the model while the parameters are to be simply determined.

18.2 Material Anisotropy

18.2.1 Description of Material Anisotropy

Solids are usually defined in such a way that the material has a reference configuration and that a resistance to deformation occurs. If the resistance of the material depends on the direction, the material is said to be anisotropic, while it is said to be isotropic if the same response is observed for any direction. The anisotropy is characterized by the existence of so-called “anisotropic axes” or “preferred orientations” in material. There are various classes of anisotropy, such as “orthotropy”, “planar anisotropy”, and so on. Here we summarize a rational method of obtaining a concrete form of an anisotropic constitutive equation based on the representation theorem for isotropic tensors [18.19]. Here it should be noted that the term “isotropic tensor” means an objective tensor that is independent of a change of frame; in other words “isotropic” means something very different here to when we use it in relation to isotropic and/or anisotropic material properties. Figure 18.4 describes the fundamental concept of material anisotropy. Let $\mathbf{m}^{(1)}, \mathbf{m}^{(2)} \dots$ be vectors lying along the anisotropic axes, whose components are given by $m_i^{(k)}$ ($k = 1, 2, \dots$) under a particular orthonormal basis \mathbf{e}_i . For example, three kinds of anisotropic axes exist in orthotropic materials, which are mutually orthogonal. Without any loss of generality we can assume that

Fig. 18.4 Basic concept of material anisotropy

each vector is a unit vector and therefore the following relationship holds:

$$m_i^{(1)} m_j^{(1)} + m_i^{(2)} m_j^{(2)} + m_i^{(3)} m_j^{(3)} = \delta_{ij} \quad (18.22)$$

Here δ_{ij} stands for the Kronecker delta.

Any tensor function used in continuum mechanics must fulfill the principle of objectivity. This requires the components to be invariant under the orthogonal transformation Q_{ij} . Suppose that a tensor $T_{ij \dots k}$ is expressible as a function with p sets of vectors $u_i^{(p)}$ and q sets of second-order tensors $U_{ij}^{(q)}$. Then it is expressed as

$$Q_{il} Q_{jm} \dots Q_{kn} T_{lm \dots n} \left[u_s^{(p)}, U_{st}^{(q)} \right] \quad (18.23)$$

$$= T_{ij \dots k} \left[Q_{ls} u_s^{(p)}, Q_{lt} U_{st}^{(q)} \right].$$

The orthogonal transformation of a vector and a second-order tensor takes the form

$$Q_{il} Q_{jm} U_{lm}^{(p)} = U_{ij}^{(p)}, \quad (18.24)$$

$$Q_{il} u_l^{(q)} = u_i^{(q)}. \quad (18.25)$$

Using the representation theorem for isotropic tensors discussed by *Spencer* [18.19], a second-order symmetric isotropic tensor function can be reduced by taking the derivative of a scalar such that

$$T_{ij} = \frac{\partial I}{\partial K_{ij}}. \quad (18.26)$$

Here the scalar function indicates an invariant scalar with arguments that is linear on a symmetric tensor K_{ij} . The scalar I is expressed as

$$I = \phi_1 J_1 + \dots + \phi_r J_r, \quad (18.27)$$

where J_r stands for invariants that are linear on K_{ij} together with arguments $U_{ij}^{(p)}$ and $u_i^{(q)}$; ϕ_r are coefficients expressed as polynomial functions of the invariants of $U_{ij}^{(p)}$, $u_i^{(q)}$ and possible combinations of them. In this case (18.26) can be rewritten in the form

$$T_{ij} = \sum_{s=1}^r \phi_s \frac{\partial J_s}{\partial K_{ij}}. \quad (18.28)$$

The full list of invariants with vectors, symmetric tensors, and skew-symmetric tensors can be found in the literature [18.19, 20]. Isotropic tensors are expressible as multilinear forms of the arguments using this technique.

When we take a symmetric tensor A_{ij} as an argument, the scalar I with K_{ij} is expressed by

$$I = \phi_1 K_{ii} + \phi_2 K_{ij} A_{ji} + \phi_3 K_{ij} A_{jk} A_{ki} \quad (18.29)$$

A second-order symmetric isotropic tensor with one kind of argument is then given via (18.28) by

$$T_{ij} = \phi_1 \delta_{ij} + \phi_2 A_{ij} + \phi_3 A_{ik} A_{kj} \quad (18.30)$$

where ϕ_r ($r = 1, 2, 3$) denote scalar coefficients which are also polynomial functions with the invariants of A_{ij} . When we adopt the second Piola-Kirchhoff stress tensor in T_{ij} and the Green strain tensor in A_{ij} , (18.30) leads to the most general representation for a hyperelastic material. When we pick a special representation which is linear on A_{ij} , (18.30) is reduced to

$$T_{ij} = \phi_1 A_{kk} \delta_{ij} + \phi_2 A_{ij} \quad (18.31)$$

where ϕ_r ($r = 1, 2$) are now constant. When we regard the Cauchy stress as T_{ij} and the infinitesimal strain as A_{ij} , this coincides with the linear elasticity constitutive equation

$$\sigma_{ij} = E_{ijkl} \varepsilon_{kl} = (\lambda \delta_{ij} \delta_{kl} + 2\mu \delta_{ik} \delta_{jl}) \varepsilon_{kl}, \quad (18.32)$$

where ϕ_r have been replaced by Lamé's constants λ and μ .

For the anisotropic elasticity model, the scalar I involves a second-order symmetric tensor A_{ij} and skew-symmetric tensors X_{ij} . Since any skew-symmetric tensor can be characterized by an axial vector m_i using the relationship

$$X_{ij} = \varepsilon_{ijk} m_k \quad (18.33)$$

we can add vectors in deducing the full representation of general anisotropic materials. In the case of planar anisotropy, where one kind of vector lies

perpendicular to the plane, we have five material parameters among the elasticity constants [18.20]. In the most general anisotropic materials within the linear formulation, we have 21 constants because of the following condition imposed on the elasticity constants:

$$E_{ijkl} = E_{jikl} = E_{ijlk} = E_{klij} \quad (18.34)$$

No other condition is imposed on the material parameters.

18.2.2 Initial Anisotropy

Next we discuss the mathematical formulation of plasticity models accounting for initially anisotropic materials that (mainly for simplicity) initially exhibit orthotropy. When materials – particularly ductile metallic materials – deform under certain conditions, the anisotropic axes may change direction. They may not then be mutually orthogonal, even though they were orthogonal in the initial state. The evolution of the anisotropic axes, if the anisotropic vectors are embedded in the material, takes the form

$$\hat{m}_i = \dot{m}_i - W_{ij} m_j = D_{ij} m_j \quad (18.35)$$

where \hat{m} means the Jaumann rate of the vector m . D and W are the stretching tensor and spin tensor respectively. It should be noted that this form is just one of the possible forms, and we do not exclude other formulations. If the orthotropy is maintained throughout the deformation, another type of evolution may be preferable.

A typical yield function for isotropic materials reads

$$F = \frac{1}{2} \sigma'_{ij} \sigma'_{ij} - \frac{1}{3} \bar{\sigma}_y^2 = 0. \quad (18.36)$$

Here σ'_{ij} denotes the deviatoric part of the stress and $\bar{\sigma}_y$ refers to the yield stress. One generalized form with a quadratic yield function was proposed by Hill [18.21], where a fourth-order tensor reflecting material anisotropy plays a central role:

$$F = \frac{1}{2} N_{ijkl} \sigma_{ij} \sigma_{kl} - \frac{1}{3} \bar{\sigma}_y^2 = 0. \quad (18.37)$$

When N_{ijkl} takes the form

$$N_{ijkl} = \frac{1}{2} (\delta_{ik} \delta_{jl} + \delta_{il} \delta_{jk}) - \frac{1}{3} \delta_{ij} \delta_{kl}, \quad (18.38)$$

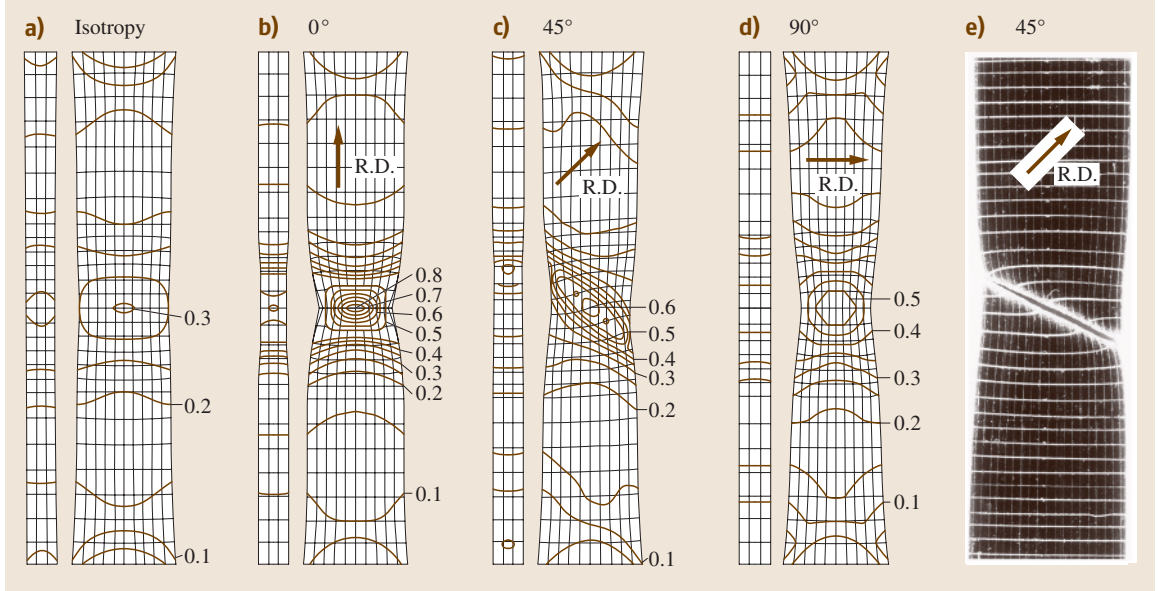

Fig. 18.5 Strain localization behavior of a rolled sheet for various stretch directions

(18.37) is reduced to (18.36). When N_{ijkl} involves $\mathbf{m}^{(1)}$ and $\mathbf{m}^{(2)}$, the fourth-order tensor takes the form

$$\begin{aligned}
 N_{ijkl} = & \lambda_1(\delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk}) + \lambda_2\delta_{ij}\delta_{kl} \\
 & + \frac{1}{2}a_1(\delta_{ij}G_{kl} + G_{ij}\delta_{kl}) \\
 & - \frac{3}{8}a_1(\delta_{ik}G_{jl} + G_{ik}\delta_{jl} + \delta_{il}G_{jk} + G_{il}\delta_{jk}) \\
 & + a_2G_{ij}G_{kl} + \frac{1}{2}a_3(\delta_{ij}H_{kl} + H_{ij}\delta_{kl}) \\
 & - \frac{3}{8}a_3(\delta_{ik}H_{jl} + H_{ik}\delta_{jl} + \delta_{il}H_{jk} + H_{il}\delta_{jk}) \\
 & + a_4H_{ij}H_{kl} + \frac{1}{2}a_5(G_{ij}H_{kl} + H_{ij}G_{kl}), \quad (18.39)
 \end{aligned}$$

where a_1 , a_2 , and a_5 are material parameters with the following symbols:

$$G_{ij} = m_i^{(1)}m_j^{(1)} - \frac{1}{3}m_k^{(1)}m_k^{(1)}\delta_{ij}, \quad (18.40a)$$

$$H_{ij} = m_i^{(2)}m_j^{(2)} - \frac{1}{3}m_k^{(2)}m_k^{(2)}\delta_{ij}. \quad (18.40b)$$

When the norm of the anisotropic vector is kept unitary, the above formulations become slightly simpler because $m_k^{(p)}m_k^{(p)} = 1$ ($p = 1, 2$). Suppose that the anisotropic axes coincide with the base vector, so that they are (1,0,0) and (0,1,0) for example; in this case we can prove that (18.37) is completely identical to Hill's original model.

Since the anisotropic axes change direction during deformation, it is preferable to generalize the representation so that it is applicable to general anisotropy, and this can be done by introducing a more general fourth-order tensor.

In order to examine the effect of initial anisotropy, finite element analysis is implemented based on the updated Lagrangian (U-L) formulation [18.22]. In the U-L formulation, the stress in the constitutive law is regarded as the Jaumann rate of the Kirchhoff stress and the strain rate as the stretching. The balance equation is based on the equilibrium under the Lagrangian system at the current state and the rate-type formulation is employed for this elastic-plastic boundary value problem. This implies that the rate of Lagrange stress is equilibrated and related to the Jaumann rate of the Kirchhoff stress. Converting these terms into discrete levels, we have

$$\begin{aligned}
 \sum_e \int_{V_e} [B^T(D^{\tan} - F)B + E^T Q E] dV \dot{\mathbf{u}}^n \\
 = \sum_e \int_{S_r} N^T \bar{\mathbf{i}} dS
 \end{aligned} \quad (18.41)$$

for the finite element stiffness in the rate-type formulation. Here N , B and E are the shape function, the strain-displacement matrix and the velocity gradient matrix; F and Q are compensation terms due to U-L formulation, and the body force is neglected for sim-

plicity. The simulation proceeds step-by-step by solving the stiffness equation to unknown nodal displacement rate $\dot{\mathbf{u}}^n$.

Figure 18.5 demonstrates the necking behavior of an initially orthotropic sheet [18.23]. A three-dimensional simulation was carried out since the anisotropic vectors could change direction during the course of deformation. The material parameters are obtained from data on carbon steel sheets. The flow stress in a steel sheet is the lowest in the rolling direction (RD) and the highest in the perpendicular direction, while aluminium sheets show an opposite tendency. Figure 18.5a shows simulated results for isotropic material, and the last photograph corresponds to the results of a uniaxial rupture test performed at 45 deg to the rolling direction. The higher the strain concentration, the lower the tensile stress. This implies that the strain concentration in b and c are reasonable, and that the onset of strain localization is affected by the flow stress in the tensile direction. Figure 18.5b shows a characteristic aspect of strain localization where the localization appears in a band inclined to both the rolling direction and the tensile direction. The same tendency is also observed in the experiment.

18.2.3 Induced Anisotropy

The Bauschinger effect is a phenomenon where materials later show anisotropy even when they exhibit isotropy in the initial state. The kinematic hardening law is useful for dealing with this type of anisotropy. In this case, the yield surface is translated in stress space while the shape is not changed. Another type of anisotropy as well as this one is usually found in experiments, called the “cross effect” or the “corner effect” according to pioneering work by *Phillips* [18.24] and *Ikegami* [18.25]. Several models have been proposed so far to describe the subsequent anisotropy, which can be roughly classified into two categories:

- (A) Where the yield function includes higher order tensors representing the anisotropy, as discussed in the previous section. *Baltov* and *Sawczuk* [18.26] proposed a model based on Hill’s quadratic yield function [18.21], and other researchers [18.27, 28] have also employed this concept. The models are simply expressed by

$$F = \frac{1}{2} N_{ijkl} \sigma_{ij} \sigma_{kl} - \frac{1}{3} \bar{\sigma}_y^2 = 0. \quad (18.42)$$

- (B) The other type of formulation assumes that the yield function is composed of the combination of the second and third invariants of the stress J_2

and J_3 . This procedure was proposed by *Drucker* and *Prager* [18.29]. A typical representation [18.30] takes the form

$$F = J_2 - \sum_I \xi_I J_2^{n_I} J_3^{m_I} - \bar{\sigma}_y^2 = 0. \quad (18.43)$$

Here ξ_I, \dots express the inelastic deformation history.

The former is superior to the latter from the viewpoint of parameter identification because (18.43) provides lots of possibilities for the concrete representation of power factors. Taking into account the back stress concept, (18.42) can be modified to

$$F = \frac{1}{2} N_{ijkl} (\sigma_{ij} - \alpha_{ij}) (\sigma_{kl} - \alpha_{kl}) - \frac{1}{3} \bar{\sigma}_y^2 = 0 \quad (18.44)$$

and the kinematic back stress α (or equivalently the plastic strain when employing the Prager hardening rule) and additional variables are introduced into the fourth-order tensor N_{ijkl} . When the fourth-order tensor involves one kind of second-order tensor ξ_{1ij} , the fourth-order tensor N_{ijkl} is simply expressed by

$$N_{ijkl} = \frac{1}{2} (\delta_{ik} \delta_{jl} + \delta_{il} \delta_{jk}) - \frac{1}{3} \delta_{ij} \delta_{kl} + P_1 \xi_{1ij} \xi_{1kl}. \quad (18.45)$$

In order to justify the physical dimension we add the nondimensional back stress: $\xi_{1ij} = \sqrt{3/2} \alpha'_{ij} / \bar{\sigma}_y$. The final form of the yield function is

$$F = \frac{1}{2} (\sigma'_{ij} - \alpha'_{ij}) (\sigma'_{ij} - \alpha'_{ij}) + \frac{3}{4 \bar{\sigma}_y^2} [(\sigma'_{ij} - \alpha'_{ij}) \alpha'_{ij}]^2 - \frac{1}{3} \bar{\sigma}_y^2 = 0 \quad (18.46)$$

although the fourth-order tensor is not a full representation. This yield function is identical to the *Baltov–Sawczuk* yield function [18.26] and it describes elliptical shapes with the yield as locus with the development of ξ_{1ij} (the kinematic back stress α_{ij} or plastic strain ε_{ij}^p). In order to describe higher order distortions [18.31] such as the cross effect, we introduce another kind of second-order tensor ξ_{2ij} into the representation of N_{ijkl} , and then we have

$$N_{ijkl} = \frac{1}{2} (\delta_{ik} \delta_{jl} + \delta_{il} \delta_{jk}) - \frac{1}{3} \delta_{ij} \delta_{kl} + P_1 \xi_{1ij} \xi_{1kl} + P_2 \xi_{2ij} \xi_{2kl} + \frac{Q}{2} (\xi_{1ij} \xi_{2kl} + \xi_{2ij} \xi_{1kl}). \quad (18.47)$$

Fig. 18.6 Descriptions of higher order anisotropy for the cross effect and the corner effect

Here we adopt a nondimensional stress deviator in ξ_{2ij} . Finally the following yield function is obtained:

$$F = (S_{ij} - A_{ij})(S_{ij} - A_{ij}) + P_1[(S_{ij} - A_{ij})A_{ij}]^2 + P_2[(S_{ij} - A_{ij})S_{ij}]^2 + Q[(S_{ij} - A_{ij})A_{ij}][(S_{kl} - A_{kl})S_{kl}] - 1 = 0, \quad (18.48)$$

where we have

$$\xi_{1ij} = \sqrt{\frac{3}{2}} \frac{\alpha'_{ij}}{\bar{\sigma}_y} \equiv A_{ij}, \quad (18.49a)$$

$$\xi_{2ij} = \sqrt{\frac{3}{2}} \frac{\sigma'_{ij}}{\bar{\sigma}_y} \equiv S_{ij}, \quad (18.49b)$$

for simplicity. In terms of choosing parameters, P_1 is dominant for the Bauschinger effect, $P_2 = 0$ ensures initial isotropy, and Q is related to the description of the cross effect. Since the second-order tensors adopted in the model reflect the current state of back stress and stress deviator, particular anisotropy with the path/history dependence can not be described by the model.

Figure 18.6 shows the basic performances of the yield functions [18.31] and the variation in yield locus is shown for a combined tension–torsion stress state, in which the axial and shear stresses are displayed in nondimensional ways such that the values are normalized by the yield stress. Dashed lines exhibit elliptical shapes given by the Baltov–Sawczuk theory, while the solid lines show the results from the higher order theory used to describe the cross effect, which exhibits characteristic hardening backward and perpendicular to the tensile direction. As the deformation increases, the kinematic back stress increases and then the elliptical shape shrinks towards the tensile direction. Since the deformation shown in the figure corresponds to a uniaxial stretch, the yield loci can be determined experimentally.

Experimental verification was performed on stainless steel at an elevated temperature, as shown in Fig. 18.7 [18.31]. Small cyclic loadings under combined tension and torsion were performed as uniaxial tension was applied, and the subsequent yield stresses for these small cycles were measured. The 304 stainless steel shows both kinematic hardening and isotropic hardening, and the parameters are chosen to obtain best fit curves for the yield loci. The development of deformation enhances the anisotropy while expanding the yield locus. The yield locus in particular expands backward and perpendicular to the loading direction. The

Fig. 18.7 Yield loci under monotonic tension

model successfully describes the development of this kind of higher order induced anisotropy. However, when one wishes to include the history effect of asymmetric shape and the corner effect at the loading point,

this model is of no use because it involves current values of stress and back stress. This problem can be overcome introducing a multisurface model in stress space [18.32].

18.3 Metallothermomechanical Coupling

18.3.1 Phase Changes

Engineering processes involving temperature changes, such as casting, welding, heat treatment and so on, are widely used to produce materials and improve their strength and/or functions. In such cases variations in temperature and internal structure dominate the dimensional accuracy of and residual stresses in the final product. Any metallic material has a specific structure, known as a “phase”, under certain conditions of stress, temperature and so on, which is virtually stable for small disturbances. Carbon steels have pearlite and bainite structures at room temperature when they are produced via moderate heat treatment processes. On the other hand, when they undergo rapid cooling from high temperatures, the phase changes from austenite to martensite, and the martensitic structure is quasi-stable at room temperature. Quite a large volumetric change is involved during the quenching process, inducing residual stresses. This implies that temperature, internal structure and stress/strain are all coupled together. Metallothermomechanical coupling theory has been proposed to deal with such processes. Figure 18.8 illustrates the interactions between temperature, structure and stress [18.33]. When the temperature changes during a process, thermal stresses (1) are induced, while the metallic phase may also change (2) depending on the conditions. Stress and strain also influence the temperature (3) due to plastic mechanical work, while they also influence the onset of phase change (6). Mechanical properties are obviously affected by the internal structure, and the volumetric change due to a phase change is a typical example of how to affect the stress/strain field (5). Latent heat (4) is generated during the phase change, which affects the temperature field.

Based on the mixture theory concept [18.34], a simplified model has been proposed for dealing with such complicated processes. Here we regard a particle at point \mathbf{x} as being occupied by a number of components, namely 1, 2, \dots and N . The material properties and/or physical quantities ϕ of the particle

are assumed to be average values based on the lever rule

$$\phi = \sum_{I=1}^N \xi_I \phi_I . \quad (18.50)$$

Here ϕ_I is the property of the I -th constituent and ξ_I indicates the volume fraction of the I -th component. Generally the following relationship holds for the volume fractions:

$$\sum_{I=1}^N \xi_I = 1 \quad (18.51)$$

This means that one of the N volume fractions is not derived independently but is automatically given by the above equation. Using this simple idea, a conventional thermoelastoplasticity theory can be extended into a theory that accounts for metallothermomechanical coupling.

The thermoelastic theory is formulated as follows [18.35, 36]. The elastic strain is expressed in terms of stress, temperature and the volumetric change in structure, and these contribute linearly to the strain. For macroscopically isotropic materials, this is expressible as

$$\varepsilon_{ij} = \left(\frac{1+\nu}{E} \delta_{ik} \delta_{jl} - \frac{1}{E} \delta_{ij} \delta_{kl} \right) \sigma_{kl} + \alpha (T - T_0) \delta_{ij} + \sum_I \beta \xi_I \delta_{ij} . \quad (18.52)$$

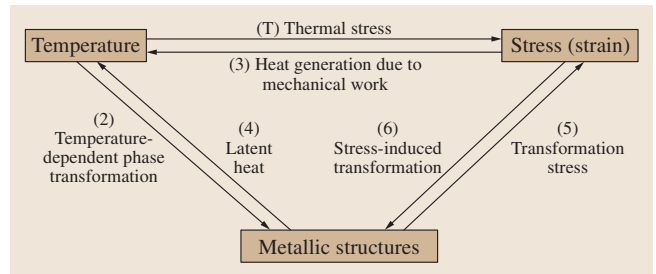

Fig. 18.8 Interaction diagram for thermometallomechanical coupling

Here E and ν are the Young's modulus and Poisson ratio of the material. α is the thermal expansion coefficient, and β_I is the dilatation parameter due to the change in the I -th constituent. The variation in the temperature T plays an important role here. The elasticity parameters and thermal expansion are averaged, and the average values are calculated through (18.50). Taking into account the mechanical work done due to inelastic (plastic) work and the latent heat generation, the heat conduction equation is given by

$$\rho c \frac{\partial T}{\partial t} = \frac{\partial}{\partial x_i} \left(k \frac{\partial T}{\partial x_i} \right) + \sigma_{ik} \dot{\epsilon}_{ki}^p + \sum_I l_I \dot{\xi}_I \quad (18.53)$$

where ρ , c and k are the mass density, the specific heat and the thermal conductivity of the mixture, which are also averaged in the sense of (18.50). Clearly the mechanical work from the second term is only generated during the process of inelastic deformation, and the latent heat of the third term is only dominant when a phase change occurs. The last two factors can be regarded as macroscopic heat generation terms. The conventional plasticity theory is also modified to a generalized form. When we employ the von Mises yield criterion with isotropic hardening, the yield function takes the form

$$F = \frac{1}{2} \sigma'_{ij} \sigma'_{ij} - \frac{1}{3} \bar{\sigma}_y(\kappa, T, \xi_I)^2 = 0 \quad (18.54)$$

in which the yield stress under uniaxial stress involves not only a hardening parameter κ , such as the equivalent plastic strain, but also the temperature T and even the volume fraction ξ_I of each constituent. In order to obtain the current stress, temperature and structures, these equations are implemented in incremental calculations, so the rate-type formulation is employed and adopted in the numerical scheme.

The kinetics of phase transformation is another issue to be discussed. Typical phase transformations in metallic structures include austenite–perlite, ferrite, martensite and bainite transformations [18.37–39]. These solid–solid phase transformations are classified into two or three categories: the diffusion-driven phase transformation, the non-diffusion-driven type transformation, and a mixture of them. The perlite and ferrite phase transformations are characterized by the first category, while the martensite transformation falls into the second category. Here we summarize typical evolution laws for volume changes due to phase transformations. The dependence of phase transformations on stress involves another topic called “transformation plasticity”, in which permanent deformation is induced by low stress levels. However, we will not discuss this topic here; instead we limit our discussions to the kinetics associated with phase changes.

Johnson and Mehl [18.40] proposed the following volume fraction for the phase transformation from austenite to perlite:

$$\xi_P = 1 - \exp(-V_e) \quad (18.55)$$

Here ξ_P refers to the perlite nucleated from the austenite. ξ_A is the volume fraction of austenite, while V_e stands for the residual volume of austenite, which is expressed by

$$V_e = \int_0^t \frac{4}{3} \pi \dot{S} R^3(t - \tau) d\tau. \quad (18.56)$$

Here \dot{S} and R are the rates of nucleation and growth respectively. It is assumed in this theory that nuclei are spherical. The integrand is affected by both temperature and stress, and so we have

$$V_e = \int_0^t f(T, \sigma_m) \cdot (t - \tau) d\tau \quad (18.57)$$

The material function $f(T, \sigma_m)$ can be specified from a so-called T–T–T diagram (or S-curve) under various stress states (pressures). The phase transformation therefore depends on both stress and temperature, and the volume change affects the stress field due to the changes in parameters, while the latent heat influences the heat conduction.

There are also several models for the process of martensite transformation, and a phenomenological treatment proposed by Magee [18.41] is introduced here. The martensite transformation starts at a point M_s where

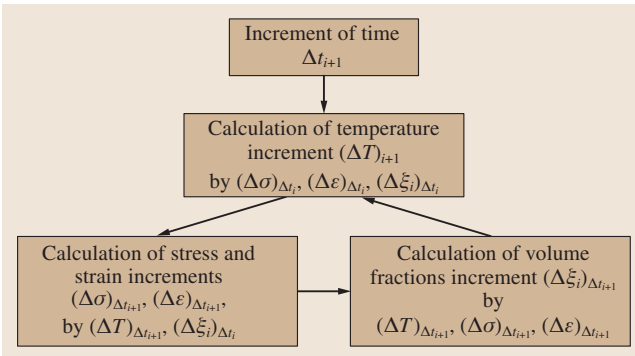

Fig. 18.9 Numerical algorithm for solving the coupled system of equations

two phases have different free energy levels. This is due to the characteristics of non-diffusion-type phase transformation. Combining the stress-induced terms, the volume of martensite ξ_M is given by

$$\xi_M = 1 - \exp \left[\phi_1 (M_s - T) + \phi_2 \sigma_m + \phi_3 J_2^{1/2} \right]. \quad (18.58)$$

Here ϕ_1 , ϕ_2 and ϕ_3 are material parameters. The temperature is dominated by the first term while the mean stress and the deviatoric stress also affect the martensite transformation. If a perlite phase ξ_P exists at the onset of martensite transformation, the above equation is modified to

$$\xi_M = (1 - \xi_P) \times \left\{ 1 - \exp \left[\phi_1 (M_s - T) + \phi_2 \sigma_m + \phi_3 J_2^{1/2} \right] \right\}. \quad (18.59)$$

This means that only the austenite contributes to the nucleation of martensite. These are typical kinetics equations of solid–solid phase transformations. As well as these equations, one has to consider solid–liquid transformation when dealing with welding and casting. In this case, however, one must return to the original idea that any material parameter is given in an averaged manner, because the constitutive equation of liquids is completely different to that of solids, and the shear viscosity is generally much smaller in liquid.

18.3.2 Numerical Methodology

It is important to find an efficient procedure that can be used to solve the process of thermometallomechanical coupling in a system. The mechanical equations comprise a set of elliptic-type differential equations, while thermal conduction is governed by a typical diffusion (parabolic) equation. The kinetics of phase transformation are also given explicitly. This implies that the temperature and stress/strain are solved using a finite element/finite volume method, while the variation in internal structure can be taken into account using internal state variables. In order to obtain the numerical solution step-by-step, a suitable algorithm needs to be constructed. Using simple estimation of the sensitivity to each term, it becomes clear that thermal conduction is generally dominant, and that the time step should be controlled with reference to the thermal conduction if the mechanical equation is based on quasi-static motion. The next greatest influence is the effect of a phase change on the stress/strain response. Using this, the following numerical scheme can be established.

A schematic of the algorithm is shown in Fig. 18.9 [18.33]. Let Δt be the time increment prescribed on an object. The temperature is first updated using the solution for ΔT where ΔT is obtained using only the values at the current time step t_i . The time increment Δt is small enough to obtain a stable solution for the temperature. Using this temperature increment ΔT , the kinetics are then updated and the volume fractions $\Delta \xi_j$ are modified during the time increment Δt . Since the change in the volume fraction affects the stress/strain field, the stress and strain are calculated, with the temperature variation, last of all. When the mechanical equation is solved for dynamic motion, substeps with smaller time increments are superimposed on the time step Δt [18.36]. Although this iterative process should proceed until the solution is converges from one time step t_i to the next t_{i+1} , reasonable solutions can be found even when the calculation only passes through each step once.

18.3.3 Applications to Heat Treatment and Metal Forming

Thermometallomechanical coupling simulations have been applied in the fields of heat treatment, welding, casting and so on, which have the greatest need for dimensional accuracy and to know residual stresses. For example, when a steel is rapidly cooled from a high-temperature austenitic state, the structure changes to martensite below the M_s transformation state. The volume increases during this process due to dilatation, which generally induces compressive stresses. We now demonstrate a few examples of this from the field of metal forming.

The austenitic stainless steel type SUS304 has a characteristic feature where the austenite at room temperature is said to be quasi-stable and transformed into martensite under large inelastic deformation. This implies that the stainless steel shows phase transformation during the course of forming. Figure 18.10 shows the volume fraction of the martensite during a stamping process [18.36]. A rigid die pushes down from the top of the object, which generates friction between the die and the material. The upper figure shows experimental data for the volume of martensite in % [18.42], while the lower figure corresponds to simulated results. The distribution of the martensite structure observed is caused by both the deformation and the rate of deformation, while the thermal conditions also influence the structural distribution to some degree. Due to the constraints from the friction between the die and material, the center of the top of the material is almost fixed and so less deforma-

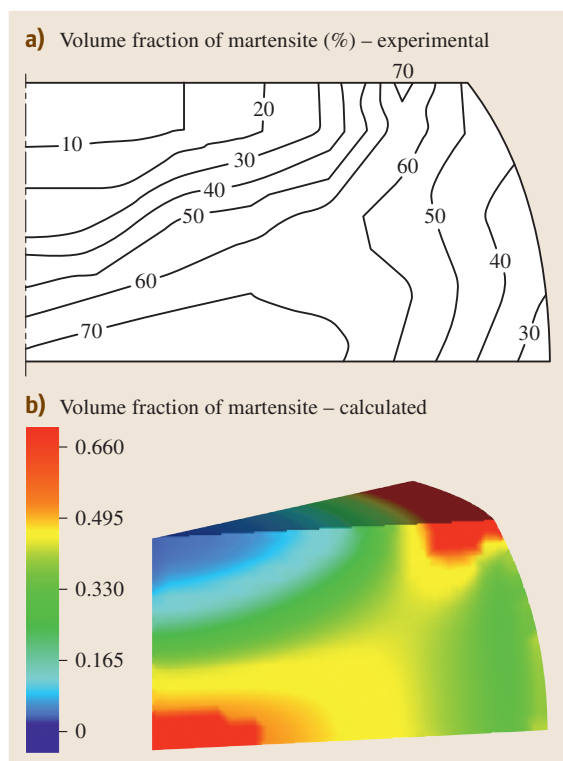

Fig. 18.10 Experimental and calculated martensite volume fractions caused by stamping

tion is induced here during the process. The martensite distribution in the experiment is obtained by a coupled usage of magnetic measurement and X-ray diffraction. The simulation successfully grasps the martensite trans-

formation and shows a good agreement in tendency with the experimental ones.

The advantage of using this type of simulation is that the temperature, stress/strain and metallic structure can be obtained at any time. The next example, shown in Fig. 18.11, demonstrates the effect of friction on the internal structure and the rate of forming on the stress level [18.43]. The upper figures indicate the residual martensite structure after the forging. The left side Fig. 18.11a shows the martensite structure when a small friction coefficient (0.1) between the die and material is used, and the right-hand side (Fig. 18.11b) corresponds to a larger friction coefficient of 0.2. Since larger shear stress is induced when overcoming the resistance from the die with larger friction, we expect more strain to be generated, particularly at the teeth of the die. This implies that more martensite appears around the bottom of the teeth. The simulated equivalent stress distributions for the first stroke with a friction coefficient of 0.1 during high strain rate and low strain rate forging are depicted in the lower parts of Figs. 18.11c, d. The martensite distributions in both of these cases at this stage are similar and small values are obtained. The stresses for a high strain rate are higher than the stresses for a low strain rate from the beginning of the stroke until the end of the loading stage shown in Figs. 18.11c, d. During this period, the hardening behavior of the material is determined mainly by austenite, since the martensite content is low. However, with the generation of martensite, the flow stress becomes strongly dependent on the martensite fraction in the material. The low strain rate produces much higher stresses at the end of the simulation due to larger amounts of martensite.

18.4 Crystal Plasticity

18.4.1 Single-Crystal Model

The phenomenological plasticity models discussed so far have been successful used to describe various classes of material behavior, not only for complex loading histories but also for nonisothermal conditions with varying temperature. However, we have not yet discussed the real physical mechanism of crystal deformation, and so this has not been reflected in the models. Real plastic deformation is mainly caused by slip in grains, as was pointed out from a continuum mechanics viewpoint by Taylor [18.44] and Hill [18.21]. Grain boundary sliding also plays an important role in mechanical behavior at elevated temperatures. Asaro and coworkers [18.45]

proposed a concise model for single crystals which relates the crystal slip to the macroscopic strain. In this section we discuss plastic material behavior from a microscopic view based on the Asaro model, and relate the microscopic deformation to continuum deformation at the macroscopic level. Infinitesimal deformation theory is employed throughout here, and this enables us to reduce the simulation load drastically. Detailed discussions on finitely deforming crystals can be found in the original and related articles.

Metallic materials have a certain regularity of atomic configuration, such as body-centered cubic (bcc), face-centered cubic (fcc), hexagonal close packed (hcp), and so on. Each crystal structure has a particular plane and

Fig. 18.11 The effects of friction and speed on the forging process. The *top* figures demonstrate the effect of friction on martensite transformation under low deformation rate, while the *bottom* figure shows the equivalent stress levels under different punch speeds

direction of permanent deformation. For example, an fcc crystal has 12 primary slip systems. Once we obtain a suitable model for describing the local slip due to the local stress acting on a crystal, we can then expect to be able to predict macroscopic deformation as the sum of all local deformations. When slip occurs in a crystal, the change of configuration can be expressed by the geometrical information of the system that has undergone slip and the amount of slip γ . Figure 18.12 illustrates the basic idea of crystal slip. Let $\mathbf{m}^{(\alpha)}$ be the plane and $\mathbf{s}^{(\alpha)}$ be the direction associated with the slip system (α). Taking into account the distortion of the crystal lattice due to elasticity, the total deformation gradient \mathbf{F} (F_{ij}) can be expressed as

$$F_{ij} = F_{ik}^* F_{kj}^p. \quad (18.60)$$

Here \mathbf{F}^* indicates the distortion and translation that are mainly due to elastic deformation, while \mathbf{F}^p is the permanent deformation due to crystal slip. The velocity

Fig. 18.12 Schematic view of a slip system and the decomposition of deformation

gradient then takes the form

$$\mathbf{L} = \dot{\mathbf{F}}^* \mathbf{F}^{*-1} + \mathbf{F}^* \dot{\mathbf{F}}^P \mathbf{F}^{P-1} \mathbf{F}^{*-1}. \quad (18.61)$$

The slip system can be addressed using infinitesimal deformation theory. Assuming that plastic deformation is only caused by the sum of primary slips, the evolution of the plastic part is composed of

$$\dot{\mathbf{F}}^P \mathbf{F}^{P-1} = \sum_{\alpha} \dot{\gamma}^{(\alpha)} \mathbf{s}^{(\alpha)} \mathbf{m}^{(\alpha)} \quad (18.62)$$

where γ^P stands for the amount of shear strain of the slip system (α). The plastic strain rate is then given by the symmetric part of the above equation. Elastic strain covers the rest of the strain rate, and the elastic rate is related to the stress rate via elasticity moduli. The resolved shear stress acting on the system (α) can be expressed using the stress theorem as

$$\tau^{(\alpha)} = \mathbf{s}^{(\alpha)} \left(\boldsymbol{\sigma}^T \mathbf{m}^{(\alpha)} \right), \quad (18.63)$$

It is then necessary to connect the shear strain rate and the resolved shear stress. A power law formula involving the resolved shear stress and strain rate was proposed by Hutchinson [18.46], Pan and Rice [18.47] as

$$\dot{\gamma}^{(\alpha)} = a_0 \left| \frac{\tau^{(\alpha)}}{g^{(\alpha)}} \right|^{1/m-1} \left[\frac{\tau^{(\alpha)}}{g^{(\alpha)}} \right]. \quad (18.64)$$

Here the function $g(\gamma^P)$ is the resistance, a kind of drag stress, under constant shear strain rate. The evolution of $g(\gamma^P)$ is governed not only by the shear slips themselves but also by the interactions of different slip systems. This implies that the rate of $g(\gamma^P)$ is expressed by

$$\dot{g}^{(\alpha)} = \sum_{\beta} h_{\alpha\beta} \left| \dot{\gamma}^{(\beta)} \right|. \quad (18.65)$$

The coefficient $h_{\alpha\beta}$ addresses the effect of slip (β) on another slip (α). This coefficient $h_{\alpha\beta}$ is suitably defined using a function involving total shear strain, critical shear stress, interaction parameters and so on. From these considerations, the total strain rate at the macroscopic level is related to the microscopic deformation as follows: (1) The stress is decomposed into the resolved shear stress of a particular slip system, (2) the local stress then acts on the shear slip, and finally (3) each slip is summed, giving the macroscopic strain. Solving the above equation for the stress rate, we obtain

$$\dot{\sigma}_{ij} = E_{ijkl} \dot{\epsilon}_{kl} - \sum_{\alpha} \dot{\gamma}^{(\alpha)} E_{ijkl} P_{kl}^{(\alpha)} \quad (18.66)$$

using the infinitesimal deformation theory. In the above equation $\dot{\gamma}^{(\alpha)} \mathbf{P}^{(\alpha)}$ stands for the symmetric part of (18.62) and therefore the plastic strain rate under infinitesimal deformation. The effect of the crystal grain size has also been considered, taking the strain gradient into account [18.48].

Fig. 18.13 Grain boundary sliding using a contact/slide element

Fig. 18.14 Strain concentration behavior with different grain boundary geometries

18.4.2 Grain Boundary Sliding

Most metallic materials are composed of large numbers of crystal grains, each of which is located in a particular neighborhood defined via grain boundaries. The orientation of each crystal is believed to be random; the macroscopic deformation behavior of polycrystalline materials is reflected in this randomness. The material isotropy of polycrystalline materials is caused by the competing/misfitting effects of crystal slip on neighborhoods. Since the grain boundary can be regarded as a discontinuous plane under strain, it is particularly important to ensure that the mechanical analysis and the boundary sliding model successfully describes not only polycrystal deformation but also damage evolution at elevated temperatures [18.49].

One simple way to idealize grain boundary sliding is to use a special contact/slip model for the grain boundary. A stiffness is introduced as shown in Fig. 18.13, where the contact model is readily applied to the contact/slide element in the finite element technique [18.50]. The local coordinate system can be defined at the grain boundary such that the connecting force is decomposed into the normal force (t_n) and shear force (t_{s1} , t_{s2}). In the case of linear stiffness, we have

$$\begin{pmatrix} t_{s1} \\ t_{s2} \\ t_n \end{pmatrix} \begin{bmatrix} k_s & 0 & 0 \\ 0 & k_s & 0 \\ 0 & 0 & k_n \end{bmatrix} \begin{pmatrix} \delta_{s1} \\ \delta_{s2} \\ \delta_n \end{pmatrix}. \quad (18.67)$$

The normal component is devoted to the opening and closing (δ_n) of the grain boundary, while the shear component is related to relative sliding (δ_{s1} , δ_{s2}). The normal stiffness k_n is set to a large enough value that it causes neither detaching nor overlapping with the neighboring crystal. Permanent shear sliding is also allowed and modeling is also performed on the basis of the Mohr–Coulomb yield condition. The constitutive model for the contact/sliding is then similar to the model for the bulk crystal. It should be pointed out, however, that stiffness parameters are rarely specified in conventional test data, and it is even believed that large variations in stiffness occur which affect the real evolution of damage. *Tvergaard* and coworkers [18.49] employed viscous sliding at the grain boundary which they applied to investigate tertiary creep and damage evolution.

18.4.3 Inhomogeneous Deformation

In this section two examples of simulation are described: one considers the role of the geometry of the grain boundary while the other investigates the development

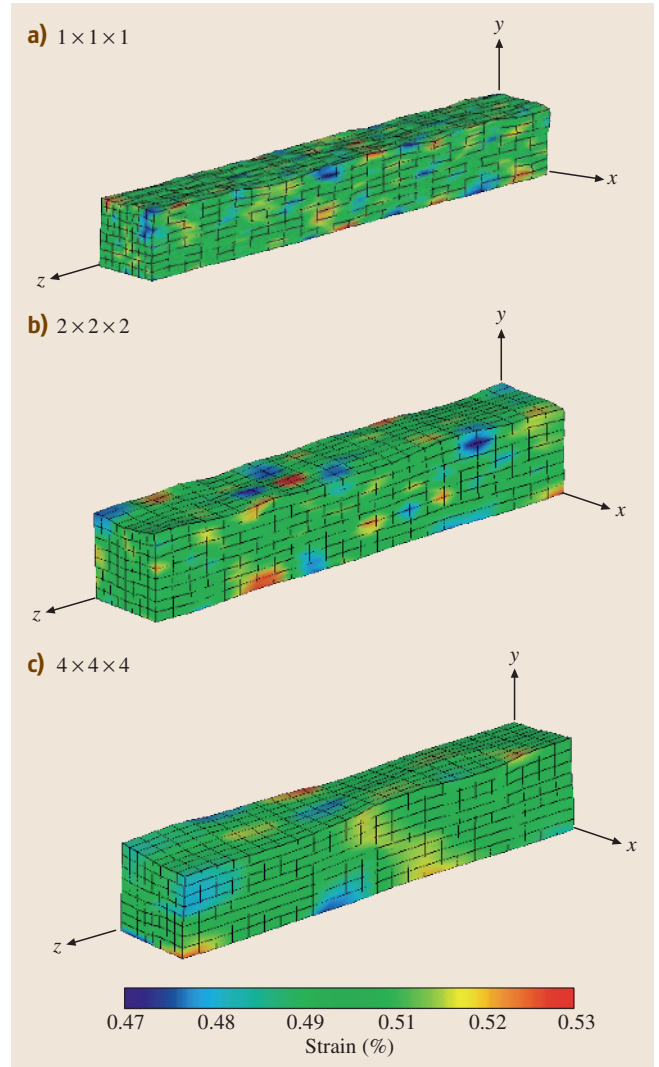

Fig. 18.15 Inhomogeneous deformation and surface roughness. The formation of a wavy pattern is observed in a large-scale simulation

of surface roughness. In order to evaluate the effects of the grain boundary, we look at (a) combinations of slip systems, (b) the contact geometry, and (c) the contact stiffness. It was found that the contact stiffness (c) and the interactions of slip systems (a) have relatively small effects on the variation in strain concentration. When the stiffness is large, nodal discrepancy is restrained and so the strain concentration is enhanced to some extent, but this is not a significant factor compared to the effect of geometry (b). Figure 18.14 shows how the strain distribution relates to the inclined geometry of the grain

boundary [18.51]. The strain distribution varies greatly in models of highly inclined crystals. Since the effect of a slip system is examined in the central figure, where the grain boundary forms a horizontally flat surface, the differences observed in the other figures reflect the effect of grain boundary geometry. It follows from these figures that the strain distribution around the grain boundary is strongly affected by its geometry. Although the influence of the boundary geometry is usually far less than the factors related to mechanical behavior, the randomness of the geometry dominates the variation in the strain, and the variation in the strain may be related to damage evolution in polycrystalline materials.

The size of the crystal grain affects statistical properties related to mechanical behavior. Here we examine the effect of size on the surface roughness. It is worth noting that the real size is not taken into account because the crystal model does not reflect the real size. Introduction of higher order variables such as strain gradient or nonlocal variables covering a certain range of physical distance is a promising way to capture the real size effect in crystal grains. Figure 18.15 depicts the deformed shape of a finite element mesh under monotonic tension along the z -direction [18.51]. Grain boundary sliding is

not introduced in the model. $8 \times 8 \times 24 = 1536$ cubic elements are located in the objective domain, and each element has random crystal slip system in Fig. 18.15a. $2 \times 2 \times 2 (= 8)$ elements compose a block corresponding to a crystal grain, associated with the same slip system used in Fig. 18.15b, and $4 \times 4 \times 4 (= 64)$ elements form a block with the same slip system used in Fig. 18.15c. The displacement on the surface is magnified to emphasize the surface state. The variation in strain occurs due to competing/misfitting effects with a neighboring grain (block); in other words the strain concentration increases when the slip system has a large misfit with the neighborhood. It should be pointed out that a wavy pattern is predicted by every simulation model, and that the wavelength seems to be proportional to the block (grain) size. In fact, experimental results suggest that surface roughness is enhanced during plastic deformation, and that the wavelength of this is equal to the several times the average crystal grain size. The simulated results qualitatively agree with this tendency, although other kinds of uncertainties, in for example mechanical parameters, grain boundary stiffness and variation in grain sizes, apply to real materials.

19. Finite Element and Finite Difference Methods

Finite element methods (FEM) and finite difference methods (FDM) are numerical procedures for obtaining approximated solutions to boundary-value or initial-value problems. They can be applied to various areas of materials measurement and testing, especially for the characterization of mechanically or thermally loaded specimens or components. (Experimental methods for these fields have been treated in Chpts. 7 and 8.)

The principle is to replace an entire continuous domain of a body of interest by a number of subdomains in which the unknown function is represented by simple interpolation functions with unknown coefficients. Thus, the original boundary-value problem with an infinite number of degrees of freedom is converted into a problem with a finite number of degrees of freedom approximately.

A finite element analysis includes the following basic steps:

- Discretization or subdivision of the domain of the body of interest.
- Selection of the interpolation functions to provide an approximation of the unknown solution within an element.
- Formulation of the system of equations (using, for example, the typical Ritz variational and Galerkin methods).

- Solution of the system of equations. If the system of equations is solved, the desired physical variables at the nodes can then be computed and the results displayed in form of curves, plots, or color pictures, which are more meaningful and interpretable.

Finite element methods (FEM) use a complex system of points called *nodes*, which make up a grid called a *mesh*. This mesh is programmed to contain the *material and structural properties* that define how the structure will

react to certain loading conditions. Nodes are assigned at a certain density throughout the material depending on the anticipated stress levels of a particular area. Regions that receive large amounts of stress usually have a higher node density than those that experience little or no stress. Points of interest may concern, for example, fracture points of previously tested materials (see Sect. 7.4) or high-stress areas. The mesh acts like a spider web in that from each node, there extends a mesh element for each of the adjacent nodes. This web of vectors is what carries the *material properties* to the object, creating many elements.

As a typical example, consider a material or a body in which the distribution of an unknown variable – such as temperature or displacement – is required. The first step of any finite element analysis is to divide the actual geometry of the structure using a collection of discrete portions called *finite elements*. The elements are joined together by shared nodes. The collection of nodes and finite elements is known as the *mesh* (Fig. 19.1).

The variable to be determined in the analysis is assumed to act over each element in a predefined manner. The number and type of elements is chosen to ensure that the variable distribution over the whole body is adequately approximated by the combined elemental representations. After the problem has been divided into discrete units, the governing equations for each element are formulated and then assembled to give a system equations that describe the behavior of the body as a whole.

Finite difference methods (FDM) are also based on the similar idea. In this method, the elements and mesh are called grids and grid, respectively (Fig. 19.2). The major differences of FDM from FEM are (1) Governing partial differential equations are approximated directly by finite difference approximation, not by interpolation functions nor via the Galerkin method, (2) The discretized whole domain is not covered by a finite number of interpolation functions, but is represented by a finite number of sampling nodes. A finite difference analysis can be summarized as follows:

- Discretization or subdivision of the domain of the body of interest.
- Selection of the finite difference functions to provide an approximation of the derivatives of unknown solution at a node.

Fig. 19.1 Collection of nodes and finite elements (mesh) in FEM

Fig. 19.2 Collection of nodes and grids in FDM

- Formulation of the system of equations at all the nodes.
- Solution of the system of equations. If the system of equations is solved, the desired physical variables at the nodes can then be computed and the results displayed in form of curves, plots, or color pictures, which are more meaningful and interpretable, just as FEM does.

In this chapter, both FEM and FDM are explained. The contents include the basics necessary to understand the formulation, more advanced topics, practical information, and information on the use of commercial software. This chapter is for nonspecialists in macroscopic mechanics and computational mechanics, so only the key concepts are focused on in the discussion. Since the reader might not be accustomed to tensor representation, all derivations are shown without tensor notations. The explanation will focus on a steady or unsteady heat conduction problem in the one-dimensional case, however, multi-dimensional and nonlinear cases are also handled within the limited pages.

19.1 Discretized Numerical Schemes for FEM and FDM

FEM and **FDM** are classified into so-called discretized numerical schemes. Discretized numerical schemes are approximated ways to solve boundary problems, described by partial differential equations, with complex shaped domain with complicated boundary conditions, which can usually not be solved analytically by hand calculation. It should be noted that **FEM** and **FDM** are not applicable to phenomena that cannot be represented by partial differential equations.

In this section, we will focus on the process of discretized numerical schemes by using a simple example of a two-coupled spring model.

The relationship between a displacement u and a force F can be connected with a spring constant k as in the following equation, based on the knowledge of high school's physics

$$ku = F. \quad (19.1)$$

Fig. 19.3 Simple spring model

For the preparation to consider a more complicated case, we'd like to extend (19.1) for a more general case by introducing a spring model element, as shown in Fig. 19.4.

Fig. 19.4 Spring model element

By introducing u_1 , F_1 , u_2 , and F_2 at nodes 1 and 2, the spring model element can be represented with matrix notation as in (19.2):

$$\begin{pmatrix} k & -k \\ -k & k \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \end{pmatrix} = \begin{pmatrix} F_1 \\ F_2 \end{pmatrix}. \quad (19.2)$$

By setting $u_1 = 0$ as a boundary condition, this matrix system is reduced to (19.1) in the following fashion:

$$\begin{pmatrix} k & -k \\ -k & k \end{pmatrix} \begin{pmatrix} 0 \\ u_2 \end{pmatrix} = \begin{pmatrix} F_1 \\ F_2 \end{pmatrix}, \quad (19.3)$$

$$\begin{pmatrix} -k \\ k \end{pmatrix} (u_2) = \begin{pmatrix} F_1 \\ F_2 \end{pmatrix}. \quad (19.4)$$

Since the first row cannot be used for calculation due to the unknown value of F_1 , we can get the same equation as (19.1) by omitting the first row in (19.4):

$$ku_2 = F_2. \quad (19.5)$$

This is just a warm-up explanation of the two-coupled spring model below.

Now let's think about the following two-spring coupling model.

Fig. 19.5 Two-coupled spring model

The two-coupled spring model can be divided into two spring-model elements as shown in Fig. 19.6.

By combining two matrices in Fig. 19.6, we get the following system of equations

$$\begin{pmatrix} k_1 & -k_1 & 0 \\ -k_1 & k_1 & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \\ u_3 \end{pmatrix} = \begin{pmatrix} F_1 \\ F_{21} \\ 0 \end{pmatrix}$$

$$\begin{pmatrix} 0 & 0 & 0 \\ 0 & k_2 & -k_2 \\ 0 & -k_2 & k_2 \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \\ u_3 \end{pmatrix} = \begin{pmatrix} 0 \\ F_{22} \\ F_3 \end{pmatrix}$$

$$\rightarrow \begin{pmatrix} k_1 & -k_1 & 0 \\ -k_1 & k_1 + k_2 & -k_2 \\ 0 & -k_2 & k_2 \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \\ u_3 \end{pmatrix} = \begin{pmatrix} F_1 \\ F_{21} + F_{22} \\ F_3 \end{pmatrix}. \quad (19.6)$$

Fig. 19.6 Two elements of the two-spring model

Since the inner force is always balanced, $F_{12} + F_{22} = 0$. Then,

$$\begin{pmatrix} k_1 & -k_1 & 0 \\ -k_1 & k_1 + k_2 & -k_2 \\ 0 & -k_2 & k_2 \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \\ u_3 \end{pmatrix} = \begin{pmatrix} F_1 \\ 0 \\ F_3 \end{pmatrix}. \quad (19.7)$$

However, the combined matrix above cannot be inverted due to the singularity of the matrix, which is physically interpreted such that the position of the balancing springs in air is not determined explicitly. We need a fixed point to solve this matrix, which is called a (first) boundary condition. Suppose that node 1 is fixed as $u_1 = 0$. In this case, the matrix becomes solvable in the following way.

1. Substitute $u_1 = 0$ into the matrix system:

$$\begin{pmatrix} k_1 & -k_1 & 0 \\ -k_1 & k_1 + k_2 & -k_2 \\ 0 & -k_2 & k_2 \end{pmatrix} \begin{pmatrix} 0 \\ u_2 \\ u_3 \end{pmatrix} = \begin{pmatrix} F_1 \\ 0 \\ F_3 \end{pmatrix}; \quad (19.8)$$

2. Omit the first column in the matrix:

$$\begin{pmatrix} -k_1 & 0 \\ k_1 + k_2 & -k_2 \\ -k_2 & k_2 \end{pmatrix} \begin{pmatrix} u_2 \\ u_3 \end{pmatrix} = \begin{pmatrix} F_1 \\ 0 \\ F_3 \end{pmatrix}; \quad (19.9)$$

3. Since F_1 is an unknown value, the first row is omitted. Then we get a 2×2 matrix system that is now

solvable:

$$\begin{pmatrix} k_1 + k_2 & -k_2 \\ -k_2 & k_2 \end{pmatrix} \begin{pmatrix} u_2 \\ u_3 \end{pmatrix} = \begin{pmatrix} 0 \\ F_3 \end{pmatrix}. \quad (19.10)$$

By solving the matrix system of (19.10), we get the following solutions, which is equivalent to the formula of the two-coupled spring model $1/k = 1/k_1 + 1/k_2$:

$$\begin{aligned} u_2 &= \frac{F_3}{k_1}, \\ u_3 &= \frac{F_3}{k_1} + \frac{F_3}{k_2}. \end{aligned} \quad (19.11)$$

The procedure above can be summarized as follows:

1. Discretize the targeted domain into basic element models.
2. Construct a balancing (equilibrium) equation (local matrix) at each basic element model.
3. Combine all local matrices, add boundary conditions, and then solve global the matrix.

The process explained above is common among so-called discretized numerical schemes such as **FEM** and **FDM**. Usually the spring constant above becomes a “spring” coefficient matrix in these methods. The only difference between **FEM** and **FDM** can be summarized in the way to derive the “spring matrix” part. We’ll treat basic derivations in **FEM** and **FDM** in the following section.

19.2 Basic Derivations in FEM and FDM

The governing equation of steady heat conduction problems in the one-dimensional case is given by the following equation, where u is a temperature, k is a heat conduction coefficient, and f is a heat source:

Fig. 19.7 One-dimensional steady heat conduction problem

$$k \frac{\partial^2 u}{\partial x^2} = -f. \quad (19.12)$$

Suppose that the boundary conditions (please recall Sect. 19.1) are provided as follows:

$$\begin{aligned} u(1) &= a \quad (u = a \text{ at } x = 1), \\ u_x(0) &= b \quad \left(\frac{\partial u}{\partial x} = b \text{ at } x = 0 \right). \end{aligned} \quad (19.13)$$

Here, $u(x_0) = a$ is called either the first boundary condition or the Dirichlet boundary condition, while the boundary condition of $u_x(x_0) = b$ is named the second boundary condition or Neumann boundary condition. The problem represented by (19.12) and (19.13) is defined as a boundary value problem. (For unsteady problems, please refer to Sect. 19.6.)

Of course, the analytical solution of this problem can be given in the following form in this case, but we would like to consider the approximated numerical simulation by FDM and FEM in the following parts:

$$u(x) = a + (x-1)b + \int_x^1 \left[\int_0^y f(z) dz \right] dy. \quad (19.14)$$

The exact solution function with respect to (wrt) the x -coordinate, under the parameters of $a = 1$, $b = 0.2$, $f = 1$, $h = 0.5$, and $k = 1$, is

$$\begin{aligned} u(x) &= -0.5x^2 + 0.2x + 1.3, \\ [u(0) &= 1.300, u(0.5) = 1.275, u(1) = 1.000]. \end{aligned} \quad (19.15)$$

19.2.1 Finite Difference Method (FDM)

In FDM, the derivatives of the governing equation are replaced by so-called finite difference approximations.

Fig. 19.8 Finite difference approximation of the first derivative of u wrt x

To approximate first derivative $\partial u / \partial x$ at node n in Fig. 19.8, there exist three schemes in FDM. The central difference scheme in (19.16) guarantees second-order accuracy with respect to x , and first-order accuracy in the other two “one-sided” methods in (19.17) and (19.18) [19.1].

Central difference scheme:

$$\begin{aligned} \frac{\partial u}{\partial x} &= \lim_{h \rightarrow 0} \frac{u(x+h) - u(x-h)}{2h} \\ &\approx \frac{u(x+h) - u(x-h)}{2h}; \end{aligned} \quad (19.16)$$

Backward difference scheme:

$$\frac{\partial u}{\partial x} = \lim_{h \rightarrow 0} \frac{u(x) - u(x-h)}{h} \approx \frac{u(x) - u(x-h)}{h}; \quad (19.17)$$

Forward difference scheme:

$$\frac{\partial u}{\partial x} = \lim_{h \rightarrow 0} \frac{u(x+h) - u(x)}{h} \approx \frac{u(x+h) - u(x)}{h}. \quad (19.18)$$

Fig. 19.9 Finite difference approximation of the second derivative of u wrt x

We can derive the following finite difference approximation on the second derivative of u , $\partial^2 u / \partial x^2$, by applying the backward difference scheme at $x = x - h/2$ and the forward difference scheme at $x = x + h/2$ on the first derivative of u , $\partial u / \partial x$:

$$\begin{aligned} \frac{\partial^2 u}{\partial x^2} &\approx \frac{\frac{\partial u}{\partial x} \Big|_{x=x+\frac{h}{2}} - \frac{\partial u}{\partial x} \Big|_{x=x-\frac{h}{2}}}{h} \\ &\approx \frac{\frac{u(x+h) - u(x)}{h} - \frac{u(x) - u(x-h)}{h}}{h} \\ &= \frac{u(x+h) - 2u(x) + u(x-h)}{h^2}. \end{aligned} \quad (19.19)$$

Now we can apply the above finite difference approximations to the given problem in Fig. 19.7:

$$k \frac{\partial^2 u}{\partial x^2} = -f, \quad (19.20)$$

$$u(1) = a(u = a \text{ at } x = 1),$$

$$u_x(0) = b \left(\frac{\partial u}{\partial x} = b \text{ at } x = 0 \right). \quad (19.21)$$

Fig. 19.10 Finite difference grids with a mirror node introduced

Suppose that the domain is discretized into two grids. Applying the difference scheme for second derivatives to the governing equation in (19.20) at the non-first-boundary condition-imposed nodes 1 and 2, we get the system of equations in (19.22). From the first and second boundary conditions in (19.21), the simultaneous equations are obtained as shown in (19.23). Here node 0 is a mirror node, which is artificially introduced as shown in Fig. 19.8, for the treatment of second boundary condition.

$$\begin{cases} \frac{u_2 - 2u_1 + u_0}{h^2} = -f \\ \frac{u_3 - 2u_2 + u_1}{h^2} = -f \end{cases}, \quad (19.22)$$

$$\begin{cases} u_3 = a \\ \frac{u_2 - u_0}{2h} = b \end{cases}. \quad (19.23)$$

Equation (19.22) leads to the following solvable system of two equations with two variables u_1 and u_2 , after deleting u_0 and u_3 by using the relationship in (19.23).

$$\begin{cases} \frac{u_2 - 2u_1 + (u_2 - 2hb)}{h^2} = -f \\ \frac{a - 2u_2 + u_1}{h^2} = -f \end{cases}. \quad (19.24)$$

If $a = 1$, $b = 0.2$, $f = 1$, $h = 0.5$, and $k = 1$, then we get the following FD-approximated solutions at nodes 1 and 2, which are numerically equivalent to the exact solutions described at the end of Sect. 19.1, by chance

$$\begin{cases} u_1 = 1.300 \\ u_2 = 1.275 \end{cases}$$

where $a = 1$, $b = 0.2$, $f = 1$, $h = 0.5$, and $k = 1$.

Once the values u at all the nodes are obtained, the derivative values $\partial u / \partial x$ can be calculated by applying finite difference approximations in (19.16–19.18).

19.2.2 Finite Element Method (FEM)

With the same problem setting as in (19.20) and (19.21), the formulation of FEM is visualized in the following part.

First of all, we introduce a weight function w , which is an arbitrary function with zero value at the nodes of first boundary conditions. Multiplying the governing equation by the weight function w , and taking the integral over the domain results in the following equation:

$$\int_0^1 \left(k \frac{\partial^2 u(x)}{\partial x^2} + f \right) w(x) dx = 0. \quad (19.25)$$

Integrating by parts gives

$$\begin{aligned} \int_0^1 f w(x) dx + k \frac{\partial u(x)}{\partial x} u(x) w(x) \Big|_0^1 \\ - \int_0^1 \frac{\partial w(x)}{\partial x} k \frac{\partial u(x)}{\partial x} dx = 0. \end{aligned} \quad (19.26)$$

Considering both the first and second boundary conditions in (19.21) and the nature of weight function w described above we obtain the following:

$$\int_0^1 k \frac{\partial w(x)}{\partial x} \frac{\partial u(x)}{\partial x} dx = \int_0^1 f w(x) dx - k w(0) b. \quad (19.27)$$

This equation is usually called the “weak form.” It should be noted that the second boundary condition is “naturally” embedded in the weak form during the derivation. Due to this characteristic, the first and second boundary conditions are called essential and natural boundary conditions in FEM, respectively.

Up to (19.27), we just used a conceptual derivation in the continuous exact model without introducing any approximated discretization. To calculate (19.27) we introduce some approximated discretized functions in u and w .

Now we consider the following finite element model with two linear finite elements.

Fig. 19.11 Finite element model

The finite difference method is a scheme with respect to nodes, while the finite element method is an element-oriented scheme with element-integral weak form. Thus (19.27) can be represented as the summation of an element-wise weak form in FEM as

$$\begin{aligned} & \int_{\text{element\#1}} k \frac{dw(x)}{dx} \frac{du(x)}{dx} dx + \int_{\text{element\#2}} k \frac{dw(x)}{dx} \frac{du(x)}{dx} dx \\ &= \int_{\text{element\#1}} fw(x) dx + \int_{\text{element\#2}} fw(x) dx - kw(0)b. \end{aligned} \quad (19.28)$$

The linear finite-element-approximated function selected here is represented in Fig. 19.10 and (19.29). The finite element function can be interpreted as an interpolation function of the physical values at nodes 1 and 2 in an element by looking at (19.29) carefully. The upper suffix h in (19.29) represents the element-wise discretized approximated function.

Since the weight function can be arbitrary with zero values at the nodes of first boundary conditions, the same function as the finite element function is applied in this case.

This setting is usually used in FEM, and is called the Galerkin (or Bubnov–Galerkin) method. If a different weight function is selected other than the finite element-approximated function, we call it the Petrov–Galerkin method, which is the stabilized upwind case FEM for

fluid dynamics [19.2]):

$$\begin{aligned} u^h(x) &= u_1 N_1(x) + u_2 N_2(x), \\ w^h(x) &= w_1 N_1(x) + w_2 N_2(x), \\ \text{where } N_1(x) &= \frac{x_2 - x}{h}, \quad N_2(x) = \frac{x - x_1}{h}. \end{aligned} \quad (19.29)$$

Matrix manipulation in both elements 1 and 2 are presented below.

Element 1:

$$\begin{aligned} & \int_{\text{element\#1}} k \frac{dw(x)}{dx} \frac{du(x)}{dx} dx = \int_{\text{element\#1}} fw(x) dx - kw(0)h, \\ & \int_{\text{element\#1}} k \begin{pmatrix} w_1 & w_2 \end{pmatrix} \begin{pmatrix} \frac{dN_1(x)}{dx} \\ \frac{dN_2(x)}{dx} \end{pmatrix} \\ & \quad \times \begin{pmatrix} \frac{dN_1(x)}{dx} & \frac{dN_2(x)}{dx} \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \end{pmatrix} dx \\ &= \begin{pmatrix} w_1 & w_2 \end{pmatrix} \int_{\text{element\#1}} f \begin{pmatrix} N_1(x) \\ N_2(x) \end{pmatrix} dx \\ & \quad - k \begin{pmatrix} w_1 & w_2 \end{pmatrix} \begin{pmatrix} N_1(0) \\ N_2(0) \end{pmatrix} b, \\ & \begin{pmatrix} w_1 & w_2 \end{pmatrix} \frac{k}{h} \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \end{pmatrix} \\ &= \begin{pmatrix} w_1 & w_2 \end{pmatrix} \begin{pmatrix} \frac{fh}{2} \\ \frac{fh}{2} \end{pmatrix} - k \begin{pmatrix} w_1 & w_2 \end{pmatrix} \begin{pmatrix} 1 \\ 0 \end{pmatrix} b; \end{aligned} \quad (19.30)$$

Element 2:

$$\begin{aligned} & \int_{\text{element\#2}} k \frac{dw(x)}{dx} \frac{du(x)}{dx} dx = \int_{\text{element\#2}} fw(x) dx, \\ & \int_{\text{element\#2}} k \begin{pmatrix} w_1 & w_2 \end{pmatrix} \begin{pmatrix} \frac{dN_1(x)}{dx} \\ \frac{dN_2(x)}{dx} \end{pmatrix} \begin{pmatrix} \frac{dN_1(x)}{dx} & \frac{dN_2(x)}{dx} \end{pmatrix} \\ & \quad \times \begin{pmatrix} u_1 \\ u_2 \end{pmatrix} dx = \begin{pmatrix} w_1 & w_2 \end{pmatrix} \int_{\text{element\#2}} f \begin{pmatrix} N_1(x) \\ N_2(x) \end{pmatrix} dx, \\ & \begin{pmatrix} w_1 & w_2 \end{pmatrix} \frac{k}{h} \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \end{pmatrix} = \begin{pmatrix} w_1 & w_2 \end{pmatrix} \begin{pmatrix} \frac{fh}{2} \\ \frac{fh}{2} \end{pmatrix}, \end{aligned} \quad (19.31)$$

$$\text{where } N_1(x) = \left(\frac{x_2 - x}{h} \right), \quad N_2(x) = \left(\frac{x - x_1}{h} \right).$$

Fig. 19.12 Two-node linear-finite-element approximated function

By combining (19.30) and (19.31) we get the following total system of equations:

$$\begin{aligned} (w_1 \ w_2 \ w_3) \frac{k}{h} \begin{pmatrix} 1 & -1 & 0 \\ -1 & 1+1 & -1 \\ 0 & -1 & 1 \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \\ u_3 \end{pmatrix} \\ = (w_1 \ w_2 \ w_3) \left[\begin{pmatrix} \frac{fh}{2} \\ \frac{fh}{2} \\ \frac{fh}{2} \end{pmatrix} - \begin{pmatrix} kb \\ 0 \\ 0 \end{pmatrix} \right]. \end{aligned} \quad (19.32)$$

Since w_3 is zero due to the nature of the weight function,

$$\begin{aligned} (w_1 \ w_2) \frac{k}{h} \begin{pmatrix} 1 & -1 & 0 \\ -1 & 2 & -1 \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \\ u_3 \end{pmatrix} \\ = (w_1 \ w_2) \left[\begin{pmatrix} \frac{fh}{2} \\ \frac{fh}{2} \end{pmatrix} - \begin{pmatrix} kb \\ 0 \end{pmatrix} \right]. \end{aligned} \quad (19.33)$$

Considering the first boundary condition of $u_3 = a$,

$$\begin{aligned} (w_1 \ w_2) \frac{k}{h} \begin{pmatrix} 1 & -1 \\ -1 & 2 \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \end{pmatrix} \\ = (w_1 \ w_2) \left[\begin{pmatrix} \frac{fh}{2} - kb \\ \frac{fh}{2} \end{pmatrix} - \frac{k}{h} \begin{pmatrix} 0 \\ -a \end{pmatrix} \right]. \end{aligned} \quad (19.34)$$

Since w_1 and w_2 are arbitrary we can get the following solvable system of two equations with two variables $\mathbf{Ku} = \mathbf{f}$ in (19.35). It should be noted that the treatment of the second boundary condition is not needed in the matrix manipulation part in **FEM**, which is a different

point from **FDM**'s case:

$$\frac{k}{h} \begin{pmatrix} 1 & -1 \\ -1 & 2 \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \end{pmatrix} = \begin{pmatrix} \frac{fh}{2} - kb \\ \frac{fh}{2} \end{pmatrix} - \frac{k}{h} \begin{pmatrix} 0 \\ -a \end{pmatrix}. \quad (19.35)$$

If $a = 1$, $b = 0.2$, $f = 1$, $h = 0.5$, and $k = 1$, then we get the following **FE**-approximated solutions at nodes 1 and 2, which are numerically the same as the exact solutions described at the end of Sect. 19.1, by chance

$$\begin{cases} u_1 = 1.300 \\ u_2 = 1.275 \end{cases}$$

where $a = 1$, $b = 0.2$, $f = 1$, $h = 0.5$, and $k = 1$.

In **FEM**, the derivative values $\partial u^h / \partial x$ are obtained from the derivative of interpolated function such as in (19.36)

$$\begin{aligned} \frac{\partial u^h(x)}{\partial x} &= u_1 \frac{\partial N_1(x)}{\partial x} + u_2 \frac{\partial N_2(x)}{\partial x}, \\ \frac{\partial w^h(x)}{\partial x} &= w_1 \frac{\partial N_1(x)}{\partial x} + w_2 \frac{\partial N_2(x)}{\partial x}, \\ \text{where } N_1(x) &= \frac{x_2 - x}{h}, \quad N_2(x) = \frac{x - x_1}{h}, \\ \frac{\partial N_1(x)}{\partial x} &= -\frac{1}{h}, \quad \frac{\partial N_2(x)}{\partial x} = \frac{1}{h}. \end{aligned} \quad (19.36)$$

This is all for the basic derivations in **FDM** and **FEM**, but a few important remarks in both **FDM** and **FEM** should be added.

1. The final shape of **FDM** and **FEM** calculation is $\mathbf{Ku} = \mathbf{f}$, where \mathbf{K} is a sparse matrix, \mathbf{u} is a solution vector and \mathbf{f} is a given force vector. \mathbf{K} can be symmetric or nonsymmetric depending of the physical problems. \mathbf{K} could be nonlinear if \mathbf{K} is a function of \mathbf{u} , although \mathbf{K} is linear in the problem above. The treatment of the nonlinear case is discussed in Sect. 19.8.
2. In this problem setting, both **FDM** and **FEM** reached numerically acceptable solutions compared with analytical exact solutions. Unfortunately this is just by chance. Usually both **FDM** and **FEM** provide only approximated solutions and in most cases you may need careful verification of the obtained numerical solutions, especially in multidimensional cases. (In the world of **FDM** and **FEM**, there exists a big difference among the one-dimensional case, two-dimensional case, and three-dimensional case.) This topic will be treated in Sect. 19.9.

3. The good news is that both **FDM** and **FEM** must be converged to more accurate solutions if the grid size or mesh size h is close to zero. To utilize this nature, the convergence test to evaluate the accuracy is possible in discretized methods, although the matrix size becomes bigger with a tiny grid or mesh size. It should be noted that the grid (mesh) size doesn't have to be uniform. If the accuracy is to be improved locally, for example, around a singular point, it is a good idea to use a smaller mesh size around the targeted local domain. However, a rapid change of mesh size distribution usually leads to bad results. An adaptive mesh in **FEM** and a boundary-fitted grid in **FDM** provide some solution to it. This important matter will be discussed in Sect. 19.9.
4. The obtained finite element function $u^h(x)$ [for example, in (19.35)] are continuous even between elements, however, the finite element derivative function $\partial u^h(x)/\partial x$ is not continuous, which means the derivative value at a node with two elements (in the 1D case) is not unique. To obtain the derivative value, such as heat flux in heat conduction problems and stress in solid mechanics (see Sect. 19.4), post-processing is inevitable and is treated in Sect. 19.9.
5. Since a function is not defined within a grid in the finite difference method, there are no problems in the derivations of the derivative value at a node. However you may have another problem regarding how to select a proper definition among (19.16–19.18). Usually, the central difference scheme has a good reputation due to second-order accuracy, but you need some tricks in the multidimensional case [19.1].
6. Mathematically, **FEM** is governed by function analysis [19.3] since the concept of “norm” can be introduced due to the shape of weak form. Using function analysis, a new established finite element formula can be evaluated in advance of real calculations in a normal sense in functional analysis.
7. As was discussed, a finite element domain is packed with element-wise finite element functions. Since the field is represented by the summation of **FE** functions, **FEM** is very strong at local resolution, for example, in stress distributions in solid mechanics, if the mesh is fine enough for the analysis. On the contrary, if the mesh is poor (too coarse for the problem), it is possible to obtain unexpected oscillations, for example, in fluid dynamics. The stabilized **FEM**, such as the streamline-upwind Petrov–Galerkin method (**SUPG**) and the Galerkin/least squares scheme (**GLS**), is one solution for it. A finite difference domain is not filled for any functions that are strong for unexpected oscillations, but not suitable for local resolution in solid mechanics.
8. As a general summary, **FEM** is good for arbitrary-shaped domains, treatment of second boundary conditions, solid mechanics, and parallel computations, while **FDM** is only valid for regular shaped domains, but suitable for fluid mechanics. The rough summary table, considering other related numerical schemes, is given in Table 19.1 in Sect. 19.9.

19.3 The Equivalence of FEM and FDM Methods

A reader might be wondering whether the treatment of **FDM** and **FEM** are equivalent to each other. In this section, we'll consider the equivalence of these two forms by explaining the variational method.

According to linear algebra [19.4], the following three forms are equivalent, where \mathbf{K} , \mathbf{f} and \mathbf{u} are a positive, definite symmetric matrix, a given force vector and a unknown vector, respectively:

$$\text{(Form 1)} \quad \mathbf{K}\mathbf{u} - \mathbf{f} = 0 \quad (19.37)$$

$$\text{(Form 2)} \quad \mathbf{w} \cdot (\mathbf{K}\mathbf{u} - \mathbf{f}) = 0, \quad \forall \mathbf{w} \in \mathbb{R}^n \quad (19.38)$$

$$\text{(Form 3)} \quad \mathbf{F}(\mathbf{v}) - \mathbf{F}(\mathbf{u}) \geq 0, \quad \forall \mathbf{v} \in \mathbb{R}^n \quad (19.39)$$

where $\mathbf{K} = \mathbf{K}^t$

$$\mathbf{F}(\mathbf{v}) = \frac{1}{2} \mathbf{v} \cdot \mathbf{K}\mathbf{v} - \mathbf{v} \cdot \mathbf{f}.$$

We now extend the discussion to the boundary-value problem below [19.5]. Again consider the same problem as treated in Sect. 19.2 by (19.20) and (19.21), which is Form 1 shown below. Form 2 is the weak form already explained in (19.27). Form 3 is called the variational form, which means the solution u is the minimizer of the function $\mathbf{F}(\mathbf{v})$.

$$\text{(Form 1)} \quad k \frac{\partial^2 u}{\partial x^2} = -f \quad \text{in } (0, 1), \quad u(1) = a, \quad \frac{\partial u}{\partial x}(0) = b; \quad (19.40)$$

$$\text{(Form 2)} \quad \int_0^1 \left(k \frac{\partial u}{\partial x} \frac{\partial w}{\partial x} - fw \right) dz - kw(0)b = 0, \quad \forall w \text{ with } w(1) = 0; \quad (19.41)$$

$$\text{(Form 3)} \quad u(1) = a, F(v) \geq F(u), \quad \forall v \text{ with } v(1) = a \quad (19.42)$$

$$\text{where} \quad F(v) = \frac{1}{2} \int_0^1 k \left(\frac{dv}{dx} \right)^2 dx - \int_0^1 f v dx - k v(0) b, \quad \forall v \text{ with } v(1) = a.$$

First we derive Form 1 from Form 3 in the following proof.

Proof [(Form 3) → (Form 1)]:

Suppose that u is the minimizer of the function F , which is satisfied with the given first boundary condition in the interval $(0, 1)$

$$u(1) = a, \quad F(v) - F(u) \geq 0, \quad \forall v \text{ with } v(1) = a. \quad (19.43)$$

Substituting $v = u \pm \varepsilon w$, by introducing w , where ε is a positive real number,

$$u(1) = a, \quad F(u \pm \varepsilon w) - F(u) \geq 0, \quad \forall w \text{ with } w(1) = 0. \quad (19.44)$$

It should be added that w is an arbitrary function such that $w(1) = 0$, since $v(1) = a$, $u(1) = a$.

By rewriting (19.44),

$$\begin{aligned} & \pm \varepsilon \left[\int_0^1 \left(k \frac{\partial u}{\partial x} \frac{\partial w}{\partial x} - f w \right) dx - k w(0) b \right] \\ & + \frac{1}{2} \varepsilon^2 \int_0^1 k \left(\frac{\partial w}{\partial x} \right)^2 dx \geq 0. \end{aligned} \quad (19.45)$$

If $\varepsilon \rightarrow 0$ after dividing the equation by $\varepsilon (> 0)$,

$$\text{(Form 2)} \quad \int_0^1 \left(k \frac{\partial u}{\partial x} \frac{\partial w}{\partial x} - f w \right) dx - k w(0) b = 0. \quad (19.46)$$

By integration by part with $w(1) = 0$,

$$\begin{aligned} & \int_0^1 \left[-\frac{\partial}{\partial x} \left(k \frac{\partial u}{\partial x} \right) - f \right] w dx \\ & + k \frac{\partial u}{\partial x} (0) w(0) - k w(0) b = 0. \end{aligned} \quad (19.47)$$

Since w and $w(1)$ are arbitrary, the equation above ascribes to the following shape, which is nothing else but Form 1.

Now we derive Form 3 from Form 1.

Proof [(Form 1) → (Form 3)]:

Subtracting $F(u)$ from $F(v)$,

$$\begin{aligned} F(v) - F(u) &= \int_0^1 \left[k \frac{\partial u}{\partial x} \frac{\partial}{\partial x} (v - u) - f(v - u) \right] dx \\ &\quad - k(v - u)(0)b + \frac{1}{2} \int_0^1 k \left[\frac{\partial}{\partial x} (v - u) \right]^2 dx. \end{aligned} \quad (19.48)$$

Since the function u and v must satisfy the first boundary condition, $(v - u)(0) = 0$ gives the following equation

$$\begin{aligned} & u(1) = a, \\ & \int_0^1 \left[k \frac{\partial u}{\partial x} \frac{\partial}{\partial x} (v - u) - f(v - u) \right] dx \\ & - h(v - u)(0)b = 0, \\ & \forall v \text{ with } v(1) = a. \end{aligned} \quad (19.49)$$

According to the derivations above, we finally obtain Form 3

$$F(v) - F(u) = \frac{1}{2} \int_0^1 k \left(\frac{d}{dx} (v - u) \right)^2 dx \geq 0. \quad (19.50)$$

It is recommended that one refer to the explanation in Sect. 19.2.2 again, after reading this section.

19.4 From Mechanics to Mathematics: Equilibrium Equations and Partial Differential Equations

Although (19.20) was given without any logical derivation, the governing partial differential equations are always derived from both equilibrium equations in a mechanical sense and material constitutive equations in

a material property sense. In this section, we derive mathematics from mechanics.

The governing equations describe the relationship between the force-related variables as input and the

motion-related variables as output. The equilibrium equations represent the mechanical balancing relationship, while material constitutive equations characterize the empirical material properties of the target. In short, the former is related to mechanics and the latter is concerned with materials:

Governing equations = Equilibrium equations (from mechanical balancing) + Material constitutive equations (from experiments).

It should be noted from Sect. 19.1 that the material constitutive equation directly represents the governing equation in (19.1), which is a special case.

19.4.1 Heat Conduction Problem in the Two-Dimensional Case

Let us take a look at the balance of heat flux in an infinitesimal element as shown in Fig. 19.13, where q_x and q_y show heat fluxes, the functions of x and y , in the x and y directions, respectively.

Considering in and out heat flux,

$$\begin{aligned} Q \nabla t = & \left\{ \left[q_x \left(x - \frac{1}{2} \nabla x, y \right) - q_x \left(x + \frac{1}{2} \nabla x, y \right) \right] \nabla y \right. \\ & - \left[q_y \left(x, y - \frac{1}{2} \nabla y \right) - q_y \left(x, y + \frac{1}{2} \nabla y \right) \right] \nabla x \\ & \left. + f \nabla x \nabla y \right\} \nabla t. \end{aligned} \quad (19.51)$$

By dividing the equation above by $\Delta x \Delta y \Delta t$ and taking the limit as Δx and $\Delta y \rightarrow 0$, we get

$$\lim_{\nabla x \nabla y \rightarrow 0} \frac{Q}{\nabla x \nabla y} = -\frac{\partial q_x}{\partial x} - \frac{\partial q_y}{\partial y} + f. \quad (19.52)$$

Fig. 19.13 Balance of heat flux in an infinitesimal element

On the other hand, Q can be defined by introducing the heat capacity c_p and the density ρ

$$Q = \rho c_p \dot{u} \Delta x \Delta y. \quad (19.53)$$

Then we obtain the following equilibrium equation

$$\rho c_p \dot{u} = -\frac{\partial q_x}{\partial x} - \frac{\partial q_y}{\partial y} + f. \quad (19.54)$$

As for the material property of heat conduction, Fourier's law, which was modeled by experiments, is known as

$$\begin{cases} q_x = -k_{xx} \frac{\partial u}{\partial x} - k_{xy} \frac{\partial u}{\partial y}, \\ q_y = -k_{yx} \frac{\partial u}{\partial x} - k_{yy} \frac{\partial u}{\partial y}. \end{cases} \quad (19.55)$$

Combining the equilibrium heat equation and the material constitutive equation, we finally obtain the unsteady heat conduction equation in the two-dimensional case. Equation (19.20) is a one-dimensional steady-state version

$$\begin{aligned} \rho c_p \dot{u} = & \frac{\partial}{\partial x} \left(k_{xx} \frac{\partial u}{\partial x} + k_{xy} \frac{\partial u}{\partial y} \right) \\ & + \frac{\partial}{\partial y} \left(k_{yx} \frac{\partial u}{\partial x} + k_{yy} \frac{\partial u}{\partial y} \right) + f. \end{aligned} \quad (19.56)$$

19.4.2 Elastic Solid Problem in the Three-Dimensional Case

Solid mechanics problems are rather complicated to explain, since there exist three components such as stress, strain, and displacement.

What is needed now are the following:

1. Equilibrium relationship on stress;
2. Displacement-strain relationship;
3. Stress-strain relationship including material constitutive equations.

The three recipes above are explained in the following parts, to derive the governing equation of elastic solid deformation problems. Some additional discussion on stress is necessary to avoid a misunderstanding of the physical meanings. The three-dimensional case is treated here, since the two-dimensional case is a degenerated case with some additional assumptions.

Equilibrium Relationship on Stress

Now let us think about the balance of forces in the x -direction in a three-dimensional infinitesimal element in Fig. 19.14, where $\sigma_{\alpha\beta}$ is a stress (local pressure) value

Fig. 19.14 Balance of forces in the x -direction in an infinitesimal element

on the α -plane (the plane perpendicular to α -coordinate) in the β -direction, which is a function of x , y , and z . For example, σ_{zx} represents the component of stress in the x -direction on the z -plane.

The equilibrium in the x -direction is

$$\begin{aligned} & \left[-\sigma_{xx} \left(x - \frac{1}{2} \nabla x, y, z \right) + \sigma_{xx} \left(x + \frac{1}{2} \nabla x, y, z \right) \right] \nabla y \nabla z \\ & + \left[-\sigma_{yx} \left(x, y - \frac{1}{2} \nabla y, z \right) + \sigma_{yx} \left(x, y + \frac{1}{2} \nabla y, z \right) \right] \nabla z \nabla x \\ & + \left[-\sigma_{zx} \left(x, y, z - \frac{1}{2} \nabla z \right) + \sigma_{zx} \left(x, y, z + \frac{1}{2} \nabla z \right) \right] \nabla x \nabla y \\ & + \varrho f_x \nabla x \nabla y \nabla z = 0. \end{aligned} \quad (19.57)$$

After dividing by $\Delta x \Delta y$ and applying $\Delta x \Delta y \rightarrow 0$, we get

$$\frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \sigma_{yx}}{\partial y} + \frac{\partial \sigma_{zx}}{\partial z} + \varrho f_x = 0. \quad (19.58)$$

Applying the same steps in the y - and z -directions leads to the following equations:

$$\begin{aligned} \frac{\partial \sigma_{xy}}{\partial x} + \frac{\partial \sigma_{yy}}{\partial y} + \frac{\partial \sigma_{yz}}{\partial z} + \varrho f_y &= 0, \\ \frac{\partial \sigma_{xz}}{\partial x} + \frac{\partial \sigma_{yz}}{\partial y} + \frac{\partial \sigma_{zz}}{\partial z} + \varrho f_z &= 0. \end{aligned} \quad (19.59)$$

Fig. 19.15 Stress components

The stress components in (19.58) and (19.59) are sometimes represented in matrix form (19.60), which is physically visualized in Fig. 19.15:

$$\boldsymbol{\sigma} = \begin{pmatrix} \sigma_{xx} & \sigma_{yx} & \sigma_{zx} \\ \sigma_{xy} & \sigma_{yy} & \sigma_{yz} \\ \sigma_{xz} & \sigma_{yz} & \sigma_{zz} \end{pmatrix}. \quad (19.60)$$

Considering the momentum equilibrium in Fig. 19.15, the symmetry of the stress is obtained. The shearing stress σ_{xy} is sometimes described as τ_{xy} , but the meaning is the same

$$\sigma_{xy} = \sigma_{yx}, \sigma_{yz} = \sigma_{zy}, \sigma_{zx} = \sigma_{xz}. \quad (19.61)$$

Displacement–Strain Relationship

Let us consider the case that a point P is moved to a point P' after some deformation of the body, as shown in Fig. 19.16.

Suppose vectors \mathbf{a} and \mathbf{x} are position vectors of points P and P' , individually. For the convenience of notation, subscripts 1,2, and 3 represent x , y , and z ,

Fig. 19.16 Deformation

respectively in the following parts:

$$\mathbf{u} = \mathbf{x} - \mathbf{a} \quad (\text{or } u_k = x_k - a_k)$$

where $x_1 = x$, $x_2 = y$, and $x_3 = z$. (19.62)

If you consider a differential line near points P and P', then

$$|dx|^2 + |da|^2 = \sum_{i=1}^3 dx_i dx_i - \sum_{k=1}^3 da_k da_k,$$

where $x_1 = x$, $x_2 = y$, and $x_3 = z$. (19.63)

According to the differential rule

$$da_k = \sum_{i=1}^3 \frac{\partial a_k}{\partial x_i} dx_i \quad (19.64)$$

(19.64) changes to

$$\begin{aligned} & \sum_{i=1}^3 dx_i dx_i - \sum_{k=1}^3 da_k da_k \\ &= \sum_{i=1}^3 dx_i dx_i - \sum_{k=1}^3 \left(\sum_{i=1}^3 \frac{\partial a_k}{\partial x_i} dx_i \right) \left(\sum_{i=1}^3 \frac{\partial a_k}{\partial x_i} dx_i \right) \\ &= \sum_{i=1}^3 \sum_{j=1}^3 \left(\delta_{ij} - \sum_{k=1}^3 \frac{\partial a_k}{\partial x_i} \frac{\partial a_k}{\partial x_j} \right) dx_i dx_j. \end{aligned} \quad (19.65)$$

If the following definition of strain tensor ε_{ij} is introduced

$$\varepsilon_{ij} = \frac{1}{2} \left(\delta_{ij} - \sum_{k=1}^3 \frac{\partial a_k}{\partial x_i} \frac{\partial a_k}{\partial x_j} \right) \quad (19.66)$$

and taking the derivative of ∂x_i in (19.63)

$$\frac{\partial u_k}{\partial x_i} = \delta_{ki} - \frac{\partial a_k}{\partial x_i} \quad (19.67)$$

then we obtain

$$\varepsilon_{ij} = \frac{1}{2} \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} - \frac{\partial u_k}{\partial x_i} \frac{\partial u_k}{\partial x_j} \right). \quad (19.68)$$

If the higher term is neglected in (19.68), we obtain the following displacement-strain relationship, which is called a Cauchy infinitesimal strain tensor. It should be noted that there exists a lot of stress tensors in non-

linear solid mechanics that allow finite deformation and rotation [19.6]

$$\varepsilon_{ij} = \frac{1}{2} \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right). \quad (19.69)$$

As a summary, the displacement and strain are connected to each other in the following relationship, where u , v , and w are displacement in the x , y , and z directions, respectively.

$$\begin{cases} \varepsilon_{xx} = \frac{\partial u}{\partial x} \\ \varepsilon_{yy} = \frac{\partial v}{\partial y} \\ \varepsilon_{zz} = \frac{\partial w}{\partial z} \\ \varepsilon_{xy} = \varepsilon_{yx} = \frac{1}{2} \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right) \\ \varepsilon_{yz} = \varepsilon_{zy} = \frac{1}{2} \left(\frac{\partial v}{\partial z} + \frac{\partial w}{\partial y} \right) \\ \varepsilon_{zx} = \varepsilon_{xz} = \frac{1}{2} \left(\frac{\partial w}{\partial x} + \frac{\partial u}{\partial z} \right) \end{cases} \quad (19.70)$$

Stress-Strain Relationship Including Material Constitutive Equations

The constitutive equation for three-dimensional isotropic elastic material, which describes the stress-strain relationship, is modeled by experiments, as an extension of Hooke's law, where E , ν , and G are Young's modulus (modulus of elasticity), Poisson's ratio, and the modulus of elasticity in shear, respectively. For the definition of Young's modulus and Poisson's ratio, please refer to Sect. 19.7.1. It should be emphasized that (19.71) and (19.72) are only valid for three-dimensional "isotropic elastic" material

$$\begin{cases} \varepsilon_{xx} = \frac{1}{E} [\sigma_{xx} - \nu (\sigma_{yy} + \sigma_{zz})] \\ \varepsilon_{yy} = \frac{1}{E} [\sigma_{yy} - \nu (\sigma_{zz} + \sigma_{xx})] \\ \varepsilon_{zz} = \frac{1}{E} [\sigma_{zz} - \nu (\sigma_{xx} + \sigma_{yy})] \\ \varepsilon_{xy} = \frac{1}{G} \sigma_{xy} \\ \varepsilon_{yz} = \frac{1}{G} \sigma_{yz} \\ \varepsilon_{zx} = \frac{1}{G} \sigma_{zx} \end{cases} \quad (19.71)$$

or

$$\boldsymbol{\sigma} = D \boldsymbol{\varepsilon}$$

where

$$\sigma = \begin{pmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_3 \\ \sigma_4 \\ \sigma_5 \\ \sigma_6 \end{pmatrix} = \begin{pmatrix} \sigma_{xx} \\ \sigma_{yy} \\ \sigma_{zz} \\ \sigma_{yz} \\ \sigma_{zx} \\ \sigma_{xy} \end{pmatrix}, \quad \epsilon = \begin{pmatrix} \epsilon_1 \\ \epsilon_2 \\ \epsilon_3 \\ \epsilon_4 \\ \epsilon_5 \\ \epsilon_6 \end{pmatrix} = \begin{pmatrix} \epsilon_{xx} \\ \epsilon_{yy} \\ \epsilon_{zz} \\ 2\epsilon_{yz} \\ 2\epsilon_{zx} \\ 2\epsilon_{xy} \end{pmatrix},$$

$$D = \begin{pmatrix} \lambda + 2G & \lambda & \lambda & 0 & 0 & 0 \\ \lambda & \lambda + 2G & \lambda & 0 & 0 & 0 \\ \lambda & \lambda & \lambda + 2G & 0 & 0 & 0 \\ 0 & 0 & 0 & G & 0 & 0 \\ 0 & 0 & 0 & 0 & G & 0 \\ 0 & 0 & 0 & 0 & 0 & G \end{pmatrix},$$

$$\lambda = \frac{Ev}{(1-2\nu)(1+\nu)}, \quad G = \frac{E}{2(1+\nu)}. \quad (19.72)$$

As in the two-dimensional case, there are two degenerated cases: the plane stress case is for plates with in-plane forces imposed, while the plane strain case is for a beam-like structure along the z direction with equally distributed forces acting on the long side. The former and latter are described by the conditions of $\sigma_{zz} = \sigma_{zx} = \sigma_{zy} = 0$ and $\epsilon_{zz} = \epsilon_{zx} = \epsilon_{zy} = 0$, respectively [19.7]:

$$\begin{pmatrix} \sigma_{xx} \\ \sigma_{yy} \\ \sigma_{xy} \end{pmatrix} = \begin{pmatrix} \frac{E}{1-\nu^2} & \frac{Ev}{1-\nu^2} & 0 \\ \frac{Ev}{1-\nu^2} & \frac{E}{1-\nu^2} & 0 \\ 0 & 0 & G \end{pmatrix} \begin{pmatrix} \epsilon_{xx} \\ \epsilon_{yy} \\ \epsilon_{xy} \end{pmatrix}$$

(plane stress case),

$$\lambda = \frac{Ev}{(1-2\nu)(1+\nu)}, \quad G = \frac{E}{2(1+\nu)}, \quad (19.73)$$

$$\begin{pmatrix} \sigma_{xx} \\ \sigma_{yy} \\ \sigma_{xy} \end{pmatrix} = \begin{pmatrix} \lambda(1-\nu) & \lambda\nu & 0 \\ \lambda\nu & \lambda(1-\nu) & 0 \\ 0 & 0 & G \end{pmatrix} \begin{pmatrix} \epsilon_{xx} \\ \epsilon_{yy} \\ \epsilon_{xy} \end{pmatrix}$$

(plane strain case),

$$\lambda = \frac{Ev}{(1-2\nu)(1+\nu)}, \quad G = \frac{E}{2(1+\nu)}. \quad (19.74)$$

So far, the derivation of the governing equation on the three-dimensional isotropic elastic solid problem

has been explained. In solid mechanics, stress values are very important and are directly linked to breakage, crash, and fatigue. A further explanation of stress is provided below to avoid a misunderstanding of physical meanings.

Further Explanation of Stress

Now let's study stress more deeply. The stress (pressure) value at a point cannot be determined uniquely if the acting plane information is not given. To represent the stress condition, the information on both an evaluation point and an evaluation plane is needed.

Figure 19.17 shows a tetrahedral element, where \mathbf{t} is a traction vector, the shaded face is a targeted plane, and \mathbf{n} is a normal unit vector of the targeted plane. It should be added that the traction vector \mathbf{t} is not an applying force from outside to the tetrahedral, but a reaction force from the tetrahedral element to outside.

Fig. 19.17 Stress components at a tetrahedral element

We represent the traction vector \mathbf{t} with stress components in xyz -coordinates. Considering the x direction in Fig. 19.17, we get the following equation, where ΔA , ΔA_α , ΔV , ρ , and f_x are the area of the shaded plane, the area of α -plane (tetrahedral face normal to α -coordinate), the volume of the tetrahedral, the density, and the x component of the volume force:

$$\sigma_{xx} \Delta A_x + \sigma_{yx} \Delta A_y + \sigma_{zx} \Delta A_z - \rho f_x \Delta V = t_x \Delta A. \quad (19.75)$$

Since $\Delta A_x = n_x \Delta A$, ... (n_x is x component of the normal unit vector \mathbf{n}), we get

$$(\sigma_{xx} n_x + \sigma_{yx} n_y + \sigma_{zx} n_z) \Delta A - \rho f_x \Delta V = t_x \Delta A. \quad (19.76)$$

Considering $\Delta A \rightarrow 0$ (at the same time, $\Delta V \rightarrow 0$),

$$\begin{aligned} t_x &= \sigma_{xx}n_x + \sigma_{yx}n_y + \sigma_{zx}n_z, \\ t_y &= \sigma_{xy}n_x + \sigma_{yy}n_y + \sigma_{zy}n_z, \\ t_z &= \sigma_{xz}n_x + \sigma_{yz}n_y + \sigma_{zz}n_z, \end{aligned} \quad (19.77)$$

or

$$\begin{pmatrix} t_x \\ t_y \\ t_z \end{pmatrix} = \begin{pmatrix} \sigma_{xx} & \sigma_{yx} & \sigma_{zx} \\ \sigma_{xy} & \sigma_{yy} & \sigma_{zy} \\ \sigma_{xz} & \sigma_{yz} & \sigma_{zz} \end{pmatrix} \begin{pmatrix} n_x \\ n_y \\ n_z \end{pmatrix}. \quad (19.78)$$

Now the traction force vector \mathbf{t} on the shaded plane is represented with a stress component matrix σ in (19.78) and a normal vector. It should be noted that the stress matrix σ is a second-rank tensor since it contains the directional information of acting force and imposed plane.

Mathematically the 3×3 matrix has the following important properties:

1. It has three eigenvalues, including multiple roots, which are real numbers;
2. The eigenvectors are orthogonal to each other.

With these properties the stress matrix can be transformed as follows after some coordinate changes. The physical meaning is illustrated in Fig. 19.18, where σ_x , σ_y , and σ_z are called the principal stress. It should be added that the left and right sides of Fig. 19.18 are physically identical since the transformation is just a change of coordinate setting.

The 3×3 stress matrix has three invariants against coordinate settings. The von Mises stress value in (19.79), which is a good estimator of the strength, is

Fig. 19.18 Principal stresses

one of them:

$$\begin{aligned} \sigma_{\text{von Mises}} &= \sqrt{\frac{1}{2} \left[(\sigma_x - \sigma_y)^2 + (\sigma_y - \sigma_z)^2 + (\sigma_z - \sigma_x)^2 \right]} \\ &= \sqrt{\frac{1}{2} \left[(\sigma_{xx} - \sigma_{yy})^2 + (\sigma_{yy} - \sigma_{zz})^2 + (\sigma_{zz} - \sigma_{xx})^2 \right] + 3(\sigma_{xy}^2 + \sigma_{yz}^2 + \sigma_{zx}^2)}. \end{aligned} \quad (19.79)$$

It must be added in this section that these governing equations are only valid for continuum mechanics since the material constitutive equations are derived from experimental data obtained in a continuum modeling sense.

19.5 From Mathematics to Mechanics: Characteristic of Partial Differential Equations

In the previous section, we studied the derivation of mathematical governing equations for heat conduction problems and solid deformation problems from mechanical points of view. In this section, we take a look at the characteristics of physical (mechanical) representations of partial differential equations, categorized in a mathematical sense.

Equation (19.80) represents the general form of second-order partial differential equations

$$\begin{aligned} A \frac{\partial^2 \phi}{\partial x^2} + B \frac{\partial^2 \phi}{\partial x \partial t} \\ + C \frac{\partial^2 \phi}{\partial t^2} + D \frac{\partial \phi}{\partial x} + E \frac{\partial \phi}{\partial t} + F \phi + G = 0. \end{aligned} \quad (19.80)$$

Depending on the value of $B^2 - 4AC$ in (19.80), it can be categorized into elliptic, parabolic, and hyperbolic types as in (19.81), which are linked with steady heat conduction problems, potential flow problems, steady perfect elastic deformation problems, and so on:

$$\begin{aligned} \text{elliptic type} & \quad B^2 - 4AC < 0, \\ \text{parabolic type} & \quad B^2 - 4AC = 0, \\ \text{hyperbolic type} & \quad B^2 - 4AC > 0. \end{aligned} \quad (19.81)$$

In the following part, we study the characteristic of three types.

19.5.1 Elliptic Type

If an independent variable t is replaced by y under the conditions of $A = C = 1$, $B = D = E = F = 0$ and $G = f(x, y)$ in (19.80), we get a so-called Poisson equation

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} = f(x, y). \quad (19.82)$$

The Laplace equation is in the case of $f(x, y) = 0$

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} = 0. \quad (19.83)$$

This type represents the problem of finding the steady distribution of the target value inside the domain with some boundary conditions such as steady heat conduction problems (see Sect. 19.4.1), potential flow problems (under the assumption of zero rotation = no viscosity) and steady perfect elastic deformation problems (see Sect. 19.4.2).

From images of these phenomena, the characteristics of elliptic-type phenomena can be summarized as:

1. The equation type is usually for steady problems,
2. The solution at some point tends to be the averaged values of the surrounding points.

19.5.2 Parabolic Type

Typical parabolic-type phenomena are unsteady heat conduction or unsteady diffusion problems. For example, by setting $A = -1$, $E = 1$, and $B = C = D = F = 0$, we obtain the following equation, where t , x , and $\phi(x, t)$ are time, the x -coordinate in one-dimension, and the physical variable dependent on x and t , such as density or temperature

$$\frac{\partial \phi}{\partial t} = \frac{\partial^2 \phi}{\partial x^2}. \quad (19.84)$$

Both unsteady heat conduction problems and unsteady diffusion problems belong to this type.

Equation (19.85) represents both unsteady heat conduction problems and unsteady diffusion problems in one-dimensional case, where k is the heat conduction coefficient and a diffusive coefficient, respectively

$$\frac{\partial u(x, t)}{\partial t} - k \frac{\partial^2 u(x, t)}{\partial x^2} = -f. \quad (19.85)$$

With the information above, the characteristics of parabolic-type phenomena can be summarized as:

1. Nondirectional distribution of the solution in space;
2. Rapid diffusion of the solution in time over the domain.

19.5.3 Hyperbolic Type

A typical hyperbolic type is the wave equation below, which is the case with $A = -c^2$, $C = 1$, and $B = D = E = F = 0$ in (19.80). This equation represents the wave propagation along the x direction with the velocity c , which is called the wave equation

$$\frac{\partial^2 \phi}{\partial t^2} = c^2 \frac{\partial^2 \phi}{\partial x^2}. \quad (19.86)$$

The second part of factorized equation below is called an advection equation, which has almost equivalent characteristics as a wave equation:

$$\frac{\partial^2 \phi}{\partial t^2} - c^2 \frac{\partial^2 \phi}{\partial x^2} = \left(\frac{\partial}{\partial t} - c \frac{\partial}{\partial x} \right) \left(\frac{\partial}{\partial t} + c \frac{\partial}{\partial x} \right) \phi. \quad (19.87)$$

The characteristics of hyperbolic-type phenomena can be summarized as

1. Directional distribution of the solution in space;
2. Diffusion of the solution with given velocity in time in some part of domain.

The advection–diffusion equation is given in (19.88), where ϕ , u , k , and f are density, advective velocity, diffusive coefficient, and source term, respectively:

$$\frac{\partial \phi}{\partial t} + u \frac{\partial \phi}{\partial x} - k \frac{\partial^2 \phi}{\partial x^2} = f. \quad (19.88)$$

As one can see from the previous explanation, hyperbolic and parabolic types show the opposite characteristics. Since the advection–diffusion equation is the combination of these two types, there exist some difficulties for numerical calculations. The flow problem, described by Navier–Stokes equation, is a nonlinear version of the advection–diffusion equation in a mathematical sense.

19.6 Time Integration for Unsteady Problems

The governing equation of the unsteady heat conduction problem in the one-dimensional case is represented as follows, where u , k , and f are the temperature, the heat conduction coefficient, and the heat source, respectively:

$$\frac{\partial u(x, t)}{\partial t} - k \frac{\partial^2 u(x, t)}{\partial x^2} = -f. \quad (19.89)$$

Suppose that we know the values of u and $\partial u / \partial x$ at time n , which is represented by u^n and \dot{u}^n . Now we want to obtain u^{n+1} from u^n and \dot{u}^n .

Figure 19.19 visualizes the problem. The shaded part is $u^{n+1} - u^n$, which is what we want to obtain. The finite difference idea is applied to this problem.

Let us simplify the problem by introducing the generalized trapezoidal method description [19.2], which is nothing but a generalized finite difference description using the parameter α

$$\begin{aligned} u^{n+1} &= u^n + \Delta t \dot{u}^{n+\alpha}, \\ \dot{u}^{n+\alpha} &= (1 - \alpha) \dot{u}^n + \alpha \dot{u}^{n+1}. \end{aligned} \quad (19.90)$$

If $\alpha = 0$, then $u^{n+\alpha} = \dot{u}^n \rightarrow u^{n+1} = u^n + \Delta t \dot{u}^n$, which means $u^{n+1} - u^n$ is calculated by the known value \dot{u}^n at the n th time step as shown by the lower dotted line in Fig. 19.19. This is a forward difference scheme *wrt* time, which is called the forward Euler or the explicit method.

If $\alpha = 1$, then $\dot{u}^{n+\alpha} = \dot{u}^{n+1} \rightarrow u^{n+1} = u^n + \Delta t \dot{u}^{n+1}$, which means $u^{n+1} - u^n$ is calculated by the unknown value \dot{u}^{n+1} at $(n + 1)$ th time step. In Fig. 19.19, the upper

dotted line illustrates this case. This is the backward difference method in time, named the backward Euler or the implicit method.

If $\alpha = 0.5$, then $\dot{u}^{n+\alpha} = (\dot{u}^n + \dot{u}^{n+1})/2 \rightarrow u^{n+1} = u^n + \Delta t (\dot{u}^n + \dot{u}^{n+1})/2$, which means $u^{n+1} - u^n$ is calculated by both known and unknown values \dot{u}^n , \dot{u}^{n+1} at the n th time step. In Fig. 19.19, this is the diagonal dotted line. This is called the trapezoidal rule, the midpoint rule, or the Crank–Nicolson method.

According to Fig. 19.19, the Crank–Nicolson method ($\alpha = 0.5$ case) seems to be the best solution, however \dot{u}^{n+1} is not known at the n th time step. Since \dot{u}^{n+1} is also calculated with the Crank–Nicolson algorithm, it is not a simple discussion. Based on experience, the Crank–Nicolson method with $\alpha = 0.51 \approx 0.55$ is recommended in most cases.

Usually the unknown value \dot{u}^{n+1} is obtained by a matrix inversion process in the implicit method or Crank–Nicolson method in discretized numerical schemes. In nonlinear cases, equilibrium iterations, for example, the Newton–Raphson method (see Sect. 19.8) within a time step is usually omitted in explicit time integration.

In the following, the derivations of FDM and FEM for the unsteady heat conduction problem in the one-dimensional case is explained by the time integration scheme explained above.

19.6.1 FDM

By applying the generalized finite difference description in time to a finite difference formulation at node $u^n(x)$, we get

$$\begin{aligned} & \frac{u^{n+1}(x) - u^n(x)}{\Delta t} \\ & - k \left[(1 - \alpha) \frac{u^n(x + h) - 2u^n(x) + u^n(x - h))}{h^2} \right. \\ & \quad \left. + \alpha \frac{[u^{n+1}(x + h) - 2u^{n+1}(x) + u^{n+1}(x - h)]}{h^2} \right] \\ & = -f. \end{aligned} \quad (19.91)$$

After modifying the equation, it becomes

$$\left(\alpha \frac{k}{h^2} \frac{1}{\Delta t} - 2\alpha \frac{k}{h^2} \right) \begin{pmatrix} u^{n+1}(x - h) \\ u^{n+1}(x) \\ u^{n+1}(x + h) \end{pmatrix}$$

Fig. 19.19 Time integration between t^n and t^{n+1}

$$\begin{aligned}
& + \left((1-\alpha) \frac{k}{h^2} - \frac{1}{\Delta t} - 2(1-\alpha) \frac{k}{h^2} \quad (1-\alpha) \frac{k}{h^2} \right) \\
& \times \begin{pmatrix} u^n(x-h) \\ u^n(x) \\ u^n(x+h) \end{pmatrix} = -f. \quad (19.92)
\end{aligned}$$

If $\alpha = 0$, the local FD equation becomes the following one in matrix representation:

$$\begin{aligned}
& \begin{pmatrix} 0 & \frac{1}{\Delta t} & 0 \end{pmatrix} \begin{pmatrix} u^{n+1}(x-h) \\ u^{n+1}(x) \\ u^{n+1}(x+h) \end{pmatrix} \\
& + \begin{pmatrix} \frac{k}{h^2} & -\frac{1}{\Delta t} - 2\frac{k}{h^2} & \frac{k}{h^2} \end{pmatrix} \begin{pmatrix} u^n(x-h) \\ u^n(x) \\ u^n(x+h) \end{pmatrix} = -f. \quad (19.93)
\end{aligned}$$

After summing this equation for all nodes, we get the following matrix system:

$$\frac{1}{\Delta t} \mathbf{I} \mathbf{u}^{n+1} + \mathbf{K}_2 \mathbf{u}^n = \mathbf{F}. \quad (19.94)$$

Equation (19.94) means that a solution vector at $(n+1)$ th time step \mathbf{u}^{n+1} can be obtained merely by $\mathbf{u}^{n+1} = \Delta t(\mathbf{F} - \mathbf{K}_2 \mathbf{u}^n)$ without any matrix inversion. This is an explicit case.

If $\alpha = 1$, we get the following local matrix system

$$\begin{aligned}
& \begin{pmatrix} \frac{k}{h^2} & \frac{1}{\Delta t} - 2\frac{k}{h^2} & \frac{k}{h^2} \end{pmatrix} \begin{pmatrix} u^{n+1}(x-h) \\ u^{n+1}(x) \\ u^{n+1}(x+h) \end{pmatrix} \\
& + \begin{pmatrix} 0 & -\frac{1}{\Delta t} \frac{k}{h^2} & 0 \end{pmatrix} \begin{pmatrix} u^n(x-h) \\ u^n(x) \\ u^n(x+h) \end{pmatrix} = -f. \quad (19.95)
\end{aligned}$$

After summing all equations,

$$\mathbf{K}_1 \mathbf{u}^{n+1} - \frac{1}{\Delta t} \frac{k}{h^2} \mathbf{I} \mathbf{u}^n = \mathbf{F}. \quad (19.96)$$

This matrix system denotes that a solution vector at the $(n+1)$ th time step \mathbf{u}^{n+1} is calculated by $\mathbf{u}^{n+1} = \mathbf{K}_1^{-1}(\mathbf{F} + 1/\Delta t \, k/h^2 \mathbf{I} \mathbf{u}^n)$ which involves the matrix inversion \mathbf{K}_1^{-1} . This is an implicit case. The Crank–Nicolson case with $\alpha = 0.51$ – 0.55 belongs to an implicit case, since it needs matrix inversion calculation.

19.6.2 FEM

In FEM, the space domain is spanned by the finite element interpolation function, but the finite difference idea in time is applied in the time domain.

Again, starting from the weak form, we get

$$\int_0^1 \left(\frac{\partial u(x, t)}{\partial t} + k \frac{\partial^2 u(x, t)}{\partial x^2} + f \right) w(x, t) dx = 0, \quad (19.97)$$

$$\begin{aligned}
& \int_0^1 w \frac{\partial u(x, t)}{\partial t} dx + \int_0^1 k \frac{\partial w(x, t)}{\partial x} \frac{\partial u(x, t)}{\partial x} dx \\
& = \int_0^1 f w(x, t) dx - k w(0) b. \quad (19.98)
\end{aligned}$$

By introducing the finite element functions as in Sect. 19.1,

$$\begin{aligned}
& \int_{\text{element } j} \begin{pmatrix} w_1(t) & w_2(t) \end{pmatrix} \begin{pmatrix} \frac{dN_1(x)}{dx} \\ \frac{dN_2(x)}{dx} \end{pmatrix} \\
& \times \begin{pmatrix} \frac{dN_1(x)}{dx} & \frac{dN_2(x)}{dx} \end{pmatrix} \begin{pmatrix} \dot{u}_1(t) \\ \dot{u}_2(t) \end{pmatrix} dx \\
& + \int_{\text{element } j} \begin{pmatrix} w_1(t) & w_2(t) \end{pmatrix} \begin{pmatrix} \frac{dN_1(x)}{dx} \\ \frac{dN_2(x)}{dx} \end{pmatrix} \\
& \times \begin{pmatrix} \frac{dN_1(x)}{dx} & \frac{dN_2(x)}{dx} \end{pmatrix} \begin{pmatrix} u_1(t) \\ u_2(t) \end{pmatrix} dx \\
& = \begin{pmatrix} w_1(t) & w_2(t) \end{pmatrix} \int_{\text{element } j} f \begin{pmatrix} N_1(x) \\ N_2(x) \end{pmatrix} dx \\
& - k \begin{pmatrix} w_1(t) & w_2(t) \end{pmatrix} \begin{pmatrix} N_1(0) \\ N_2(0) \end{pmatrix} b. \quad (19.99)
\end{aligned}$$

Omitting weight function vector,

$$\begin{aligned}
& \sum_{\text{element } j} \int \begin{pmatrix} \frac{dN_1(x)}{dx} \\ \frac{dN_2(x)}{dx} \end{pmatrix} \\
& \times \begin{pmatrix} \frac{dN_1(x)}{dx} & \frac{dN_2(x)}{dx} \end{pmatrix} dx \begin{pmatrix} \dot{u}_1(t) \\ \dot{u}_2(t) \end{pmatrix} \\
& + \sum_{\text{element } j} \int k \begin{pmatrix} \frac{dN_1(x)}{dx} \\ \frac{dN_2(x)}{dx} \end{pmatrix} \\
& \times \begin{pmatrix} \frac{dN_1(x)}{dx} & \frac{dN_2(x)}{dx} \end{pmatrix} dx \begin{pmatrix} u_1(t) \\ u_2(t) \end{pmatrix} \\
& - \sum_{\text{element } j} \int f \begin{pmatrix} N_1(x) \\ N_2(x) \end{pmatrix} dx - k \begin{pmatrix} N_1(0) \\ N_2(0) \end{pmatrix} b = 0. \quad (19.100)
\end{aligned}$$

Now we get the following matrix representation, where \mathbf{M} and \mathbf{K} are called the mass matrix and stiffness matrix, respectively:

$$\begin{aligned} \mathbf{M}\dot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) &= \mathbf{F}(t) \\ \text{where } \mathbf{M} &= \sum_{\text{element } j} \int \left(\frac{dN_1(x)}{dx} \frac{dN_2(x)}{dx} \right) \\ &\quad \times \left(\frac{dN_1(x)}{dx} \frac{dN_2(x)}{dx} \right) dx, \\ \mathbf{K} &= \sum_{\text{element } j} \int k \left(\frac{dN_1(x)}{dx} \frac{dN_2(x)}{dx} \right) \\ &\quad \times \left(\frac{dN_1(x)}{dx} \frac{dN_2(x)}{dx} \right) dx, \\ \mathbf{F} &= \sum_{\text{element } j} \int f \begin{pmatrix} N_1(x) \\ N_2(x) \end{pmatrix} dx \\ &\quad - k \begin{pmatrix} N_1(0) \\ N_2(0) \end{pmatrix} b. \end{aligned} \quad (19.101)$$

Combining the definition of the generalized trapezoidal method as follows:

$$\begin{aligned} \mathbf{M}\dot{\mathbf{u}}^{n+1} + \mathbf{K}\mathbf{u}^{n+1} &= \mathbf{F}^{n+1}, \\ \mathbf{u}^{n+1} &= \mathbf{u}^n + \Delta t \dot{\mathbf{u}}^{n+\alpha}, \\ \dot{\mathbf{u}}^{n+\alpha} &= (1-\alpha)\dot{\mathbf{u}}^{n+\alpha} \dot{\mathbf{u}}^{n+1}, \end{aligned} \quad (19.102)$$

we finally get the following algorithm:

$$\begin{aligned} &\frac{1}{\alpha \Delta t} (\mathbf{M} + \alpha \Delta t \mathbf{K}) \mathbf{u}^{n+1} \\ &= \mathbf{F}^{n+1} + \frac{1}{\alpha \Delta t} \mathbf{M} [\mathbf{u}^n + (1-\alpha) \Delta t \dot{\mathbf{u}}^n]. \end{aligned} \quad (19.103)$$

It should be noted that both \mathbf{u}^n and $\dot{\mathbf{u}}^n$ should be stored in the code for the Crank–Nicolson method.

In the case of $\alpha = 0$, that is, the forward Euler case, if the left-hand side mass matrix \mathbf{M} is lumped (summing the diagonal terms), \mathbf{u}^{n+1} can be obtained without serious matrix inversion. This is an explicit method, where **LS-DYNA** and **PAM-CRASH** for crash **FE** analysis are the most common pieces of software used for this type.

In the explicit time integration scheme (both in **FDM** and **FEM**), the Courant–Friedrichs–Lewy (**CFL**) condition is a key issue to determine a proper time step. The **CFL** condition says that a time step must be less than the time for some significant action to occur. In other words, the Courant number defined in (19.104) must be less than 1, where c , h , and Δt are dissipation speed, mesh size, and time step. This means if one uses a very fine mesh, one should also use a proper tiny time step. The mesh size and the time step are linked together in the explicit method by

$$v = \frac{c}{\left(\frac{h}{\Delta t}\right)} = c \frac{\Delta t}{h}. \quad (19.104)$$

19.7 Multidimensional Case

The multidimensional case is basically the extension of one-dimensional case, but it is usually difficult to have an image of derivations in matrix forms. Here we study it without tensor description.

Let us consider the two-dimensional heat conduction problem, described by (19.105). In this case, we consider isotropic heat conduction without any directional references (see (19.56) for a general description):

$$\frac{\partial q_x}{\partial x} + \frac{\partial q_y}{\partial y} = f, \quad (19.105)$$

$$\text{with } u = a \text{ on } \Gamma_a, \quad -qn = b \text{ on } \Gamma_b,$$

$$\begin{aligned} \text{where } \mathbf{q} &= \begin{pmatrix} q_x \\ q_y \end{pmatrix} = - \begin{pmatrix} k & 0 \\ 0 & k \end{pmatrix} \begin{pmatrix} \frac{\partial u(x, y)}{\partial x} \\ \frac{\partial u(x, y)}{\partial y} \end{pmatrix} \\ &\quad (\text{Fourier's law in the isotropic case}). \end{aligned}$$

By substituting Fourier's law to the partial differential equation (19.105), we get

$$k \left(\frac{\partial^2 u(x, y)}{\partial x^2} + \frac{\partial^2 u(x, y)}{\partial y^2} \right) = -f. \quad (19.106)$$

In the following part, we only consider (19.106) without boundary conditions for simplicity.

19.7.1 Finite Difference Method

By extension of the one-dimensional definition in finite difference operators, we can easily obtain the following operators in the two-dimensional case

$$\begin{aligned} \frac{\partial \phi(x, y)}{\partial x} &\approx \frac{\phi(x+h, y) - \phi(x-h, y)}{2h_x}, \\ \frac{\partial \phi(x, y)}{\partial y} &\approx \frac{\phi(x, y+h) - \phi(x, y-h)}{2h_y}, \end{aligned}$$

$$\begin{aligned}\frac{\partial^2 u(x, y)}{\partial x^2} &\approx \frac{u(x+h, y) - 2u(x, y) + u(x-h, y)}{h_x^2}, \\ \frac{\partial^2 u(x, y)}{\partial y^2} &\approx \frac{u(x, y+h) - 2u(x, y) + u(x, y-h)}{h_y^2}.\end{aligned}\quad (19.107)$$

Now let us consider two-dimensional finite difference grids in Fig. 19.20.

Fig. 19.20 Finite difference grids in the two-dimensional case

Applying (19.107) to (19.106) at node 5 in Fig. 19.19 gives

$$\begin{aligned}k \left(\frac{\partial^2 u(x, y)}{\partial x^2} + \frac{\partial^2 u(x, y)}{\partial y^2} \right) \\ \approx k \left(\frac{u_4 - 2u_5 + u_6}{h_x^2} + \frac{u_2 - 2u_5 + u_8}{h_y^2} \right),\end{aligned}\quad (19.108)$$

which is visualized by the local and global matrix representations in Fig. 19.21. The whole global matrix for (19.106) is piled up without any overlap between rows.

19.7.2 Finite Element Method

As in Sect. 19.2, the weak form can be generated by multiplying the weight function w with the governing equation in (19.106). It should be noted that all functions are assumed to be functions wrt x and y .

$$\int_{\Omega} \left(\frac{\partial q_x(x, y)}{\partial x} + \frac{\partial q_y(x, y)}{\partial y} - f \right) w(x, y) d\Omega = 0 \quad (19.109)$$

By applying integration by parts, or the Green–Gauss theorem, we obtain

$$-\int_{\Omega} f w(x, y) d\Omega + \int_{\Gamma_b} w(x, y) \left(\frac{\partial q_x}{\partial x} n_x + \frac{\partial q_y}{\partial y} n_y \right) d\Gamma$$

Fig. 19.21 Local (upper) and global matrix in two-dimensional FDM

$$-\int_{\Omega} \left(\frac{\partial w(x, y)}{\partial x} q_x + \frac{\partial w(x, y)}{\partial y} q_y \right) d\Omega = 0. \quad (19.110)$$

After substituting Fourier's law into (19.110), we get the matrix form

$$\begin{aligned}\int_{\Omega} \left(\frac{\partial w(x, y)}{\partial x} \frac{\partial w(x, y)}{\partial y} \right) \begin{pmatrix} k & 0 \\ 0 & k \end{pmatrix} \begin{pmatrix} \frac{\partial u(x, y)}{\partial x} \\ \frac{\partial u(x, y)}{\partial y} \end{pmatrix} d\Omega \\ = \int_{\Omega} f w(x, y) d\Omega + \int_{\Gamma_b} w(x, y) b d\Gamma.\end{aligned}\quad (19.111)$$

Now we consider the left-hand term only, which is

$$\int_{\Omega_j} \left(\frac{\partial w(x, y)}{\partial x} \frac{\partial w(x, y)}{\partial y} \right) \begin{pmatrix} k & 0 \\ 0 & k \end{pmatrix} \begin{pmatrix} \frac{\partial u(x, y)}{\partial x} \\ \frac{\partial u(x, y)}{\partial y} \end{pmatrix} d\Omega. \quad (19.112)$$

As in Sect. 19.1, the variable (and its derivatives) are represented by finite element shape functions, where we consider the four-node bilinear quadrilateral finite

element:

$$\begin{aligned}
 & \begin{pmatrix} \frac{\partial u(x, y)}{\partial x} \\ \frac{\partial u(x, y)}{\partial y} \end{pmatrix} \\
 &= \begin{pmatrix} \frac{\partial N_1(x, y)}{\partial x} & \frac{\partial N_2(x, y)}{\partial x} & \frac{\partial N_3(x, y)}{\partial x} & \frac{\partial N_4(x, y)}{\partial x} \\ \frac{\partial N_1(x, y)}{\partial y} & \frac{\partial N_2(x, y)}{\partial y} & \frac{\partial N_3(x, y)}{\partial y} & \frac{\partial N_4(x, y)}{\partial y} \end{pmatrix} \\
 & \times \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{pmatrix}. \quad (19.113)
 \end{aligned}$$

Substituting (19.113) into (19.112) gives

$$\begin{aligned}
 & \int_{\Omega_j} \begin{pmatrix} w_1 & w_2 & w_3 & w_4 \end{pmatrix} \begin{pmatrix} \frac{\partial N_1}{\partial x} & \frac{\partial N_1}{\partial y} \\ \frac{\partial N_2}{\partial x} & \frac{\partial N_2}{\partial y} \\ \frac{\partial N_3}{\partial x} & \frac{\partial N_3}{\partial y} \\ \frac{\partial N_4}{\partial x} & \frac{\partial N_4}{\partial y} \end{pmatrix} \begin{pmatrix} k & 0 \\ 0 & k \end{pmatrix} \\
 & \times \begin{pmatrix} \frac{\partial N_1}{\partial x} & \frac{\partial N_2}{\partial x} & \frac{\partial N_3}{\partial x} & \frac{\partial N_4}{\partial x} \\ \frac{\partial N_1}{\partial y} & \frac{\partial N_2}{\partial y} & \frac{\partial N_3}{\partial y} & \frac{\partial N_4}{\partial y} \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{pmatrix} d\Omega. \quad (19.114)
 \end{aligned}$$

Omitting vectors \mathbf{w} and \mathbf{u} ,

$$\begin{aligned}
 K_j &= \int_{\Omega_j} \begin{pmatrix} \frac{\partial N_1}{\partial x} & \frac{\partial N_1}{\partial y} \\ \frac{\partial N_2}{\partial x} & \frac{\partial N_2}{\partial y} \\ \frac{\partial N_3}{\partial x} & \frac{\partial N_3}{\partial y} \\ \frac{\partial N_4}{\partial x} & \frac{\partial N_4}{\partial y} \end{pmatrix} \\
 & \times \begin{pmatrix} k & 0 \\ 0 & k \end{pmatrix} \begin{pmatrix} \frac{\partial N_1}{\partial x} & \frac{\partial N_2}{\partial x} & \frac{\partial N_3}{\partial x} & \frac{\partial N_4}{\partial x} \\ \frac{\partial N_1}{\partial y} & \frac{\partial N_2}{\partial y} & \frac{\partial N_3}{\partial y} & \frac{\partial N_4}{\partial y} \end{pmatrix} d\Omega. \quad (19.115)
 \end{aligned}$$

Since FEM handles an arbitrary shaped domain, an element's shape is usually arbitrary. For this reason, finite element functions in natural coordinates are used in the

Fig. 19.22a,b Bilinear quadrilateral element (a) Physical coordinates (b) Natural coordinates

multidimensional case

$$\begin{aligned}
 u(x, y) &= \sum_{k=1}^4 u_k N_k(s, t), \\
 x(s, t) &= \sum_{k=1}^4 x_k N_k(s, t), \\
 y(s, t) &= \sum_{k=1}^4 y_k N_k(s, t), \\
 \frac{\partial [x(s, t), y(s, t)]}{\partial (s, t)} &= \begin{pmatrix} \frac{\partial x(s, t)}{\partial s} & \frac{\partial x(s, t)}{\partial t} \\ \frac{\partial y(s, t)}{\partial s} & \frac{\partial y(s, t)}{\partial t} \end{pmatrix}, \\
 \begin{cases} N_1(s, t) = \frac{1}{4}(1-s)(1-t), \\ N_2(s, t) = \frac{1}{4}(1+s)(1-t), \\ N_3(s, t) = \frac{1}{4}(1+s)(1+t), \\ N_4(s, t) = \frac{1}{4}(1-s)(1+t). \end{cases} \quad (19.116)
 \end{aligned}$$

It should be noted that all finite element functions always have, in general, the following property:

$$\begin{cases} N_\alpha(s_\beta, t_\beta) = \delta_{\alpha\beta}, \\ \sum_{\alpha=1}^n N_\alpha(s, t) = 1. \end{cases} \quad (19.117)$$

Considering the Jacobian matrix between (x, y) and (s, t) ,

$$K_j = \int_{\Omega_j} \begin{pmatrix} \frac{\partial N_1}{\partial s} & \frac{\partial N_1}{\partial t} \\ \frac{\partial N_2}{\partial s} & \frac{\partial N_2}{\partial t} \\ \frac{\partial N_3}{\partial s} & \frac{\partial N_3}{\partial t} \\ \frac{\partial N_4}{\partial s} & \frac{\partial N_4}{\partial t} \end{pmatrix} \begin{pmatrix} k & 0 \\ 0 & k \end{pmatrix} d\Omega \quad (19.118)$$

$$\times \begin{pmatrix} \frac{\partial N_1}{\partial s} & \frac{\partial N_2}{\partial s} & \frac{\partial N_3}{\partial s} & \frac{\partial N_4}{\partial s} \\ \frac{\partial N_1}{\partial t} & \frac{\partial N_2}{\partial t} & \frac{\partial N_3}{\partial t} & \frac{\partial N_4}{\partial t} \end{pmatrix} \left| \frac{\partial(x, y)}{\partial(s, t)} \right| d\Omega.$$

Local and global matrix representations around node 5 are visualized in Fig. 19.23.

Let us now show that the local stiffness matrix \mathbf{K}_j in the linear elastic solid case, which is treated in Sect. 19.4, has the following form for the reader's future reference.

The relationship in (19.70) and (19.72) can be summarized as shown in (19.119):

$$\begin{pmatrix} \varepsilon_{xx} \\ \varepsilon_{yy} \\ \varepsilon_{zz} \\ 2\varepsilon_{yz} \\ 2\varepsilon_{zx} \\ 2\varepsilon_{xy} \end{pmatrix} = \begin{pmatrix} \frac{\partial}{\partial x} & 0 & 0 \\ 0 & \frac{\partial}{\partial y} & 0 \\ 0 & 0 & \frac{\partial}{\partial z} \\ 0 & \frac{\partial}{\partial z} & \frac{\partial}{\partial y} \\ 0 & \frac{\partial}{\partial z} & \frac{\partial}{\partial x} \\ \frac{\partial}{\partial y} & \frac{\partial}{\partial x} & 0 \end{pmatrix} \begin{pmatrix} \frac{\partial u}{\partial x} \\ \frac{\partial u}{\partial y} \\ \frac{\partial u}{\partial z} \end{pmatrix}. \quad (19.119)$$

Considering (19.119), the local stiffness matrix $\mathbf{K}^{\text{element } j}$ for an eight-node brick element can be defined as below, where the \mathbf{D} matrix is the same as in (19.72) for the isotropic elastic cases. This is schematic view of the $\mathbf{K}^{\text{element } j}$ matrix and the treatment in Fig. 19.22 is not visualized here. For further details, please refer to [19.2].

$$\mathbf{K}^{\text{element } j} \mathbf{u}^{\text{element } j} = \left(\int_{\Omega_j} \mathbf{B}^T \mathbf{D} \mathbf{B} d\Omega \right) \mathbf{u}^{\text{element } j}$$

where $\mathbf{B} = \begin{bmatrix} \frac{\partial N_1}{\partial x} & 0 & 0 & \dots & \frac{\partial N_8}{\partial x} & 0 & 0 \\ 0 & \frac{\partial N_1}{\partial y} & 0 & \dots & 0 & \frac{\partial N_8}{\partial y} & 0 \\ 0 & 0 & \frac{\partial N_1}{\partial z} & \dots & 0 & 0 & \frac{\partial N_8}{\partial z} \\ 0 & \frac{\partial N_1}{\partial z} & \frac{\partial N_1}{\partial x} & \dots & 0 & \frac{\partial N_8}{\partial z} & \frac{\partial N_8}{\partial x} \\ \frac{\partial N_1}{\partial z} & 0 & \frac{\partial N_1}{\partial x} & \dots & \frac{\partial N_8}{\partial z} & 0 & \frac{\partial N_8}{\partial x} \\ \frac{\partial N_1}{\partial y} & \frac{\partial N_1}{\partial x} & 0 & \dots & \frac{\partial N_8}{\partial y} & \frac{\partial N_8}{\partial x} & 0 \end{bmatrix},$

$$\mathbf{u}^{\text{element } j} = \begin{pmatrix} u_1^{\text{element } j} \\ v_1^{\text{element } j} \\ w_1^{\text{element } j} \\ \vdots \\ u_8^{\text{element } j} \\ v_8^{\text{element } j} \\ w_8^{\text{element } j} \end{pmatrix}. \quad (19.120)$$

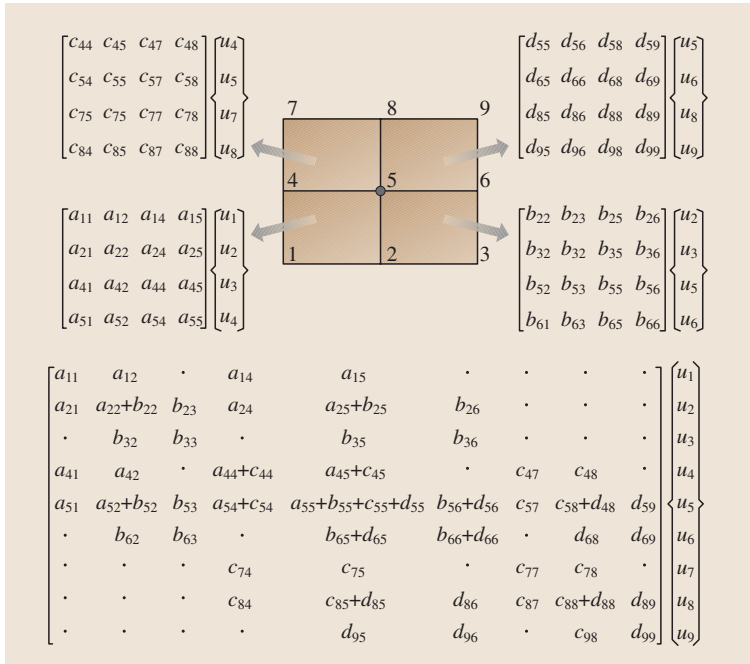

Fig. 19.23 Local and global matrix in two-dimensional FEM

19.8 Treatment of the Nonlinear Case

Nonlinear problems can be classified into several patterns, such as material nonlinearity, geometrical nonlinearity (including large strain/stress and buckling), and boundary nonlinearity (including moving boundary and contact/friction). Since nonlinearity among these classes is so different on a numerical sense, the reader should be careful, when using nonlinear commercial software. Even the defined strain is different in some settings (for further information, refer to [19.6]).

As for the numerical treatment of the nonlinear problem, we want to pick up one typical method here. The Newton–Raphson method [19.4] is the method used to solve a nonlinear equation $g(x) = 0$ by iterative calculation of the derivative of $g(x)$ (or Jacobian in the multidimensional case) as shown in (19.121)

$$g(x) = 0. \quad (19.121)$$

By applying a Taylor's expansion to the nonlinear iterative equation $g(x^{k+1}) = 0$ around x^k and omitting higher-order terms, we get

$$g(x^{k+1}) \approx g(x^k) + g'(x^k)(x^{k+1} - x^k) = 0. \quad (19.122)$$

Rewriting (19.122) results in the following representation, which drives the $k + 1$ th step approximated solution x^{k+1} from the value x^k at the previous k th step

$$x^{k+1} = x^k - [g'(x^k)]^{-1} g(x^k), \quad g'(x^k) \neq 0. \quad (19.123)$$

It should be noted that Newton–Raphson method is valid for multidimensional nonlinear problems as shown

Fig. 19.24 Newton–Raphson method

in (19.124)

$$\begin{aligned} g_1(x_1, \dots, x_n) &= 0, \\ &\dots \\ g_n(x_1, \dots, x_n) &= 0. \end{aligned} \quad (19.124)$$

If the nonlinearity of the equation is not severe and the initial guess x^0 is not far from the solution, this algorithm offers a numerically acceptable converged solution x^* by applying (19.123) iteratively from an initial guess x^0 , as shown in Fig. 19.24. However if an initial guess x^0 is too far from a converged solution x^* (for example, the point Q is selected as an initial guess x^0 in Fig. 19.24) or if the function $g(x) = 0$ is highly nonlinear, the method might still diverge, even after many iterations. In this case, more stable methods such as the Riks method [19.6] should be applied.

19.9 Advanced Topics in FEM and FDM

Some advanced topics are treated in this section. You may encounter some of the problems when you use FEM or FEM software packages. The explanation below is just a sample for the reader, with references provided for more information.

19.9.1 Preprocessing

Until now we have been talking about theoretical aspects with an algorithm explanation. However, the most time-consuming part in the numerical analysis (especially

in three-dimensional case) is modeling, which is the process of making FE mesh or FD grids in advance of simulation.

Some so-called “automatic” mesh/grid generator software is available, however, the reader should recognize that there are two categories of automatic model generation schemes: the interactive mapped mesh half-automatic generation approach and the noninteractive nonmapped mesh full-automatic generation approach. The former requires an interactive, time-consuming task to help the automatic mesh generation software. The ba-

sic idea of mapped mesh approach [19.8] is based on the conforming mapped function as shown in Fig. 19.22ab.

Since FDM handles regular shaped domains in most cases because of its limitation, mesh generation is done using the interactive mapped mesh approach basically [19.9]. However, FEM can treat the domain of an arbitrary shape, thus the noninteractive non-mapped mesh approach might be a better tool for modeling [19.10].

It should be noted that the modeling method greatly affects the quality of solution in discretized methods. The reader should always recognize that what the discretized numerical method can do is provide an approximated solution.

19.9.2 Postprocessing

As mentioned in remark (4) in Sect. 19.2.2, the first derivative of an FE function is discontinuous between elements. This implies that a node has m derivative values if the node is surrounded by m elements. To obtain a representative value at a node, Winslow's weighted averaging scheme (19.125) in [19.11] or super convergent patch scheme [19.12] is usually applied, which is nothing but a process to convert element-wise values to nodal values

$$x_n = \frac{\sum_{n,j=1}^{m,j} x_{g_{nj}} w_{nj}}{\sum_{n,j=1}^{m,j} w_{nj}}, \quad (19.125)$$

where x_n is the target variable at node n , x_{nj} is the centroid coordinates at finite elements j ($j = 1, m$) connected with the node n , and w_{nj} is a weight (1 in this case) at element j . Visualization software sometimes does this kind of postprocessing automatically, which can conceal unacceptable unsmoothed solutions with nice visualizations in some cases.

19.9.3 Numerical Error

If we get some unacceptable numerical results as compared with experimental data, there might be several causes for the errors. Basically, a numerical simulation involves three stages, as shown in Fig. 19.25. The major error source might lie between the “real problem” and “physical model”, which is related to the simplification process of the real target problem with selecting a proper physical property. For example, if

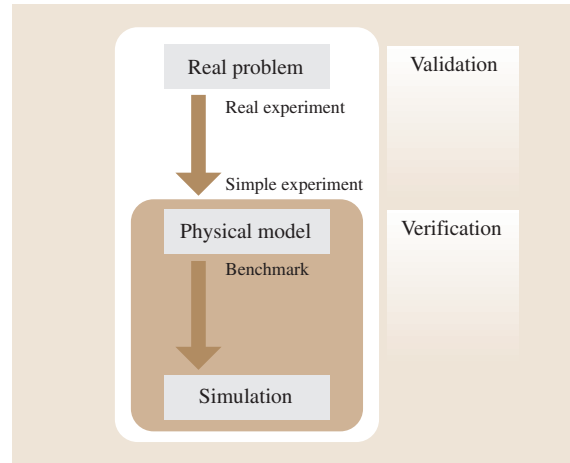

Fig. 19.25 Three stages of simulation

the head conduction coefficient is improper (inaccurately approximated) to model the considered problem, we cannot get an acceptable numerical solution even with very accurate numerical schemes applied. The responsibility of numerical schemes only covers physical models and simulation, although it gives rise to serious error due to an inefficient number of grids or meshes. To distinguish the discussion between the former and the latter, the terminology “verification and validation” is sometimes used [19.13]. Validation is “confirmation by examination and provisions of objective evidence that the particular requirements for a specific intended use are fulfilled”, while verification is “confirmation by examination and provisions of objective evidence that specified requirements have been fulfilled”, according to IEEE definition [19.13]. Thus, in discussion above, the former is related to validation, while the latter is linked with verification.

As described above, infinitely fine mesh/grid leads to the exact solution, which requires an infinite scale matrix calculation. It is an important idea for engineers to establish acceptable numerical analysis within the limitation of real computational power available. Since the quality of FD/FE analysis greatly depends on the quality of mesh/grid, the reader must be careful in real simulations. Automatic mesh/grid control schemes, such as the adaptive finite element method [19.12] or boundary-fitted finite difference method [19.9], can be useful for this purpose. Most commercial software provides this function for better results. It should be emphasized that this is only related to the verification stage.

As for the worse cases, solutions themselves can sometimes not be obtained due to the improper settings in numerical analyses. For example, the treatment of incompressibility in fluids and solids is one of the typical matters to be noted. In incompressible flows, the equations for velocity and pressure are usually solved separately in a weakly coupled fashion. In this case, the feasible combination of velocity-element and pressure-element is limited by the Ladyzhenskaya–Babuska–Brezzi (LBB or BB) condition in the usual FE formulation [19.14], while staggered-type grids are needed in popular FD formulation [19.14]. It should be added that there are no uniform general numerical formulation proposed that are valid for both incompressible and compressible flows. In the same manner for fluid, the treatment of incompressible materials in solid FEA should be carefully treated, which can be a cause of so-called locking in the simulation. The treatment of magnetic problems usually needs some techniques. The problems above might be described in the manuals in most commercial FE/FD software, but the reader should keep them in mind.

Usually FEM and FDM are conducted with the information of material properties, domain's shape, and boundary conditions, to obtain the distribution of temperature in thermodynamics, displacement/strain/stress in solid mechanics, velocity/pressure in fluid dynamics, and so on. If and only if the quality of the simulation is highly reliable, material properties can be “measured” by applying FEM and FDM iteratively with the technique of minimum search. This inverse problem setting is sometimes useful, especially when the direct measurement is impossible for some reason, although the uniqueness of the inverse solutions is not always guaranteed. For information on the state-of-the-art of this subject, please refer to [19.15].

19.9.4 Relatives of FEM and FDM

There exist other methods categorized in discretized numerical schemes. We briefly introduce some of them.

Finite Volume Method (FVM)

FVM is an effective scheme for fluid dynamics, where flux-balancing is considered in a finite volume (control volume) [19.16]. The domain is discretized into infinite number of finite volumes, and its shape can be arbitrary. Unknown variables are defined at the center of the control volume, while the flux on its boundary is linked with the unknown variables in some way.

Boundary Element Method (BEM)

The derivation of BEM is based on Green's theorem with the use of fundamental solutions in various phenomena [19.17]. BEM mainly supports linear analysis. According the Green's theorem, an n -dimensional problem can be treated as an $(n - 1)$ -dimensional problem setting but only homogenous material can be handled in BEM. The main advantage of this method is that it can treat infinite domain such as in magnetic or acoustic problems without any theoretical difficulties. The matrix is a dense matrix, while it is a sparse matrix in other discretized methods.

Constrained Interpolated Profile (CIP) Method

The CIP method is very powerful for moving boundary problem and multiphysics problems [19.18, 19]. It is one of multimeasure methods with a spline-interpolation function in FDM's category, which utilizes both variables and its derivatives for calculation.

Particle Method

The biggest weak point of discretized methods is that it cannot easily handle complicated moving boundary unsteady problems, including explosions, since the topology of grid/mesh must be fixed during time-step calculations. Particle methods, such as the discrete element method (DEM), smooth particle hydrodynamics method (SPH), and related various methods, are good for these unflavored problems. Because of limited space in this chapter, please refer to [19.20] for details.

Including the additional methods treated above, a rough summary of the properties of each method is shown in Table 19.1. The information listed might be not a complete set, but serves as a reference for a reader.

19.9.5 Matrix Calculation and Parallel Computations

As shown above, the coefficient matrix in FEM and FDM is a diagonal-dominated (banded) sparse matrix. The matrix can be symmetrical in heat and elastic solid problem or nonsymmetrical in fluid and nonlinear solid problems.

There are two categories in matrix calculation: direct method and iterative method. The direct matrix solvers are based on Gauss-elimination and its modifications, such as the skyline method for symmetric matrices, frontal (wave front) method for a nonsymmetric matrix. Since the banded size around the diagonal varies according to the numbering of the nodes, which greatly

Table 19.1 Summary of discretized numerical schemes

	Strong points	Weak points	Major targets	Software
FEM	2nd BC treatment Local resolution Arbitrary shape	Calculation time Complex derivation Sensitive solution	Nonlinear Solid/ Thermal/Fluid/ Vibration	ANSYS (Multiphysics) LS-DYNA (Crash/Solid) FIDAP (Fluid), etc.
FDM	Calculation time Stable solution Simple derivation	Stable solution Regular shape Heuristic aspects	Simple derivation	Flow-3D (Fluid), etc.
FVM	Calculation time Stable solution Moving boundary	Local resolution Heuristic aspects	Thermal/Fluid	FLUENT (Fluid), etc.

CIP	Complex problem Stable solution Multiphysics	New method No sales software	Thermal/Fluid/ Solid	[19.17]
PM	No mesh/grid Explosion Highly nonlinear	Calculation time New method No sales software	Nonlinear Solid/ Explosion	[19.18]

affects the calculation time and required memory size, some renumbering algorithms to reduce the bandwidth are proposed.

The iterative methods can be classified into two groups: (1) The stationary iterative methods, such as the Jacobi method, Gauss–Seidel method, and successive overrelaxation (SOR) method, and (2) the nonstationary method, such as the conjugate gradient (CG) method, the biconjugate gradient stabilized (Bi-CGSTAB) method, quasiminimal residual (QMR) method, and generalized minimal residual (GMRES) method [19.21]. The rough algorithm in the stationary iterative methods can be represented by (19.126):

$$\begin{aligned} \mathbf{Ax} = \mathbf{b} &\rightarrow \mathbf{Mx} = (\mathbf{M} - \mathbf{A})\mathbf{x} + \mathbf{b}, \\ \mathbf{Mx}^{k+1} &= (\mathbf{M} - \mathbf{A})\mathbf{x}^k + \mathbf{b}, \end{aligned} \quad (19.126)$$

where (1) \mathbf{M} = diagonal part of \mathbf{A} , (2) \mathbf{M} = triangular part of \mathbf{A} , and (3) \mathbf{M} = combination of (1) and (2) part of \mathbf{A} .

The basic algorithm on nonstationary method is represented in (19.127), where \mathbf{r} , \mathbf{p} , and \mathbf{x} are the residual vector, direction vector, and the solution vector, respectively.

$$\begin{aligned} \mathbf{r}^0 &= \mathbf{b} - \mathbf{Ax}^0 \\ \text{for } k &= 0, 1, 2, \dots \end{aligned}$$

$$\begin{aligned} \mathbf{p}^{k+1} &= \mathbf{p}^k + \alpha \mathbf{r}^k \\ \mathbf{x}^{k+1} &= \mathbf{x}^k + \beta \mathbf{p}^{k+1} \\ \mathbf{r}^{k+1} &= \mathbf{b} - \mathbf{Ax}^{k+1} \\ \text{convergence check} \\ \text{end.} \end{aligned} \quad (19.127)$$

To accelerate convergence of the iterations, the algorithm with some preconditioners is proposed as in [19.21]:

$$\begin{aligned} \mathbf{r}^0 &= \mathbf{b} - \mathbf{Ax}^0 \\ \text{for } k &= 0, 1, 2, \dots \\ \mathbf{z}^k &= \mathbf{M}^{-1} \mathbf{r}^k \\ \mathbf{p}^{k+1} &= \mathbf{p}^k + \alpha \mathbf{z}^k \\ \mathbf{x}^{k+1} &= \mathbf{x}^k + \beta \mathbf{p}^{k+1} \\ \mathbf{r}^{k+1} &= \mathbf{b} - \mathbf{Ax}^{k+1} \\ \text{convergence check} \\ \text{end.} \end{aligned}$$

Some of the related subroutines above are available from [19.22].

For the parallel calculation method such as the domain decomposition method, please refer to [19.23] and [19.24]. Table 19.2 shows the summary of matrix calculation methods.

Table 19.2 Summary of matrix calculation methods

19.9.6 Multiscale Method

To bridge the macroscopic scale and mezosopic scale, the multiscale approach was recently considered to be important. The homogenization method is one of the

solutions that carries numerical material testing between macroscale (usual FE mesh) and microscale (FE mesh at material level) to get real-time stress–strain constitutive behavior for FEA in macroscale. The key points of this method are introduced in reference [19.25].

19.10 Free Codes

Some internet URLs for FEM and FDM are provided for the reader's convenience. This is not a recommended selection; the reader must use the information at their own risk.

1. Information on modeling, FEM, and FDM
http://www.engr.usask.ca/~macphed/finite/fe_resources/fe_resources.html (Internet Finite Element Resources; general information on FEM including free codes)

The CALPHAD

20. The CALPHAD Method

Phase diagrams offer various areas of materials science and technology indispensable information for the comprehension of the properties of materials. The microstructure of solid materials is generally classified according to the size of the constituents – for example, at the electron, atomic, or granular level (see Chap. 3). Accordingly, fundamental principles like quantum mechanics, statistical mechanics, or thermodynamics are applied individually to describe the physical properties. Phases are important features of material because they characterize homogeneous aggregations of matter with respect to chemical composition and uniform crystal structure. The various functions of a material are closely related to the phases and structures of the material's composition. Therefore, to develop a material with a maximum level of desired functions, it is essential to undertake design of the structure in advance.

Phase diagrams are composed by means of experimental measurements, as well as statistical thermodynamic analysis. The construction of phase diagram calculations based on experiments and thermodynamic analysis are generally referred to as the calculation of phase diagrams (**CALPHAD**) approach [20.1]. This method provides a very accurate understanding of the properties originating in the macroscopic character of the material under study.

This chapter is organized in three parts:

- In the first part, a brief outline of the **CALPHAD** method is summarized.
- In the second part, the method for deriving the Gibbs free energies incorporating the *ab initio* calculations is presented in order to clarify the uncertainty of thermodynamic properties for metastable solution phases, taking the Fe–Be-based **bcc** phase as an example. Some results

for metastable phase equilibria in the Fe–Be, and Co–Al binary systems are shown.

- In the third part the application to predict thermodynamic properties of compound phases is discussed. The thermodynamic modeling for the Perovskite carbide with an $E2_1$ -type structure in the Fe–Al–C, Co–Al–C and Ni–Al–C ternary systems is illustrated, and constructions of phase diagrams are performed.

20.1 Outline of the CALPHAD Method

Phase diagrams provide basic and important information especially for the design of new materials. However, by using experimental techniques only, a lot of time and labor is required in construction of even a partial region of a phase diagram, because the practical materials are composed of multicomponent alloys, more than ternary systems. In order to break this difficult situation, the method of calculation of phase diagrams was advocated and is referred to as the **CALPHAD** method. **CALPHAD** was originally a name for this researcher's group, however it has recently become the name for the technique by which a phase diagram is calculated on the basis of thermodynamics. In this method a variety of experimental values concerning the phase boundaries and the thermodynamic properties is analyzed according to an appropriate thermodynamic model and the interaction energies between atoms are evaluated. By using this technique, phase diagrams outside the experimental range can be calculated based on thermodynamic proof. Difficulty in extension of the calculated results to higher-order systems is much less than that in the case of experimental work, since the essence of the calculation does not change so much between a binary system and a higher-order system. This method provides a very accurate understanding of the properties originating in the macroscopic character of the material under study. However, a shortcoming of this approach is that it is hard to obtain information on metastable equilibria, or on undiscovered phases, since the thermodynamic parameters from this method can only be evaluated from experimental data.

The empirical model of *de Boer* et al. [20.2] has often been used to deduce the thermodynamic quantities of systems where the experimental values do not exist. In this model, generally called Miedema's model, the crystal lattice is divided into Wigner–Seitz cells. The simple expression for the formation energy in alloys is derived by considering the change in the electron density states at the interface between the cells, as shown in (20.1)

$$\Delta E \propto -P (\Delta\Phi)^2 + Q \left(\Delta n_{\text{WS}}^{1/3} \right)^2. \quad (20.1)$$

Here, Δn_{WS} is the difference in electron density based on the volume of the Wigner–Seitz cell between different species of atoms. This term always leads to local perturbations that give rise to a positive energy contribution in (20.1). On the other hand, $\Delta\Phi$ presents a difference between the chemical potentials of the different species of atoms at the cell surfaces, and leads

to an attractive term in (20.1). The constants P and Q are proportionality constants, derived empirically. Equation (20.1) does not contain any parameters that refer to the crystal structure, and therefore, the heats of solution of face-centered-cubic (fcc), body-centered-cubic (bcc), and hexagonal-close-packed (hcp) structures, as well as liquids, are predicted. However, it is known that the absolute values are not always predicted accurately, although this model predicts the correct sign for the formation enthalpy in various alloy systems. For example, thermodynamic analysis of the Fe–Pd system predicts the enthalpy of formation for the L_{10} and the L_{12} ordered phases to be -14 kJ/mol and -22 kJ/mol, respectively, while the predicted values from Miedema's model are -6 kJ/mol for the L_{10} phase and -4 kJ/mol for the L_{12} phase [20.3]. The large difference between these values means that incorporating Miedema's model with a thermodynamic analysis is rather difficult.

Such serious problems, which are intrinsic to the **CALPHAD** approach, should be solved with the assistance of the first principle energetic calculation method. Thus, in the present chapter, a new approach to introduce some thermodynamic quantities obtained by the *ab initio* band energy calculations in the conventional **CALPHAD**-type analysis of some alloy systems is presented.

20.1.1 Description of Gibbs Energy

Gibbs Free Energy

Using the Regular Solution Approximation

The selection of a thermodynamic model by which Gibbs free energy of an alloy system is described is the most important factor when using the **CALPHAD** method. In a system in which interaction between alloying elements is not so strong, the regular solution model is well known to describe the thermodynamic properties of the alloys comparatively well. For instance, the free energy of the A–B binary alloy is expressed as (20.2)

$$G_m = x_A {}^0G_A + x_B {}^0G_B + x_A x_B L_{AB} + RT(x_A \ln x_A + x_B \ln x_B), \quad (20.2)$$

where 0G_i is the Gibbs energy of the pure component i in the standard, and x_i is the mole fraction of i . L_{AB} shows the interaction energy for A atoms and B atoms, and is given by

$$L_{AB} = NZ \left[\varepsilon_{AB} - \frac{1}{2} (\varepsilon_{AA} + \varepsilon_{BB}) \right], \quad (20.3)$$

where N denotes the so called Avogadro's number, Z is the coordination number, and ε_{AB} , ε_{AA} and ε_{BB} show the cohesion energies between A–B, A–A, B–B atomic pair, respectively. The ordering between unlike atoms occurs for $L_{AB} < 0$ because the A–B atom pair is more stable than the average of the A–A and B–B atom pairs. On the other hand, the clustering of the like atom is caused in case of $L_{AB} > 0$. For $L_{AB} = 0$, no atomic interaction exists, and then the solution shows the random mixing of atoms. This interaction parameter should not be constant but a function of the temperature and the chemical compositions of alloys. From a qualitative point of view, the first term of (20.2) represents the energies of mechanical mixing, the second term stands for excess energy which shows deviation from the ideal solution, and the third is ideal mixing entropy.

Gibbs Free Energy Using the Sublattice Model

For the simplest case of the sublattice model [20.4], let us consider a phase represented by the formula $(A, B)_a(C, D)_b$, containing two elements A and B in one sublattice “1” and two elements C and D in the other sublattice “2”. The coefficients a and b show the number of sites in each sublattice and the size of the sublattices may be generally chosen as $a + b = 1$ for convenience. There are four elements in the system, however the degrees of freedom in varying in composition are two, because the total numbers of atoms in each sublattice are fixed. Thus these two composition parameters are conveniently plotted on a square where the corners represented the four

basic end members A_aC_b , A_aD_b , B_aC_b , and B_aD_b , as shown in Fig. 20.1a. The symbols y_B^1 and y_D^2 denote the mole fractions, respectively, for the sublattices 1 and 2, and they are represented as follows:

$$y_B^1 = \frac{n_B^1}{n_A^1 + n_B^1}, \quad y_D^2 = \frac{n_D^2}{n_C^2 + n_D^2}. \quad (20.4)$$

In this equation n_i^j denotes the number of i atoms in the j sublattice. The nonplanar surface composed of four reference states, i. e., one each for the compounds A_aC_b , A_aD_b , B_aC_b , and B_aD_b , is called the surface of reference as shown in Fig. 20.1b, and represented by

$$G_m^{\text{ref}} = y_A^1 y_C^2 {}^0G_{A_aC_b} + y_A^1 y_D^2 {}^0G_{A_aD_b} \\ + y_B^1 y_C^2 {}^0G_{B_aC_b} + y_B^1 y_D^2 {}^0G_{B_aD_b}. \quad (20.5)$$

For the entropy term, the following Gibbs energy of mixing can be obtained, assuming the atoms mix randomly within each sublattice

$$G_{\text{mix}}^{\text{ideal}} = RT \left[a \left(y_A^1 \ln y_A^1 + y_B^1 \ln y_B^1 \right) \right. \\ \left. + b \left(y_C^2 \ln y_C^2 + y_D^2 \ln y_D^2 \right) \right]. \quad (20.6)$$

It seems difficult to accept that the interaction between A and B atoms should be quite independent of whether the other sublattice is occupied by C and D atoms. Thus the regular solution model should be defined as the power series representation of excess Gibbs free energy

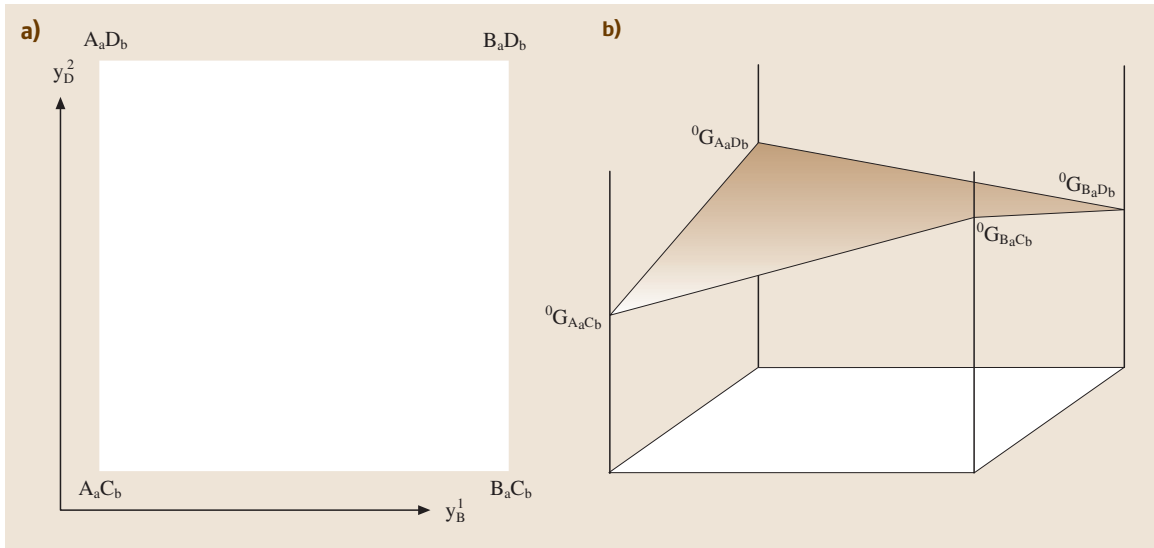

Fig. 20.1 (a) Composition square in a quaternary system $(A, B)_a(C, D)_b$ and (b) surface of reference for the free energy

by the following equation

$$G_{\text{mix}}^{\text{xs}} = y_{\text{A}}^1 y_{\text{B}}^1 y_{\text{C}}^2 L_{\text{A,B:C}} + y_{\text{A}}^1 y_{\text{B}}^1 y_{\text{D}}^2 L_{\text{A,B:D}} \\ + y_{\text{C}}^2 y_{\text{D}}^2 y_{\text{A}}^1 L_{\text{A:C,D}} + y_{\text{C}}^2 y_{\text{D}}^2 y_{\text{B}}^1 L_{\text{B:C,D}}, \quad (20.7)$$

where $L_{i,j:k}$ (or $L_{i:j,k}$) is the interaction parameter between unlike atoms on the same sublattice. Consequently the Gibbs energy for one mole of the phase, denoted as $(\text{A}, \text{B})_{\text{a}}(\text{C}, \text{D})_{\text{b}}$, can be represented by the two-sublattice model as shown in (20.8):

$$G_m = G_m^{\text{ref}} + G_{\text{mix}}^{\text{ideal}} + G_{\text{mix}}^{\text{xs}}. \quad (20.8)$$

Gibbs Energy for Interstitial Solutions Represented by Sublattice Model

The Gibbs energy for interstitial phases is very important in steels and ferrous alloys, where the elements such as C, N, S, or B occupy the interstitial sites of solid solutions. The structure of such a phase is considered as consisting of two sublattices, one occupied by substitutional elements and the other occupied by the interstitial elements as well as vacancies. Let us consider the austenite phase for the Fe–Cr–C system, for instance. The occupation of the sublattices is shown as $(\text{Cr}, \text{Fe})_1(\text{C}, \text{Va})_1$, since the number of sites in each sublattice is 1 : 1 in the case of an fcc structure. The Gibbs energy is given by the following equation:

$$G_m = y_{\text{Cr}}^1 y_{\text{Va}}^2 {}^0G_{\text{Cr:Va}} + y_{\text{Fe}}^1 y_{\text{Va}}^2 {}^0G_{\text{Fe:Va}} \\ + y_{\text{Cr}}^1 y_{\text{C}}^2 {}^0G_{\text{Cr:C}} + y_{\text{Fe}}^1 y_{\text{C}}^2 {}^0G_{\text{Fe:C}} \\ + RT \left[\left(y_{\text{Cr}}^1 \ln y_{\text{Cr}}^1 + y_{\text{Fe}}^1 \ln y_{\text{Fe}}^1 \right) \right. \\ \left. + \left(y_{\text{C}}^2 \ln y_{\text{C}}^2 + y_{\text{Va}}^2 \ln y_{\text{Va}}^2 \right) \right] \\ + y_{\text{Cr}}^1 y_{\text{Fe}}^1 y_{\text{Va}}^2 \sum_v {}^vL_{\text{Cr,Fe:Va}} \left(y_{\text{Cr}}^1 - y_{\text{Fe}}^1 \right)^v \\ + y_{\text{Cr}}^1 y_{\text{Fe}}^1 y_{\text{C}}^2 \sum_v {}^vL_{\text{Cr,Fe:C}} \left(y_{\text{Cr}}^1 - y_{\text{Fe}}^1 \right)^v \\ + y_{\text{Cr}}^1 y_{\text{C}}^2 y_{\text{Va}}^2 \sum_v {}^vL_{\text{Cr:C,Va}} \left(y_{\text{C}}^2 - y_{\text{Va}}^2 \right)^v \\ + y_{\text{Fe}}^1 y_{\text{C}}^2 y_{\text{Va}}^2 \sum_v {}^vL_{\text{Fe:C,Va}} \left(y_{\text{C}}^2 - y_{\text{Va}}^2 \right)^v. \quad (20.9)$$

The first two terms represent the Gibbs energy of fcc Cr and Fe, because the second sublattice consists of vacancies. The next two terms represent the Gibbs energy of

the CrC and FeC compounds, where the interstitial sites are completely filled with C. The second line shows the ideal entropy term, while the residual lines represents the excess terms of the Gibbs energy. When $y_{\text{C}}^2 = 0$ in the equation, the Gibbs energy equation coincides with the equation for the simple substitutional mixing of Cr and Fe.

Magnetic Contribution to Gibbs Energy

In magnetic materials containing Fe, Ni and Co, there is polarization of electron spins, and it is necessary to consider the magnetic contribution to the Gibbs energy, by adding the extra term to the paramagnetic Gibbs energy G_m as follows:

$$G = G_m + G_{\text{mag}}. \quad (20.10)$$

The magnetic contribution to the Gibbs free energy, G_{mag} , is given by the expression

$$G_{\text{mag}} = RTf(\tau) \ln(\beta + 1), \quad (20.11)$$

where

$$f(\tau) = 1 - \frac{1}{A} \left[\frac{79\tau^{-1}}{140p} + \frac{474}{497} \left(\frac{1}{p} - 1 \right) \right. \\ \left. \times \left(\frac{\tau^3}{6} + \frac{\tau^9}{135} + \frac{\tau^{15}}{600} \right) \right], \text{ for } \tau < 1 \quad (20.12)$$

and

$$f(\tau) = -\frac{1}{A} \left(\frac{\tau^{-5}}{10} + \frac{\tau^{-15}}{315} + \frac{\tau^{-25}}{1500} \right), \text{ for } \tau \geq 1, \quad (20.13)$$

and

$$A = \frac{518}{1125} + \frac{11692}{15975} \left(\frac{1}{p} - 1 \right). \quad (20.14)$$

The variable τ is defined as T/T_{C} , where T_{C} is the Curie temperature and β is the mean atomic moment expressed in Bohr magnetons μ_{B} . The value of p depends on the structure, and $p = 0.28$ for the fcc phase.

20.1.2 Equilibrium Conditions

Figure 20.2 shows the so-called Gibbs energy-composition diagram for the A–B binary system. This figure schematically shows the relationship between a eutectic type of binary phase diagram and the Gibbs energy curves of each phase. Let us consider the case in which the microstructure of the alloy is composed of the α and β phases. When the Gibbs energies of the α and

Fig. 20.2 Eutectic type of phase diagram and corresponding Gibbs energy-composition diagram for hypothetical A–B binary system

β phases are given by the points $a_1 (G_1^\alpha)$ and $b_1 (G_1^\beta)$, respectively, the total energy of the solution is represented by the line $a_1 b_1$ in the figure. At the alloy composition x_B^1 , the Gibbs energy is G_1 and each phase has the volume fraction of f^α and f^β . Then the following relation holds:

$$G_1 = G_1^\alpha f^\alpha + G_1^\beta f^\beta. \quad (20.15)$$

The thermodynamic equilibrium is achieved under the condition of the lowest energy of the alloy. According to this criterion, the point G_1 is not the lowest energy state, but decreases further to G_e by changing f^α and f^β .

The line $a_e b_e$ is a common tangent of Gibbs energy G^α and G^β , and the equilibrium composition of each phase is given as x_B^α and x_B^β . In the calculation of the phase equilibrium, it is convenient to use these chemical potentials as the basic equations. For instance, to obtain the equilibrium between phase α and phase β , (20.4) should be calculated by using the numerical analytic method

$$\begin{aligned} \mu_A^\alpha &= \mu_A^\beta, \\ \mu_B^\alpha &= \mu_B^\beta. \end{aligned} \quad (20.16)$$

The chemical potential μ of each element is obtained by using

$$\mu_i = G_m - \sum_{j=1}^2 x_j \frac{\partial G_m}{\partial x_j} + \frac{\partial G_m}{\partial x_i} \quad (20.17)$$

and hence the chemical potentials of A and B species in the ϕ phase are expressed as:

$$\begin{aligned} \mu_A^\phi &= {}^0G_A^\phi + RT \ln x_A^\phi + (x_B^\phi)^2 L_{AB}^\phi, \\ \mu_B^\phi &= {}^0G_B^\phi + RT \ln x_B^\phi + (x_A^\phi)^2 L_{AB}^\phi. \end{aligned} \quad (20.18)$$

20.1.3 Evaluation of Thermodynamic Parameters

The interaction parameters included in the free energy expression can be directly evaluated from the experimental values on activity. For example the activity of Pb over the Pb–Sb binary liquid have been determined as shown in Table 20.1 [20.5]. The liquid state of the elements is adopted as its standard. If the composition dependency of the interaction parameter is expressed as (20.19), the chemical potential of Pb in the binary system can be derived as (20.20)

$$L_{\text{PbSb}} = {}^0L_{\text{PbSb}} + (x_{\text{Pb}} - x_{\text{Sb}})^1 L_{\text{PbSb}}, \quad (20.19)$$

$$\begin{aligned} \mu_{\text{Pb}} &= {}^0G_{\text{Pb}} + RT \ln x_{\text{Pb}} + (1 - x_{\text{Pb}})^2 \\ &\quad \times \left[{}^0L_{\text{PbSb}} + (4x_{\text{Pb}} - 1)^1 L_{\text{PbSb}} \right]. \end{aligned} \quad (20.20)$$

Table 20.1 Experimental data on activity of Pb in the Pb–Sb binary liquid

x_{Pb}	0.05	0.1	0.2	0.3	0.4	0.5
a_{Pb}	0.04	0.08	0.162	0.247	0.338	0.433
x_{Pb}	0.6	0.7	0.8	0.9	0.95	
a_{Pb}	0.555	0.674	0.785	0.897	0.946	

This is straightforwardly arranged as

$$\frac{RT \ln(a_{\text{Pb}}/x_{\text{Pb}})}{(1-x_{\text{Pb}})^2} = \left({}^0L_{\text{PbSb}} - {}^1L_{\text{PbSb}} \right) + 4x_{\text{Pb}} {}^1L_{\text{PbSb}} \quad (20.21)$$

since the relation $\mu_{\text{Pb}} = {}^0G_{\text{Pb}} + RT \ln a_{\text{Pb}}$ holds. Therefore, if the left-hand side of (20.21) is calculated from the activity data shown in Table 20.1 and the each value is plotted against x_{Pb} , the interaction parameters ${}^0L_{\text{PbSb}}$, ${}^1L_{\text{PbSb}}$ can be obtained, respectively, from the intercept of the ordinate and the slope of the straight line as:

$${}^0L_{\text{PbSb}} = -2900 \text{ J/mol}, \quad {}^1L_{\text{PbSb}} = -200 \text{ J/mol}. \quad (20.22)$$

The calculated activity of Pb in the liquid phase was compared with the experimental values in Fig. 20.3. Considering the other observed data set at a different temperature yields the dependence on the temperature for the interaction parameters ${}^0L_{\text{PbSb}}$, ${}^1L_{\text{PbSb}}$.

Fig. 20.3 Calculated activity of Pb in the Pb–Sb binary liquid compared with experimental values [20.5]

20.2 Incorporation of the First Principle Calculations into the CALPHAD Approach

In this section, in order to clarify the uncertainty of thermodynamic properties for metastable solution phases, the method for deriving the Gibbs free energies incorporating the first principle calculations is presented, taking the Fe–Be–based *bcc* phase as the example. First, a set of some superstructures is selected to be representative of a series of *bcc*-based ordered phases, and the total energies are calculated using the first principle calculations. Next, the effective cluster interaction energies can be extracted from these formation energies using the cluster expansion method (CEM). This leads to a set of composition-independent parameters, from which the energy of the set of superstructures can be reproduced in terms of a set of correlation functions. Once we know the cluster interaction energies for the alloy system, the enthalpy term is expressed by the combination of effective cluster interaction and the correlation functions for the clusters. The entropy term in the Gibbs energy expression is calculated using the cluster variation method (CVM) with the tetrahedron approximation to calculate the configurational entropy.

Minimizing the grand potential with respect to all the correlation functions allows for the Gibbs energy of mixing to be obtained as a function of composition at a constant temperature.

20.2.1 Outline of the First Principle Calculations

First principle calculations using density functional theory (DFT) have proved to be quite reliable in condensed matter physics. There still remains a barrier to overcome in application to materials science, for instance, stoichiometric deviations, surfaces, impurities, and grain boundaries, however, for certain materials, the direct application of this technique has been attempted in studying the various properties using 100 or more atoms in a unit cell. According to the theorem based on DFT, the total energy E_{tot} of a nonspin-polarized system of interacting electrons in an external potential is given as a function of the ground state electronic density ρ as in the following

equation:

$$E_{\text{tot}}(\rho) = \int V(r)\rho(r)d^3r + T[\rho] + \frac{e^2}{2} \int \frac{\rho(r)\rho(r')}{|r-r'|} d^3r d^3r' + E_{\text{XC}}[\rho]. \quad (20.23)$$

Here the first term $\int V(r)\rho(r)d^3r$ denotes the Coulomb interaction energy between the electrons and nuclei, $T[\rho]$ is the single-particle kinetic energy, $\frac{e^2}{2} \int \frac{\rho(r)\rho(r')}{|r-r'|} d^3r d^3r'$ is the Hartree component of the electron–electron energy, and $E_{\text{XC}}[\rho]$ is the exchange–correlation functional.

Kohn and Sham [20.6] showed that the correct density in the equation is given by the self-consistent solution of a set of single particles following Schrödinger-like equations as

$$\varepsilon_i \Psi_i(r) = \left[-\frac{\hbar}{2m} \nabla^2 + V(r) + e^2 \int \frac{\rho(r')}{|r-r'|} d^3r' + V_{\text{XC}}(r) \right] \Psi_i(r). \quad (20.24)$$

In (20.24), V_{XC} represents the exchange correlation potential and $V_{\text{XC}}(r) = \partial E_{\text{XC}}[\rho]/\partial \rho(r)$. Thus we can obtain an appropriate electronic density in much easier way as compared with solving a many-body Schrödinger equation. In calculations, the single particle Kohn–Sham equation in (20.24) is solved separately on a grid of sampling points in the irreducible part of the Brillouin zone, and the obtained orbitals are used to construct the charge density.

The first principle calculations based on DFT may be, at this time, divided into two methods; one employing pseudopotentials and relatively simple basis sets,

and the other using much more complex basis sets such as the full potential linearized augmented plane wave (FLAPW), which gives accurate results on formation energies for metals. The FLAPW method, as embodied in the WIEN2k software package [20.7], is one of the most accurate schemes for electronic calculations, and allows for very precise calculations of the total energies in a solid, and will be employed in the present energetic calculations. The FLAPW method uses a scheme for solving many-electron problems based on the local spin density approximation (LSDA) technique. In this framework, a unit cell is divided into two regions: nonoverlapping atomic spheres and an interstitial region. Inside the atomic spheres, the wave functions of the valence states are expanded using a linear combination of radial functions and spherical harmonics, while a plane wave expansion is used in the interstitial region. The LSDA technique includes an approximation for both the exchange and correlation energies, and it has been recently enhanced by the addition of electron density gradient terms to the exchange–correlation energy. This has led to a generalized gradient approximation (GGA), as suggested by Perdew et al. [20.8], and we used this improved method rather than the LSDA approach.

20.2.2 Gibbs Energies of Solution Phases Derived by the First Principle Calculations

The formation enthalpies of some binary ordered structures derived by the first principle calculations are compared with experimental data in Table 20.2 [20.9]. In this comparison, alloy systems where the thermodynamic analysis had already been completed, are selected. The bcc- and fcc-based ordered phases are included

Table 20.2 Comparison of the estimated formation enthalpies for some ordered structures with the appropriate evaluated data

Alloy systems	Structures	Temperature (K)	Experimental values (kJ/mol)	Calculated values (kJ/mol)
Al–Ni	B2	298	–71.7	–69.5
	L1 ₂	298	–41.0	–40.5
Al–Ti	L1 ₀	298	–39.8	–39.6
	D0 ₁₉ (Ti ₃ Al)	298	–27.5	–27.3
Be–Cu	B2	298	–21.4	–19.0
Fe–Pd	B2	298	–15.6	–13.2
Fe–Ti	B2	298	–51.6	–46.5
Ni–Ti	B2	999	–34.2	–34.1
	D0 ₂₄ (Ni ₃ Ti)	827	–54.0	–51.4
Al–Li	B32	298	–22.8	–23.1

in the calculations. As can be seen in this table, the calculated values and evaluated data are reasonably consistent, and this close agreement encourages us to proceed to the next step to evaluate the Gibbs free energies of solution phases.

First Principle Calculations
of the Gibbs Free Energy

The **bcc** phase in the Fe–Be binary system is illustrated as an example to derive the Gibbs energy on the basis of ab initio method, since the phase is metastable and located in the central part of the phase diagram, the thermodynamic properties in this region are unknown.

An outline for deriving the Gibbs free energies of the **bcc**-based structures incorporating the ab initio calculations is as follows. First, a set of superstructures {A-A2, A₃B–D0₃, AB-B2, AB-B32, AB₃–D0₃, B-A2} are selected to be representative of a series of **bcc**-based ordered phases, the total energies were calculated using the **FLAPW** method. With the known total energies, the formation energy of the **bcc**-based superstructures, $\Delta E_{\text{form}}^{\phi}$, is defined by averaging the total energy of the elements with chemical composition to the segregation limit, as shown in the following equation

$$\Delta E_{\text{form}}^{\phi}(V) = E_{\text{tot}}^{\phi}(V) - \left(1 - x_{\text{Be}}^{\phi}\right) E_{\text{tot}}^{\text{bccFe}}(V_{\text{Fe}}) - x_{\text{Be}}^{\phi} E_{\text{tot}}^{\text{bccBe}}(V_{\text{Be}}), \tag{20.25}$$

where ϕ denotes the type of superstructure and V is the volume.

Then, the effective cluster interaction energies, $\{v_i(V)\}$, can be extracted from these formation energies using the cluster expansion method (**CEM**) developed by *Connolly* and *Williams* [20.10]. This leads to a set of composition-independent parameters, from which the energy of the set of superstructures can be reproduced in terms of a set of correlation functions $\{\xi_i^{\phi}\}$,

$$\Delta E_{\text{form}}^{\phi}(V) = \sum_{i=0}^{\gamma} v_i(V) \times \xi_i^{\phi}, \tag{20.26}$$

where $v_i(V)$ is the effective interaction energy of the i -point cluster, and ξ_i^{ϕ} is the correlation function for cluster i in the phase ϕ ; ξ_i^{ϕ} is defined as the ensemble average of the spin operator $\sigma(p)$, which takes values of ± 1 , depending on the atom occupancy of the lattice site p . The values of ξ_i^{ϕ} for the superstructures considered in this study are summarized in Table 20.3. The formation energies to the segregation limit for the Fe–Be binary system in the D0₃, B2, B32, and A2 structures in the ground state are summarized in Table 20.4 [20.11].

The upper limit of the summation in (20.26) γ specifies the largest cluster that participated in the expansion. In the case of the Fe–Be system, a tetrahedron cluster is considered, as schematically illustrated in Fig. 20.4, as being the largest cluster, since in the **bcc** structure, the tetrahedron forms an irregular shape containing both the first- and second-nearest neighbor distances. The second

Table 20.4 The formation energies to the segregation limit for the Fe–Be binary system in the D0₃, B2, B32, and A2 structures in the ground state

Basic lattice	Composition of Be		Strukturbericht	Formation enthalpy (kJ/mol)
bcc	0	Fe	A2	0.0
bcc	0.25	Fe ₃ Be	D0 ₃	– 12.3
bcc	0.5	FeBe	B2	– 31.4
bcc	0.5	FeBe	B32	– 9.3
bcc	0.75	FeBe ₃	D0 ₃	– 18.6
bcc	1	Be	A2	0.0

Fig. 20.4 Various clusters consisting of ordered structures

pair interaction was also taken into account, which leads to the consequence that mathematically, five γ should represent six types of cluster. From Table 20.3, we can see that $\{\xi_i^\phi\}$ is a 6×6 matrix and that it is a regular matrix. The matrix inversion of (20.26) yields the effective interaction energies as

$$v_i(V) = \sum_{i=0}^5 \left(\xi_i^\phi \right)^{-1} \Delta E_{\text{form}}^\phi(V).$$

(20.27)

Thus the interatomic interactions can be estimated by expanding the total energies of the ordered structures obtained from the band-energy calculations.

Using the *Murnaghan* equation of states [20.12], as shown in (20.28), the total energies of the A2, B2, B32, and the D0₃ structures were expressed as a function of the volume

$$E(V) = \frac{BV}{B'(B'-1)} \left[B' \left(1 - \frac{V_0}{V} \right) + \left(\frac{V_0}{V} \right)^{B'} - 1 \right] + E(V_0),$$

(20.28)

where B , B' , and V_0 are the bulk modulus, its pressure derivative, and the equilibrium volume, respectively, at normal pressures. Table 20.5 shows the coefficients in (20.28) for each ordered structure. In this table, $E(V)$ is the total energy of each ordered structure in the equilibrium volume of the B2 structure; i.e., $V_0 = 124.0438 \text{ a.u.}^3$. The formation energy of each structure is represented as $\Delta E_{\text{form}}^\phi$, by defining the average concentration of the total energy of the **bcc** Fe and the **bcc** Be phases at the segregation limit. By applying (20.28) to these formation energies, the

effective interaction, $\{v_i(V)\}$, corresponding to each cluster is calculated, as shown in Table 20.6, where the positive numbers define the attractive force working between unlike atoms. The value of v_2 represents the interaction energy between the nearest neighbor atoms, while v_3 denotes the next-nearest neighbor interaction.

The Gibbs free energies of the metastable bcc-based phase in the Fe–Be binary system are evaluated using the effective cluster interaction energies up to the tetrahedron cluster, including a second pair interaction as

$$\Delta E = \sum_{i=0}^5 v_i \xi_i. \quad (20.29)$$

At a finite temperature T the free energy of a phase of interest ΔG can be obtained by adding a configurational entropy term ΔS to the internal energy as follows [20.13, 14]:

$$\Delta G = \Delta E - T \Delta S. \quad (20.30)$$

The cluster variation method (CVM) with the tetrahedron approximation are used to calculate the configurational entropy. For the bcc structure, the en-

ropy formula is

$$\Delta S = k_B \times \ln \frac{\left\{ \prod_{i,j,k} (N z_{ijk})! \right\}^{12} \left\{ \prod_i (N x_i)! \right\}}{\left\{ \prod_{i,j,k,l} (N w_{ijkl})! \right\}^6 \left\{ \prod_{i,j} (N y_{ij})! \right\}^4 \left\{ \prod_{i,j} (N y_{ij})! \right\}^3}, \quad (20.31)$$

where x_i , y_{ij} , y_{ij} , z_{ijk} , and w_{ijkl} are the cluster probabilities of finding the atomic configurations specified by the subscript(s) at a point, the nearest neighbour pair, the second-nearest neighbour pair, the triangle, and the tetrahedron clusters, respectively, and N is the number of lattice points. Minimizing the grand potential with respect to all the correlation functions allows for the Gibbs energy of mixing to be obtained as a function of composition at a constant temperature, T .

The compositional variation of the formation enthalpy derived by the cluster expansion and the cluster variation methods is shown in Fig. 20.5 [20.11]. The solid lines show the results of thermodynamic analyses described in the following section. The open squares denote the corresponding Gibbs free energy derived by the method shown in this section.

Fig. 20.5 The Gibbs energies of mixing in the α bcc solid solution at 227 °C and 727 °C based on ab initio energetic calculations

20.2.3 Thermodynamic Analysis of the Gibbs Energies Based on the First Principle Calculations

The Gibbs free energy of the **bcc** phase derived using the first principle calculations is analyzed according to the two-sublattice model. According to Table 20.4, the most stable ordered structure in the Fe–Be **bcc** phase is recognized as a B2 structure, and hence the Gibbs free energy for this simple structure is described in this section. The Gibbs energy for one mole of ϕ phase, denoted as $(\text{Fe}, \text{Be})_m(\text{Fe}, \text{Be})_n$, is represented by the two-sublattice model as described in Sect. 20.1.1 as the following equation:

$$\begin{aligned} G^\phi = & y_{\text{Fe}}^1 y_{\text{Fe}}^2 {}^0G_{\text{Fe:Fe}}^\phi + y_{\text{Fe}}^1 y_{\text{Be}}^2 {}^0G_{\text{Fe:Be}}^\phi \\ & + y_{\text{Be}}^1 y_{\text{Fe}}^2 {}^0G_{\text{Be:Fe}}^\phi + y_{\text{Be}}^1 y_{\text{Be}}^2 {}^0G_{\text{Be:Be}}^\phi \\ & + RT \left[\frac{m}{m+n} \left(y_{\text{Fe}}^1 \ln y_{\text{Fe}}^1 + y_{\text{Be}}^1 \ln y_{\text{Be}}^1 \right) \right. \\ & \left. + \frac{n}{m+n} \left(y_{\text{Fe}}^2 \ln y_{\text{Fe}}^2 + y_{\text{Be}}^2 \ln y_{\text{Be}}^2 \right) \right] \\ & + {}^{\text{ex}}G^\phi + G_{\text{mag}}. \end{aligned} \quad (20.32)$$

The term y_i^s denotes the site fraction of element i in the sublattice s . The terms m and n are variables denoting the size of the sublattice s , and straightforwardly, the relationships of $m = 0.5$ and $n = 0.5$ hold for the B2 structure. ${}^0G_{i,j}$ denotes the Gibbs energy of a hypothetical compound $i_{0.5}j_{0.5}$, and terms relative to the same stoichiometry are identical, whatever the occupation of the sublattice. The excess Gibbs energy term, ${}^{\text{ex}}G^\phi$, contains the interaction energy between unlike atoms, and is expressed using the following polynomial

$$\begin{aligned} {}^{\text{ex}}G^\phi = & y_{\text{Fe}}^1 y_{\text{Be}}^1 y_{\text{Fe}}^2 L_{\text{Fe,Be:Fe}} + y_{\text{Fe}}^1 y_{\text{Be}}^1 y_{\text{Be}}^2 L_{\text{Fe,Be:Be}} \\ & + y_{\text{Fe}}^2 y_{\text{Be}}^2 y_{\text{Fe}}^1 L_{\text{Fe:Fe,Be}} + y_{\text{Fe}}^2 y_{\text{Be}}^2 y_{\text{Be}}^1 L_{\text{Be:Fe,Be}}, \end{aligned} \quad (20.33)$$

where $L_{i,j,k}$ (or $L_{i,j,k}$) is the interaction parameter between unlike atoms on the same sublattice. The magnetic contribution to the Gibbs free energy G_{mag} was given by (20.11).

The thermodynamic parameters obtained by fitting the ab initio values to (20.32) are shown as follows:

$$\begin{aligned} G_{\text{Be:Fe}}^\beta - 0.5 {}^0G_{\text{Be}}^{\text{bcc}} - 0.5 {}^0G_{\text{Fe}}^{\text{bcc}} \\ = -37\,100 + 9T \text{ (J/mol)}, \end{aligned}$$

$$\begin{aligned} G_{\text{Fe:Be}}^\beta - 0.5 {}^0G_{\text{Be}}^{\text{bcc}} - 0.5 {}^0G_{\text{Fe}}^{\text{bcc}} \\ = -37\,100 + 9T \text{ (J/mol)}, \end{aligned}$$

$${}^0L_{\text{Be,Fe:Be}}^\beta = {}^0L_{\text{Be:Be,Fe}}^\beta = -4T \text{ (J/mol)},$$

$${}^0L_{\text{Fe:Be,Fe}}^\beta = {}^0L_{\text{Be,Fe:Fe}}^\beta = -380 - 4T \text{ (J/mol)}.$$

The calculated Gibbs energies of mixing in the α **bcc** solid solution at 227 and 727 °C are drawn in Fig. 20.5 using the solid lines for the ordered state (**bcc**–B2) and the disordered state (**bcc**–A2), respectively. The convex curvature of the free energy in the vicinity of the equiatomic composition corresponds to the formation of the B2 structure.

20.2.4 Construction of Stable and Metastable Phase Diagrams

The information on the experimental data on the phase boundaries and other thermodynamic quantities are thermodynamically analyzed together with the estimated metastable quantities of the **bcc** phase described in the foregoing section.

The calculated results of the Fe–Be phase diagram are compared with the experimental data in Fig. 20.6. The shaded area shown in this figure is the metastable (**bcc**+B2) two-phase region, which is accompanied by the ordering of the **bcc** structure on formation. The dotted line shows the order–disorder transition line, along which the two-phase field expands into the higher temperature range. The age hardening of this alloy has been investigated experimentally and the results are summarized in [20.15], and a brief outline of the ageing process of this alloy is as follows. The disordered **bcc** structure forms in the initial stage, and consequently, the B2-type ordered structure separates in the **bcc** phase. A $\langle 100 \rangle$ modulated structure with changes in concentration was observed in some samples using electron microscopy. This ordering behavior of the **bcc** structure is possibly explained by the metastable equilibria in Fig. 20.6.

It is well known that the solubility of Be in **bcc** Fe (α) deviates significantly from the Arrhenius equation; i. e., a proportional relationship exists between the logarithm of the solubility and the reciprocal of the temperature. The solubility of Be in the α phase is shown in Fig. 20.7. The solubility would be denoted by the broken line if there were neither an order–disorder transition nor a magnetic transition in the **bcc** Fe phase. This is approximated by the straight line following the Arrhenius law for dilute solutions. Thus, the deviation of the solubility from the ideal Arrhenius law is repre-

Fig. 20.6 Calculated Fe–Be phase compared with experimental data

Fig. 20.7 Solubility of Be in the α phase

sented by the shaded areas. The dashed lines show the order–disorder transition temperature and the magnetic transition temperature of the bcc Fe phase. The solubility of Be decreases in the lower temperature region below 650°C , while it increases in the higher temperature region. The decrease in solubility in the lower temperature region can be explained from the viewpoint of the change in magnetism [20.16]. On the other hand, the solubility increases owing to the order–disorder transition of the bcc phase in the higher temperature range. Figure 20.8 shows the change in the order parameter along a solubility line for the α phase. The order parameter was defined by

$$\eta = y_{\text{Be}}^1 - y_{\text{Be}}^2. \quad (20.34)$$

The solubility line in Fig. 20.8a intersects the order–disorder transition line indicated by the dotted line at about 650°C . As can be seen in Fig. 20.8b, the order parameter along the solubility line increases at a higher temperature than 650°C , yielding the progress of the B2 ordering in the bcc disordered phase.

Fig. 20.8 (a) Enlarged Fe-rich portion of the calculated Fe–Be binary phase diagram. The dotted line shows the order–disorder transition line. (b) Change in the order parameter along the solubility line for the α phase

20.2.5 Application to More Complex Cases

In the foregoing Sect. 20.2.3, two-sublattice formalism was applied to describe the Gibbs energies derived from the first principle calculations. However, it is generally true that a more complex thermodynamic formalism such as a four-sublattice model is appropriate so as to reflect directly the results of the *ab initio* values in phase diagram computations, since several stoichiometric compositions are selected for superstructures, i. e., A_3B – $D0_3$, AB – $B2$, AB – $B32$, AB_3 – $D0_3$ etc. in the *bcc* phase. Then in this section, an analysis of metastable phase separation of *bcc* phase in the Co–Al and Ni–Al binary systems is presented [20.17] using the four-sublattice model. The more complex thermodynamic modeling brings a detailed knowledge about the metastable phase equilibria in these binary systems.

The Co–Al phase diagram consists of liquid, two *fcc* solid solutions γ (Co) and γ (Al), *hcp* Co(ϵ), β with CsCl structure, and the intermetallic phases Co_2Al_5 , $CoAl_3$, Co_4Al_{13} , and Co_2Al_9 , as shown in Fig. 20.9. There exists one eutectic reaction concerning the liquid phase and six invariant reactions between the solid phases. The $B2$ (β) phase has a large homogeneity range at higher temperatures, but the range decreases remarkably in the lower temperature region. It has been confirmed experimentally that the two-phase region for the $Al(\gamma)/B2(\beta)$ phases extends over a wide composition range with decreasing temperature. Owing to a sudden drop in the homogeneous region, these experimental values were debatable.

Fig. 20.9 Outline of the Co–Al binary phase diagram

Formation Energies of Superstructures for the Co–Al System

The formation energies to the segregation limit for the Co–Al system in the $D0_3$, $B2$, $B32$ structures in the ground state are summarized in Table 20.7, where the corresponding values for the Ni–Al system are included. The Gibbs free energies of the metastable *bcc*-based phase are evaluated using the effective cluster interaction energies up to the tetrahedron cluster, including the second pair interactions. Using the same procedure as in Sect. 20.2.2, the Gibbs energy of mixing can be obtained as a function of composition at a constant temperature T .

Table 20.7 Formation energies to the segregation limit for Co–Al and Ni–Al in the D0₃, B2, B32, and A2 structures in the ground state

Alloy system	Molar fraction of Al	Structure	Formation energy (kJ/mol)
Co–Al	0.25	D0 ₃	– 12.7
	0.5	B2	– 62.3
	0.5	B32	– 23.7
	0.75	D0 ₃	– 18.3
Ni–Al	0.25	D0 ₃	– 40.7
	0.5	B2	– 69.5
	0.5	B32	– 34.0
	0.75	D0 ₃	– 18.2

Expression of Gibbs Energy of the B2 Phase Using the Four-Sublattice Model

The β phase was described using a four-sublattice model, so as to reflect the results of the ab initio calculations on the phase diagram computation as

$$\left(\text{Al}_{y_{\text{Al}}^1}^1 \text{M}_{y_{\text{M}}^1}^1 \right)_{0.25} \left(\text{Al}_{y_{\text{Al}}^2}^2 \text{M}_{y_{\text{M}}^2}^2 \right)_{0.25} \left(\text{Al}_{y_{\text{Al}}^3}^3 \text{M}_{y_{\text{M}}^3}^3 \right)_{0.25} \left(\text{Al}_{y_{\text{Al}}^4}^4 \text{M}_{y_{\text{M}}^4}^4 \right)_{0.25} \quad (20.35)$$

The number of each sublattice site is 0.25, and the four sites are therefore equivalent. The disordered state is described when the site fractions of the different species are the same in the four sublattices. For the ordered structures, if two sublattices have the same site fractions, as do the two others, but are different, then the model describes the B2 and B32 phases. If three sublattices have the same site fractions, and are different from the fourth, then D0₃ ordering is described.

The Gibbs energy of the β phase is expressed by

$$\begin{aligned} G_m = & \sum_i \sum_j \sum_k \sum_l y_i^1 y_j^2 y_k^3 y_l^4 {}^0G_{i,j,k,l} \\ & + \frac{RT}{4} \sum_{s=1}^4 \sum_i y_i^s \ln(y_i^s) \\ & + \sum_{s=1}^4 \sum_i \sum_{j>i} \sum_k \sum_l \sum_m y_i^s y_j^s y_k^r y_l^r y_m^u L_{i,j,k,l,m} \end{aligned} \quad (20.36)$$

where ${}^0G_{i,j,k,l}$ denotes the Gibbs energy of a compound $i_{0.25}j_{0.25}k_{0.25}l_{0.25}$, and terms relative to the same stoichiometry are identical, whatever the occupation of the sublattice. $L_{i,j,k,l,m}$ is the interaction parameter between unlike atoms on the same sublattice.

Calculated Phase Equilibria in the Co–Al Binary System

The calculated Gibbs free energy of the bcc phases at 727 °C was compared with the results from the ab initio energetic calculations in Fig. 20.10. The calculated Co–Al binary phase diagram is compared with the experimental data in Fig. 20.11. The characteristic features of the binary phase diagram are well reproduced by the calculations. The dotted line shows the metastable two-phase separated region between the A2 (bcc-Co) and the B2 (β) phases. The two-phase separation, based on the bcc structure, closely relates the anomaly in the phase boundaries in the Co–Al binary system. This situation is schematically illustrated in Fig. 20.12, where the Gibbs free energies of the B2 (β) and the A1 (γ -Co) phases are drawn. The two-phase separation of the β phase does

Fig. 20.10 The calculated Gibbs free energy of the bcc phase in the Co–Al binary system at 727 °C compared with the results from the ab initio energetic calculations

Fig. 20.11 A comparison of the calculated Co–Al binary phase diagram with previous work

Fig. 20.12 The schematic Gibbs free energies of the B2 (β) and A2 (γ Co) phases in the Co–Al system

not occur at higher temperatures T_1 mainly owing to the effect of the entropy of random mixing on the atomic arrangement. On the other hand, the tendency towards ordering becomes stronger at lower temperatures T_2 . In

Fig. 20.13 Calculated Gibbs free energy of the bcc phase in the Ni–Al binary system at 727°C compared with the results from the ab initio energetic calculations

the B2 structure, the interaction between unlike atoms strengthens around the 50% Al composition, since the degree of order reaches a maximum at the equiatomic composition. The decrease in the enthalpy term due to the attractive interaction results in the acute point in the free energy curve in the vicinity of the 50% Al composition, and consequently, a two-phase separation in the β phase forms. This situation yields a significant shift of the phase boundary for the $(\gamma(\text{Co}) + \beta)/\beta$ composition to the equiatomic composition.

The procedure used for the Co–Al binary system is applied to the Ni–Al binary system. The calculated Gibbs free energy of the bcc phase is compared with the results of the ab initio energetic calculations in Fig. 20.13. The calculated Ni–Al binary phase diagram is compared with the experimental data in Fig. 20.14. The phase separation of the A2 and B2 structures can not be observed in this binary system.

Origin of Phase Separation in the Co–Al and Ni–Al Systems

The formation energies to the segregation limit for Co–Al and Ni–Al in the D0₃, B2, B32, and A2 structures in the ground state, as listed in Table 20.7, are plotted versus Al concentration in Fig. 20.15. In comparing the two systems, it can be seen that in the Co–Al

Fig. 20.14 A comparison of the calculated Ni–Al binary phase diagram with previous work

Fig. 20.15 Variation of the formation energies to the segregation limit for Co–Al and Ni–Al with concentration of Al

system, the energy of the D0₃ structure at the 25% Al composition is located slightly above the straight line connecting the energy values at the 0% Al and 50% Al compositions, which results in a two-phase separation of the A2 (bcc-Co) and B2 (β) structures in Co–Al that is more stable than the formation of the Co₃Al–D0₃ structure in the ground state. On the other hand, the energy plot of the Ni–Al system shows the stabilization of the Ni₃Al–D0₃ structure compared with the two-phase separation of the A2 (bcc-Ni) and B2 (β) structures, since the formation energy of the D0₃ phase is lower than the straight line connecting the energy values at the 0% Al

and 50% Al compositions. This energetic analysis suggests that a two-phase separation of the bcc-Co and B2 (β) phases occurs on the Co rich side in Co–Al system, while such a separation is not realized in the Ni–Al system.

Figure 20.16 shows the density of states (DOS) of the B2 (β) structure in the Co–Al and Ni–Al alloy systems. In this figure, E_F denotes the Fermi energy, where no electrons occupy the electronic states above this energy level. It can be seen that the distribution of the DOS of the B2 phase in the two systems is similar, with both showing a low DOS at the Fermi level. However, when observing the DOS of the D0₃ phase for these two systems, as shown in Fig. 20.17, we observe a marked difference between these two systems, in that the Fermi level is located near the peak of the DOS for the Co₃Al–D0₃ phase but decreases in a region with a very low DOS in the Ni₃Al–D0₃ phase. This fact indicates that from an energetic point of view, the stable D0₃ structure of the Ni₃Al phase is highly preferred, while in the Co₃Al–D0₃ phase is unstable with respect to separation of the A2 and B2 phases in the Co–Al system.

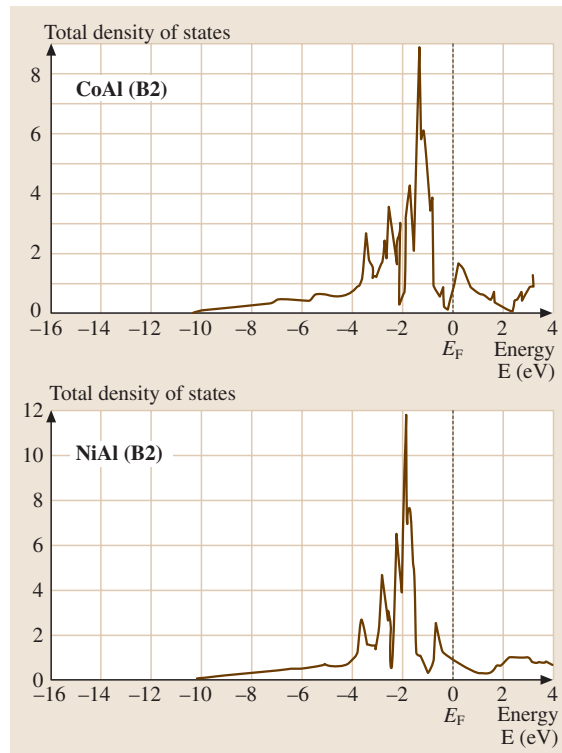

Fig. 20.16 The density of states of the B2 (β) structure in the Co–Al and Ni–Al alloy systems

Fig. 20.17 The density of states of the D0_3 structure in the Co–Al and Ni–Al alloy systems

This difference in the density of states at the Fermi level might be considered to be the result of the extra d-electron in Ni versus Co. From the point of view of the rigid band approximation, this difference in the number of electrons for two neighboring elements shifts the Fermi level towards the higher energy side in the Ni–Al system versus the Co–Al system. This raises the different relative positions of the Fermi level in the DOS curve, which consequently leads to the different structural stabilities.

The ground state analysis of the Ni–Al system suggests that the phase separation concerning the D0_3 structure forms at absolute zero. When assuming that such a two-phase separation forms at a finite temperature, however, the agreement between the calculated phase boundaries and experimental data is insufficient. For example, Fig. 20.18 shows the phase diagram in the case that a two-phase separation between the metastable D0_3 and B2 structures occurs around 500°C . The homogeneity range of the B2 single phase is comparatively

Fig. 20.18 The calculated Ni–Al phase diagram assuming that the critical temperature of the two-phase separation between the metastable D0_3 and B2 structures was around 500°C

reduced owing to the influence of the metastable miscibility gap with decreasing temperature, and accordingly, the calculated phase boundaries deviate from the exper-

imental data. Therefore, the phase separation of the D0₃ structure is not likely in the experimentally observable temperature range.

20.3 Prediction of Thermodynamic Properties of Compound Phases with First Principle Calculations

In an analysis of phase equilibria containing compound phases, physical properties of metastable structures are often required. The necessity appears clearly for instance in the following case. Figure 20.19 shows the isothermal phase diagram for the Fe–Cr–C ternary system. In this ternary system, several types of carbides form in which some amount of alloying element is soluble. If we consider the cementite, Cr substitutes more than 10% of Fe, and it forms the ternary line compound. In such a case, the Gibbs energy of the cementite phase is usually described by using sublattice model as the (Fe, Cr)₃C formula. Then if we want to evaluate the thermodynamic function for this phase, we need the formation energy of Cr₃C, which is metastable in the Cr–C binary system. In the procedure of CALPHAD approach, this parameter is usually determined on the basis of the experimental data in the Fe-rich side. However, it could be easily understood that this technique follows large amount of errors in estimation. Applying the first principle calculation may possibly solve this difficulty. Thus in the present section, some examples for application to predicting thermodynamic properties of compound phases and phase diagram calculations will be illustrated.

Carbides and nitrides play a key role in the microstructure control of steels, due to a fine dispersion of these precipitates. The effectiveness of the first principle calculations to the analysis of thermodynamic properties of these compounds might be an interesting issue. A comparison of the calculated formation energies with the experimental values is attempted for some typical carbides observed in steels to clarify the validity of the FLAPW method. Table 20.8 [20.18] shows the formation energy, $\Delta E_{\text{form}}^{\phi}$, defined by averaging the total energy of the constituent elements with chemical composition up to the segregation limit, as follows

$$\Delta E_{\text{form}}^{\phi} = E_{\text{tot}}^{\phi} - x_M^{\phi} E_{\text{tot}}^M - (1 - x_M^{\phi}) E_{\text{tot}}^C, \quad (20.37)$$

where ϕ denotes the type of carbide, and M and C represent a metallic element and graphite, respectively. For example, the formation energy of Fe₃C in the paramagnetic state is calculated to be 17.9 kJ/mol, while

the formation energy of Fe₃C, by considering the spin polarization, is 8.1 kJ/mol. This result shows the effect of the ferromagnetism of the Fe₃C phase in the lower temperature region. Furthermore, because the formation energy from bcc-Fe and graphite is positive, the Fe₃C structure is less stable than graphite at absolute zero. The calculated formation energies for the Cr₇C₃ and Cr₂₃C₆ phases show a reasonable agreement with the thermodynamic data reported in the literature [20.19]. From consideration of the data shown in Table 20.8, the thermodynamic properties for metallic carbides evaluated by the first principle calculations can be applied to the general procedures used in the CALPHAD method.

20.3.1 Thermodynamic Analysis of the Fe–Al–C System

The Perovskite carbide in this ternary system, Fe₃AlC (κ), is an fcc-based ordered phase with an E2₁-type

Fig. 20.19 The isothermal phase diagram for the Fe–Cr–C ternary system

Table 20.8 Comparison of the calculated formation energies with the experimental values for some typical steel carbides

Carbides	Space group	Calculated lattice parameter (nm)	Observed lattice parameter (nm)	Calculated formation enthalpy in the ground state (kJ/mol)	Observed formation enthalpy at 25 °C (kJ/mol)
Fe ₃ C (paramagnetic)	Pnma	$a = 0.4871$ $b = 0.6455$ $c = 0.4330$	— — —	+ 17.9	— — —
Fe ₃ C (ferromagnetic)	Pnma	$a = 0.5018$ $b = 0.6650$ $c = 0.4460$	$a = 0.5078$ $b = 0.67297$ $c = 0.45144$	+ 8.1	+ 6.3
Cr ₇ C ₃	Pnma	$a = 0.4373$ $b = 0.6772$ $c = 1.1730$	$a = 0.4526$ $b = 0.7010$ $c = 1.2142$	− 19.8	− 22.8
Cr ₂₃ C ₆	Fm-3m	$a = 1.0475$	$a = 1.06595$	− 21.8	− 19.7

structure. The application of this material as a heat resistant alloy from the formation of a coherent fine microstructure consisting of an fcc solid solution and the κ phase is attracting great attention [20.20]. Regardless of such a promising potential for this new material, little information on the thermodynamic properties of this carbide phase is known. Thus, an attempt to calculate the full phase equilibria of the Fe–Al–C ternary system is made, introducing the first principle values for Fe₃AlC into a CALPHAD-type thermodynamic analysis.

In the Fe₃AlC structure, the Fe and Al atoms are arranged in an L1₂-type superlattice, in which the C atoms occupy interstitial sites, resulting in an E2₁ superstructure. Figures 20.20a, 20.20b show schematic diagrams of the Fe₃Al–L1₂ and Fe₃AlC–E2₁ structures, respectively. If the C atom occupies only the body-centered sites, then it is surrounded by six Fe atoms, and this is preferable from an energetic point of view. Occupation of the other fcc interstitial sites enhances the tetragonality of the L1₂ crystal structure, yielding a larger strain energy. The only difference between these two structures is the existence of C atoms in the octahedral interstitial sites. Therefore, the Gibbs free energies of these two ordered structures should be described by the same thermodynamic model. The two-sublattice model denoted by the formula,

$$\left(\text{Fe}_{y_{\text{Fe}}^{(1)}}\text{Al}_{y_{\text{Al}}^{(1)}}\right)_3\left(\text{Fe}_{y_{\text{Fe}}^{(2)}}\text{Al}_{y_{\text{Al}}^{(2)}}\right)_1,$$

was generally applied to the L1₂ structure, and the three-sublattice model,

$$\left(\text{Fe}_{y_{\text{Fe}}^{(1)}}\text{Al}_{y_{\text{Al}}^{(1)}}\right)_3\left(\text{Fe}_{y_{\text{Fe}}^{(2)}}\text{Al}_{y_{\text{Al}}^{(2)}}\right)_1\left(\text{C}_{y_{\text{C}}^{(3)}}\text{Va}_{y_{\text{Va}}^{(3)}}\right)_1,$$

Fig. 20.20a,b Crystal structures for (a) Fe₃Al–L1₂ and (b) Fe₃AlC–E2₁

is applied to the κ phase. The Gibbs free energy for the κ phase is calculated using (20.38):

$$\begin{aligned} G^{\kappa} = & y_{\text{Al}}^{(1)} y_{\text{Al}}^{(2)} y_{\text{C}}^{(3)} G_{\text{Al:Al:C}}^{\kappa} + y_{\text{Al}}^{(1)} y_{\text{Al}}^{(2)} y_{\text{Va}}^{(3)} G_{\text{Al:Al:Va}}^{\kappa} \\ & + y_{\text{Al}}^{(1)} y_{\text{Fe}}^{(2)} y_{\text{C}}^{(3)} G_{\text{Al:Fe:C}}^{\kappa} + y_{\text{Al}}^{(1)} y_{\text{Fe}}^{(2)} y_{\text{Va}}^{(3)} G_{\text{Al:Fe:Va}}^{\kappa} \\ & + y_{\text{Fe}}^{(1)} y_{\text{Al}}^{(2)} y_{\text{C}}^{(3)} G_{\text{Fe:Al:C}}^{\kappa} + y_{\text{Fe}}^{(1)} y_{\text{Al}}^{(2)} y_{\text{Va}}^{(3)} G_{\text{Fe:Al:Va}}^{\kappa} \end{aligned}$$

$$\begin{aligned}
& + y_{\text{Fe}}^{(1)} y_{\text{Fe}}^{(2)} y_{\text{C}}^{(3)} G_{\text{Fe:Fe:C}}^{\kappa} + y_{\text{Fe}}^{(1)} y_{\text{Fe}}^{(2)} y_{\text{Va}}^{(3)} G_{\text{Fe:Fe:Va}}^{\kappa} \\
& + 3RT \left(y_{\text{Al}}^{(1)} \ln y_{\text{Al}}^{(1)} + y_{\text{Fe}}^{(1)} \ln y_{\text{Fe}}^{(1)} \right) \\
& + RT \left(y_{\text{Al}}^{(2)} \ln y_{\text{Al}}^{(2)} + y_{\text{Fe}}^{(2)} \ln y_{\text{Fe}}^{(2)} \right) \\
& + RT \left(y_{\text{C}}^{(3)} \ln y_{\text{C}}^{(3)} + y_{\text{Va}}^{(3)} \ln y_{\text{Va}}^{(3)} \right) \\
& + y_{\text{Al}}^{(1)} y_{\text{Fe}}^{(1)} y_{\text{Al}}^{(2)} y_{\text{C}}^{(3)} L_{\text{Al,Fe:Al:C}}^{\kappa} \\
& + y_{\text{Al}}^{(1)} y_{\text{Fe}}^{(1)} y_{\text{Al}}^{(2)} y_{\text{Va}}^{(3)} L_{\text{Al,Fe:Fe:Va}}^{\kappa} \\
& + y_{\text{Al}}^{(1)} y_{\text{Fe}}^{(1)} y_{\text{Fe}}^{(2)} y_{\text{C}}^{(3)} L_{\text{Al,Fe:Fe:C}}^{\kappa} \\
& + y_{\text{Al}}^{(1)} y_{\text{Fe}}^{(1)} y_{\text{Fe}}^{(2)} y_{\text{Va}}^{(3)} L_{\text{Al,Fe:Fe:Va}}^{\kappa} \\
& + y_{\text{Al}}^{(1)} y_{\text{Al}}^{(2)} y_{\text{Fe}}^{(2)} y_{\text{C}}^{(3)} L_{\text{Al:Al,Fe:C}}^{\kappa} \\

& + y_{\text{Al}}^{(1)} y_{\text{Al}}^{(2)} y_{\text{C}}^{(3)} y_{\text{Va}}^{(3)} L_{\text{Al:Al:C,Va}}^{\kappa} \\
& + y_{\text{Al}}^{(1)} y_{\text{Fe}}^{(2)} y_{\text{C}}^{(3)} y_{\text{Va}}^{(3)} L_{\text{Al:Fe:C,Va}}^{\kappa} \\
& + y_{\text{Fe}}^{(1)} y_{\text{Al}}^{(2)} y_{\text{C}}^{(3)} y_{\text{Va}}^{(3)} L_{\text{Fe:Al:C,Va}}^{\kappa} \\
& + y_{\text{Fe}}^{(1)} y_{\text{Fe}}^{(2)} y_{\text{C}}^{(3)} y_{\text{Va}}^{(3)} L_{\text{Fe:Fe:C,Va}}^{\kappa} .
\end{aligned} \tag{20.38}$$

Calculation of the Thermodynamic Properties of the κ Phase

The thermodynamic parameters required by the model in the $(\text{Fe}, \text{Al})_3(\text{Fe}, \text{Al})_1(\text{C}, \text{Va})_1$ form are evaluated using first principle calculations and the results are listed in Table 20.9. The calculated values denote the formation enthalpies based on the stable structure of the pure element in the ground state. The ferromagnetic state of the κ phase is calculated to be almost 10 kJ/mol more stable than its paramagnetic state, and the magnetic moment of the phase was calculated to be 3.05 μ_{B} . Besides these cohesive energies for the stoichiometric components, the interactions between atoms on the same sublattice are defined in the same way as for the thermodynamic parameters, and these interaction parameters, as well as the entropy term of the formation energy, are estimated using the experimental phase boundaries.

Electronic Structure and Phase Stability of the κ Phase

As shown in Fig. 20.20, a crystallographic similarity exists between the Perovskite carbide κ and the $\text{Fe}_3\text{Al-L1}_2$ structure, i.e., a C atom is placed in the center of an octahedron composed of six Fe atoms occupying the face-centered positions in the L1_2 structure. The actual calculated equilibrium lattice constant of the $\text{Fe}_3\text{Al-L1}_2$ structure is 0.3502 nm, while that of the κ phase is 0.3677 nm, which correspond well with the experimental results of Palm and Inden [20.21]. This fact implies that occupation by the C atoms in the octahedral interstitial sites causes an expansion of the L1_2 lattice. Since the calculated enthalpy of formation of the κ phase (-27.9 kJ/mol of atoms) is much lower than that of the $\text{Fe}_3\text{Al-L1}_2$ structure (-8.8 kJ/mol of atoms), it is concluded that the interstitial C atoms enhance the stability of the L1_2 structure. Thus, the role of the C atoms will be discussed in the context of their electronic structure.

Table 20.9 Calculated thermodynamic parameters required by the $(\text{Fe}, \text{Al})_3(\text{Fe}, \text{Al})_1(\text{C}, \text{Va})_1$ -type three-sublattice model

Structure	Strukturbericht symbol	Magnetism	Calculated lattice parameter (nm)	Observed lattice parameter (nm)	Calculated formation enthalpy in the ground state (kJ/mol of compound)
Fe_3AlC	E2_1	Paramagnetic	0.3677	—	-128.5
		Ferromagnetic	0.3677	0.3781	-139.5
Al_3FeC	E2_1	Paramagnetic	0.3890	—	$+190.5$
Fe_3Al	L1_2	Paramagnetic	0.3502	—	-35.2
FeAl_3	L1_2	Paramagnetic	0.3734	—	-67.6
Fe_4C	—	Paramagnetic	0.3645	—	$+88.4$
Al_4C	—	Paramagnetic	0.4057	—	$+160.5$

Figures 20.21 and 20.22 show the total density of states (total DOS) and the angular-momentum-resolved density of state for each element (p-DOS) for the $\text{Fe}_3\text{AlC-E}2_1$ (κ) and $\text{Fe}_3\text{Al-L}1_2$ structures, respectively. The term E_F denotes the Fermi energy, and no electrons occupy electronic states above this energy level. In both structures, the DOS mainly consist of the contribution from the Fe d-electrons. However, while observing

these diagrams, we noticed a marked difference between these two structures, in that the Fermi level is located near the peak of the total DOS for the $\text{Fe}_3\text{Al-L}1_2$ structure, but decreases in a region with a very low DOS in the $\text{Fe}_3\text{AlC-E}2_1$ structure. This fact indicates that from an energetic point of view, the stable $\text{E}2_1$ structure of the κ phase is highly preferred, compared with the $\text{Fe}_3\text{Al-L}1_2$ structure.

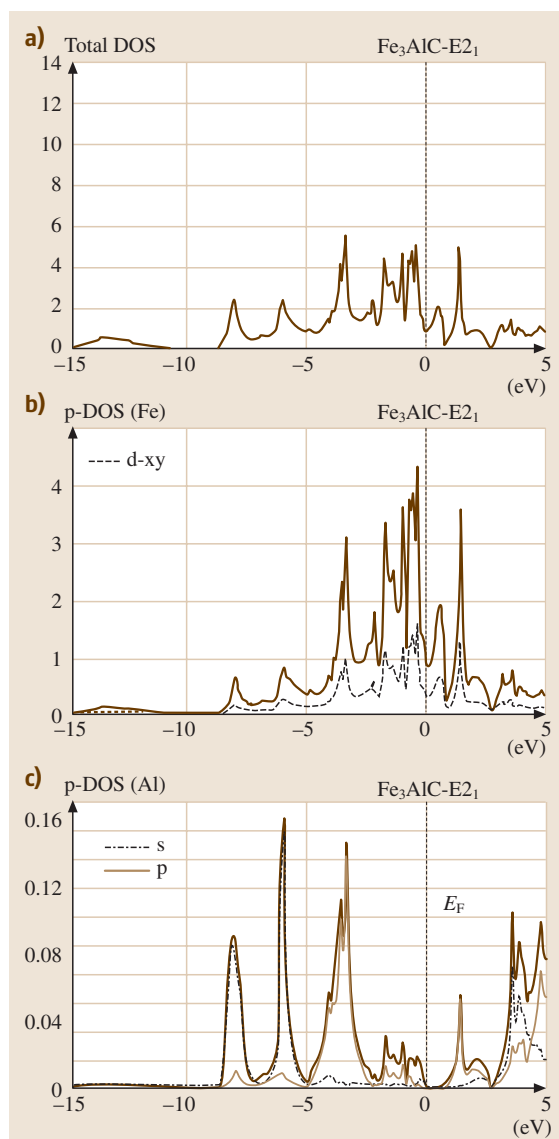

Fig. 20.21 (a) Total density of states, and angular-momentum-resolved density of states for: (b) Fe and (c) Al for the $\text{Fe}_3\text{AlC-E}2_1$ (κ) structure

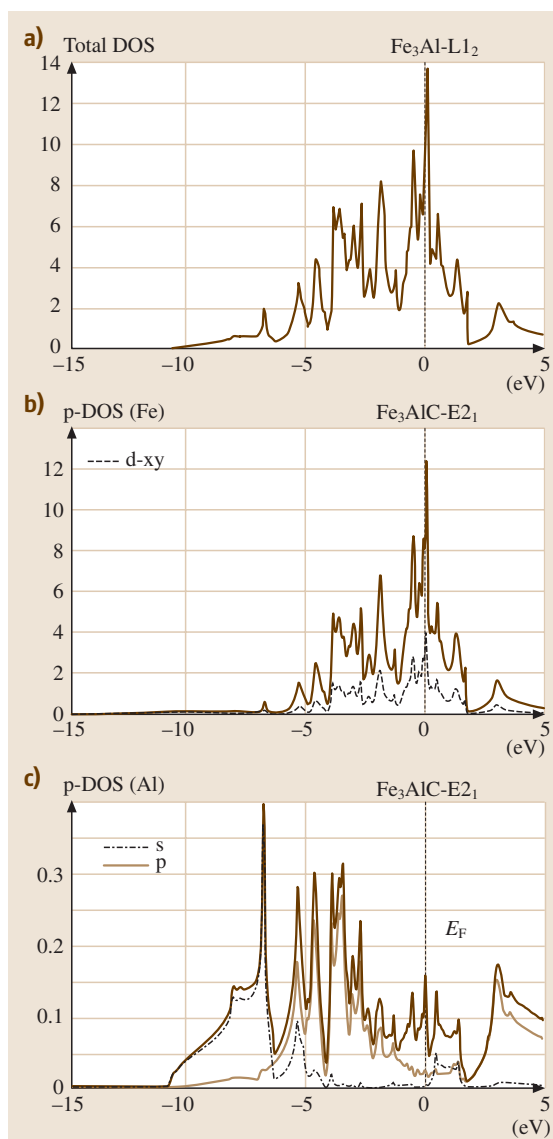

Fig. 20.22 (a) Total density of states, and angular-momentum-resolved density of states for: (b) Fe and (c) Al for the $\text{Fe}_3\text{Al-L}1_2$ structure

Figures 20.23a and 20.23b show the calculated electron charge density plots of the $\text{Fe}_3\text{AlC-E2}_1$ (κ) and $\text{Fe}_3\text{Al-L1}_2$ structures in the $(00\frac{1}{2})$ plane, where the contour lines correspond to an electron density of 100 e/nm^3 . The Fe atoms can be seen in the middle of the horizontal and vertical axes, while the C atoms are located in the center of the Fig. 20.23a. From these con-

tour plots, it can be seen that bonding between the Fe and C atoms occurs in the $\text{Fe}_3\text{AlC-E2}_1$ structure, since a finite charge density between these atoms can be observed. This interaction between the atoms enhances the energetic stability of the $\text{Fe}_3\text{AlC-E2}_1$ structure.

Comparison of the Calculated Phase Equilibria with the Experimental Data

The calculated Fe–Al–C ternary phase diagrams are shown in Fig. 20.24 for temperatures, $T = 800, 1000$, and 1200°C . The enlarged portion of the isothermal section diagrams is compared with the experimental phase boundaries determined using X-ray diffraction and metallographic observation [20.21]. From EPMA measurements, they reported that the chemical composition of the κ phase shifted remarkably from its stoichiometric composition. The homogeneity range of the κ phase extends from $\text{Fe}_{2.9}\text{Al}_{1.1}\text{C}_{0.7}$ to $\text{Fe}_{2.8}\text{Al}_{1.2}\text{C}_{0.7}$ according to the calculations.

20.3.2 Thermodynamic Analysis of the Co–Al–C and Ni–Al–C Systems

The microstructures of Ni-based superalloys contain the $\text{Ni}_3\text{Al-L1}_2$ phase, which shows an anomalous flow-stress dependence on temperature [20.22]. In addition, because they exhibit very high melting temperatures and have good resistance to oxidation, alloys with complex phase structures containing the NiAl-B2 , fcc-Ni , and $\text{Ni}_3\text{Al-L1}_2$ phases have been investigated for technological applications. On the other hand, it is difficult to produce Co–Al-based superalloys with a microstructure consisting of fcc-Ni and $\text{Ni}_3\text{Al-L1}_2$, because of the absence of a stable strengthening L1_2 phase in the Co–Al binary system. However, the addition of carbon to this alloy stabilizes the formation of the Perovskite type carbide (E2_1) with the composition, M_3AlC (κ phase), as seen in Fig. 20.18, and this carbide is anticipated to form a fine coherent microstructure in a Co-based solid solution. Then the entire phase equilibria of the Co–Al–C ternary system is attempted to be clarified by coupling the CALPHAD and ab initio calculations. The same procedure is applied to the Ni–Al–C system, and the results are compared to the Co–Al–C system.

Calculation of the Co–Al–C Phase Diagram

The same thermodynamic model as $(\text{Fe}, \text{Al})_3(\text{Fe}, \text{Al})_1(\text{C}, \text{Va})_1$ is applied to the Co–Al–C and Ni–Al–C based κ phase, and the parameters necessary for this model are evaluated using first principle calculations, as listed in Table 20.10. The calculated Co–Al–C

Ni_3Al	L1_2	0.3504	0.3572	−169.5
NiAl_3	L1_2	0.3774	—	−91.6
Ni_4C	—	0.3645	—	+61.0

ternary phase diagrams are shown in Fig. 20.25 for temperatures of 900 °C, 1100 °C, and 1300 °C. The enlarged portion of the isothermal section diagrams at 1100 °C was compared with the experimental data [20.21].

The κ phase only appears at the stoichiometric composition in our results, while a small homogeneity range is exhibited by this phase in the experimental phase diagrams. This aspect is closely related to the large, positive formation energies in the metastable ordered structures, such as Al_3CoC and Al_4C . As the formation energy of Co_3AlC shows an extremely large negative value when compared to these structures, the κ phase only forms at the stoichiometric position. The homogeneity can be expressed by introducing interaction parameters between unlike atoms in the same sublattice. However, this treatment is not applied in the present analysis, because the experimental phase boundaries of the κ phase are still uncertain.

The calculated vertical section diagrams at constant 10 mol % C and 30 mol % Al are shown in Fig. 20.26. The calculated values agree well with the experimental results, and hence, the new type of approach based on the incorporation of the CALPHAD method into ab initio calculations has proven to be applicable to phase diagram calculations for higher-order systems.

Calculation of the Ni–Al–C Phase Diagram

In the Ni–Al–C system, on the other hand, it has been experimentally verified that the κ phase does not appear in the vicinity of the stoichiometric composition. Figures 20.27a–c show the calculated isothermal section diagrams at 900, 1000, and 1300 °C, respectively.

Phase Separation of the κ Phase in the Co–Ni–Al–C Quaternary System

According to the first principle calculations, there was a large difference in the phase stability between the Co_3Al – L1_2 and Ni_3Al – L1_2 phases, compared to the difference between the Ni_3AlC – E2_1 and Co_3AlC – E2_1 phases. In such an energetic situation, a two-phase separation should occur, depending on the difference in the formation energies of the compounds, given by the following expression

$$\Delta G = {}^0G_{\text{Ni}_3\text{Al}} + {}^0G_{\text{Co}_3\text{AlC}} - {}^0G_{\text{Co}_3\text{Al}} - {}^0G_{\text{Ni}_3\text{AlC}} \quad (20.39)$$

This miscibility gap originates in the energy difference between the terminal compounds, and as the absolute value of ΔG increases, then the critical temperature of the miscibility gap increases. Such a phase separation is often observed in some complex carbonitrides or alloy semiconductor systems. Figure 20.28 shows the calculation of a miscibility gap in the Co_3AlC – Ni_3AlC – Co_3Al – Ni_3Al pseudoquaternary system at $T = 1000$ °C. In this model calculation, only the formation enthalpies of the stoichiometric compounds are used, designated by the four vertices of the composition square. One can see that a two-phase separation forms in the direction of the Co_3AlC and Ni_3Al diagonal. Therefore, a two-phase separation between these terminal compounds will be involved in the phase equilibria of the quaternary system.

Using the thermodynamic description of the four ternary systems that comprise the Co–Ni–Al–C quaternary system, a vertical section diagram is calculated

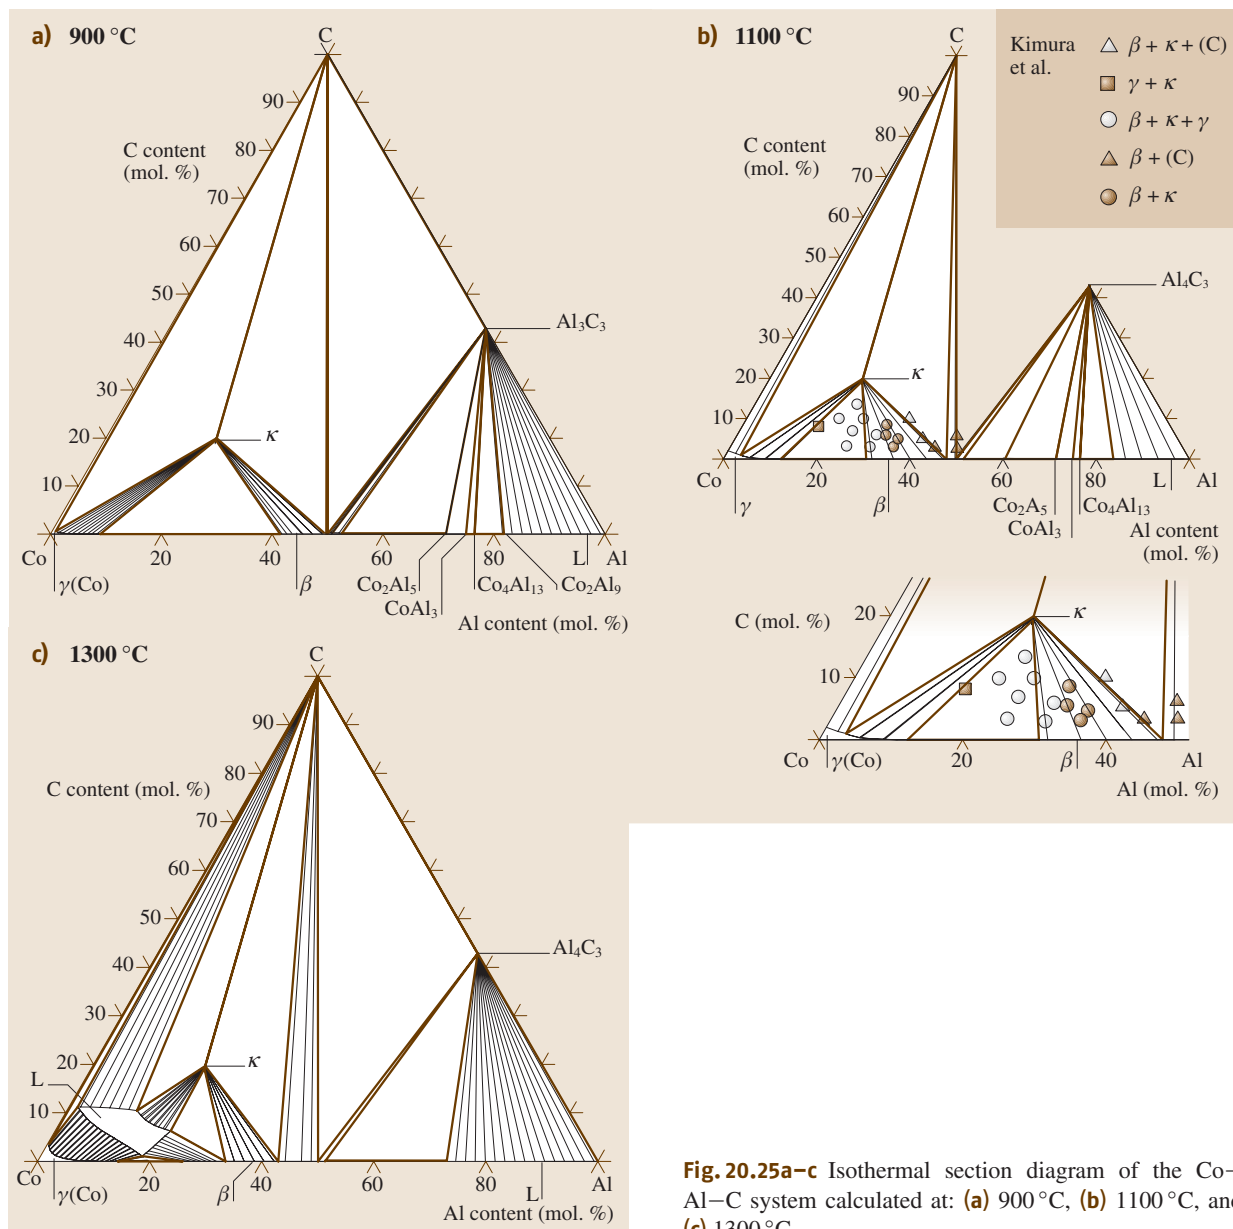

Fig. 20.25a–c Isothermal section diagram of the Co–Al–C system calculated at: (a) 900 °C, (b) 1100 °C, and (c) 1300 °C

at a constant C content of 4 mol %, and an Al content of 23 mol %, as shown in Fig. 20.29. In this figure, the term κ_1 denotes the Ni-based L₁₂ structure, while the Co-based Perovskite structure is represented by κ_2 . At higher temperatures, the E2₁ structure forms a homogeneous solution, and this phase is designated as κ .

The κ phase gradually changes its character from the Co₃AlC-based carbide to the Ni₃Al-based intermetallic compound with increasing Ni content in the alloy. The precipitates decompose into almost stoichiometric Co₃AlC and Ni₃Al phases in the lower temperature range.

Phase Field

21. Phase Field

The term *phase field* has recently become known across many fields of materials science. The meaning of phase field is the spatial and temporal order parameter field defined in a continuum–diffused interface model. By using the phase field order parameters, many types of complex microstructure changes observed in materials science are described effectively. This methodology has been referred to as the phase field method, phase field simulation, phase field modeling, phase field approach, etc. In this chapter, the basic concept and theoretical background for the phase field approach is explained in Sects. 21.1 and 21.2. The overview of recent applications of the phase field method is demonstrated in Sects. 21.3 to 21.6.

Phase field models have been successfully applied to various materials processes including solidification, solid–state phase transformations and microstructure changes. Using phase field methodology, one can deal with the evolution of arbitrary morphologies and complex microstructures without explicitly tracking the positions of interfaces. This approach can describe different processes such as diffusion–controlled phase separation and diffusionless phase transition within the same formulation. It is rather straightforward to incorporate the effect of coherency and applied stresses, as well as electrical and magnetic fields.

Since phase field methodology can model complex microstructure changes quantitatively, it will be possible to search for the most desirable microstructure using this method as a design simulation, i. e., through computer trial–and–error testing. Therefore, the most effective strategy for developing advanced materials is as follows. First, we elucidate the mechanism of microstructure changes experimentally, then we model the microstructure evolutions using the phase–field method based on the experimental results, and

finally we search for the most desirable microstructure while simultaneously considering both the simulation and experimental data.

21.1 Basic Concept of the Phase-Field Method

Over the last two decades, the phase-field approach [21.1–7] has been developed for many fields in materials science as a powerful tool to simulate and predict complex microstructure developments (for example, solidification [21.3, 8–12], spinodal decomposition [21.13, 14], Ostwald ripening [21.15], crystal growth and recrystallization [21.16–19], domain microstructure evolutions in ferroelectric materials [21.20, 21], martensitic transformation [21.22], dislocation dynamics [21.23–25], crack propagation [21.26], etc.).

An essence of the phase-field method is based on a diffuse-interface approach [21.6] proposed more than a century ago by *van der Walls* [21.27] and independently almost a half-century ago by *Cahn* and *Hilliard* [21.28, 29]. Because the phase-field methodology has an efficient ability to model various types of complex microstructure changes quantitatively, there is large possibility to search for the most desirable microstructure using this method as a design simulation, i. e., trial-and-error testing on a computer.

Since the phase-field method has developed over a wide range within the field of materials science, the definition of the method has divided into two main categories. One is the interface-tracking approach commonly used in solidification simulation of dendrite growth, and the other is the continuum diffuse-interface model, which describes the temporal and spatial developments of the dynamics of inhomogeneous order parameter fields during phase transformations.

In phase-field modeling, the determination of order parameters that are well defined and called phase-field variables is the most important step. The order parameters are, in general, classified into two types: the conserved order parameters and the nonconserved ones. Typical examples of the former and the latter are the composition of a solute atom and the long-range order parameter describing an order–disorder phase transition, respectively. There is no systematic criterion for selecting the order parameters, but it is usually enough for the order parameters to describe the targeted microstructure morphology and its total free energy, quantitatively.

In order to simulate the temporal and spatial microstructure developments the total free energy of the inhomogeneous microstructure should first be evaluated. The total free energy of microstructure G_{sys} is defined by a sum of a chemical free energy density g_c , a gradient energy density f_{grad} , an elastic strain energy density e_{str} , a magnetic energy density f_{mag} , and an electric energy density f_{ele} , so that the functional G_{sys} is written

as

$$G_{\text{sys}} = \int_{\mathbf{r}} \left[g_c(c_i, s_j) + f_{\text{grad}}(c_i, s_j) + e_{\text{str}}(c_i, s_j) + f_{\text{mag}}(c_i, s_j) + f_{\text{ele}}(c_i, s_j) \right] d\mathbf{r}, \quad (21.1)$$

where $c_i(\mathbf{r}, t)$ and $s_i(\mathbf{r}, t)$ are the order parameters of the conserved and nonconserved fields, respectively, and these are the function of spatial position \mathbf{r} and time t . The subscripts i and j of each order parameter are the numbers by which it is determined if the order parameter belongs to the same category. The order parameters, such as $c_i(\mathbf{r}, t)$ and $s_i(\mathbf{r}, t)$, are commonly called the phase-field variables in the phase-field method. Since g_c , f_{grad} , e_{str} , f_{mag} , and f_{ele} are expressed as a function of order parameters $c_i(\mathbf{r}, t)$ and $s_i(\mathbf{r}, t)$, these parameters interact with each other through the total free energy during microstructure changes.

The temporal evolution of field variables in a phase-field model can be obtained by solving (21.2) and (21.3) including the dynamic coupling term of the time variation of the order parameters (see the second term of the right-hand side of both equations):

$$\frac{\partial c_i(\mathbf{r}, t)}{\partial t} = \nabla \cdot \left[M_{ij} \left(\nabla \frac{\delta G_{\text{sys}}}{\delta c_j} + \xi_{c_j} \right) \right] + K_{ij}^c \frac{\partial s_j(\mathbf{r}, t)}{\partial t}, \quad (21.2)$$

$$\frac{\partial s_i(\mathbf{r}, t)}{\partial t} = -L_{ij} \left(\frac{\delta G_{\text{sys}}}{\delta s_j} + \xi_{s_j} \right) + K_{ij}^s \frac{\partial c_j(\mathbf{r}, t)}{\partial t}, \quad (21.3)$$

where the symbols M_{ij} and L_{ij} is the mobility concerning the changes of the corresponding order parameters. These are precisely described as a function of the order parameters, but in many actual calculations the mobility is often set constant or regarded as a function of temperature. ξ_p is a Gaussian thermal noise term for the order parameter p ($= c_i$ or s_i). The second terms in the right-hand side of (21.2) and (21.3) represent the dynamic coupling of each phase-field variable, where K_{ij}^c and K_{ij}^s are the coupling coefficients. These are often assumed to be constant, or set to 0 when the dynamic interaction between order parameters is ignored. The microstructure change, which this coupling term should introduce, is actually limited to the case when a highly complex morphology of microstructure is formed almost as far from equilibrium, e.g., the dendrite growth, the fractal pattern formation, and so on.

21.2 Total Free Energy of Microstructure

In order to simulate microstructure changes quantitatively, the precise evaluation of the total free energy of the microstructure is required. In this section, the detail of the equations used for estimating the total free energy of microstructure is explained.

21.2.1 Chemical Free Energy

Several types of description for chemical free energy for a homogeneous state (i.e., mean field) have been proposed for phase-field simulations. They are mainly classified into two categories. One is the expression based on the polynomial expansion with respect to the order parameters known as a Landau expansion method [21.30], the other is the case where the well-defined chemical free energy curves for specific crystal structures are connected to each other continuously using phase-field variables. Some typical examples are provided below.

Grain Growth

The chemical free energy density g_c utilized for a crystal grain growth in polycrystalline single-phase materials is given by

$$g_c(s_1, s_2, s_3, \dots, s_p) = \sum_{i=1}^p \left(-\frac{A}{2} s_i^2 + \frac{B}{4} s_i^4 \right) + C \sum_{i=1}^p \sum_{j>i}^p s_i^2 s_j^2, \quad (21.4)$$

where $s_i = s_i(\mathbf{r}, t)$, ($i = 1, 2, \dots, p$) are the order parameters describing the probability to find the crystal with its orientation designated by i at position \mathbf{r} and time t [21.16]. Each integer number i ($= 1 \sim p$) corresponds to the specific orientation of the crystal structure, respectively. The probability of finding the grain with orientation i at position \mathbf{r} and time t is defined by $|s_i(\mathbf{r}, t)|$. The symbols A , B , and C are the numerical constants determined phenomenologically. If we only employ $i = 1$, (21.4) reduces to

$$g_c(s_1) = -\frac{A}{2} s_1^2 + \frac{B}{4} s_1^4 \quad (21.5)$$

$$= -\frac{A}{2} s_1^2 \left(1 + s_1 \sqrt{\frac{B}{2A}} \right) \left(1 - s_1 \sqrt{\frac{B}{2A}} \right).$$

Hence $g_c(s_1) = 0$ is satisfied at $s_1 = 0, \pm \sqrt{2A/B}$, and the function $g_c(s_1)$ has a maximum at $s_1 = 0$, a minimum at $s_1 = \pm \sqrt{A/B}$, which is determined from the condition $\partial g_c / \partial s_1 = 0$.

The last term in the right-hand side of (21.4) is the penalty term, which forbids the coexistence of crystals with different orientation at the same position (because the coefficient C is defined as $C > 0$).

As an extended application of (21.4) to the two-phase mixture [21.31], the chemical free energy for a polycrystal containing grains of different phase is written as

$$\begin{aligned} g_c & \left(c; s_1^\alpha, s_2^\alpha, \dots, s_p^\alpha; s_1^\beta, s_2^\beta, \dots, s_q^\beta \right) \\ &= -\frac{A}{2} (c - c_m)^2 + \frac{B}{4} (c - c_m)^4 + \frac{C_\alpha}{4} (c - c_\alpha)^4 \\ & \quad + \frac{C_\beta}{4} (c - c_\beta)^4 \\ & \quad + \sum_{i=1}^p \left[-\frac{U_\alpha}{2} (c - c_\beta)^2 (s_i^\alpha)^2 + \frac{V_\alpha}{4} (s_i^\alpha)^4 \right] \\ & \quad + \sum_{i=1}^q \left[-\frac{U_\beta}{2} (c - c_\alpha)^2 (s_i^\beta)^2 + \frac{V_\beta}{4} (s_i^\beta)^4 \right] \\ & \quad + \frac{W}{2} \sum_{\alpha} \sum_{\beta} \sum_{i=1}^p \sum_{j=1}^q (s_i^\alpha)^2 (s_j^\beta)^2, \end{aligned} \quad (21.6)$$

where the composition field $c = c(\mathbf{r}, t)$ is also considered, and c_α and c_β are the composition of α and β phase, respectively; c_m is defined by $c_m = (c_\alpha + c_\beta)/2$. Symbols A , B , C_α , C_β , U_α , U_β , V_α , V_β and W are the phenomenologically determined numerical constants. The phase-field order parameters for different crystal structures, α and β , are denoted by $s_i^\alpha = s_i^\alpha(\mathbf{r}, t)$ and $s_i^\beta = s_i^\beta(\mathbf{r}, t)$, respectively.

Phase Separation Between Different Crystal Structure Phases (Landau Expansion)

A typical example is the case that both a phase separation and a structural phase transition from cubic to tetragonal occur simultaneously [21.32]. The chemical free energy function is expressed based on the Landau expansion as

$$\begin{aligned} g_c(c, s_1, s_2, s_3) &= \frac{1}{2} A (c - c_1)^2 + \frac{1}{2} B (c - c_2) (s_1^2 + s_2^2 + s_3^2) \\ & \quad - \frac{1}{4} C (s_1^4 + s_2^4 + s_3^4) + \frac{1}{6} D (s_1^6 + s_2^6 + s_3^6) \\ & \quad + U (s_1^2 s_2^2 + s_2^2 s_3^2 + s_3^2 s_1^2) \\ & \quad + V [s_1^4 (s_2^2 + s_3^2) + s_2^4 (s_1^2 + s_3^2) + s_3^4 (s_1^2 + s_2^2)] \\ & \quad + W s_1^2 s_2^2 s_3^2, \end{aligned} \quad (21.7)$$

where $s_i = s_i(\mathbf{r}, t)$ are the order parameters indicating the probability of finding the tetragonal phase designated by i at position \mathbf{r} and time t . Index i ($= 1, 2$, and 3) corresponds to the direction of the c -axis of the tetragonal phase. (In the structural phase transition from cubic to tetragonal, there are three orientation relations between cubic and tetragonal phases, i.e., three variants.) The specific state $s_1 = s_2 = s_3 = 0$ corresponds to cubic phase. The order parameter $c = c(\mathbf{r}, t)$ is a solute composition at position \mathbf{r} and time t . The symbols c_1 , c_2 , A , B , C , D , U , V , and W are constants.

Phase Separation Between Different Crystal Structure Phases (Use of Thermodynamic Database of Phase Diagrams)

The construction method of chemical free energy using a thermodynamic database of phase diagrams is proposed in the phase-field method for alloy solidification [21.1, 2, 9]. In this formulation, since the chemical free energy is directly related to the real phase diagrams and we can simulate phase transformations in accord with the phase diagrams, this methodology is quite important and useful for practical engineering purposes, and the details are as follows.

First we suppose, for instance, that the α and β phase have different crystal structure in the A–B binary alloy system, and that the chemical free energy curves for these two phases are denoted as $g_c^\alpha(c, T)$ and $g_c^\beta(c, T)$, respectively, where c is the solute composition of component B. The chemical free energy function for each phase is easily obtained from the thermodynamic database of phase diagrams such as ThermoCalc, Pandat, etc. [21.33].

Next, we define the phase-field variable $s = s(\mathbf{r}, t)$, that is, the probability of finding the β phase at position \mathbf{r} and time t . Therefore, the cases $s = 0$ and $s = 1$ correspond to the α single phase and the β one, respectively. Utilizing the phase-field variable s , we are able to formulate the chemical free energy surface as a function of c and s , which is expressed as

$$g_c(c, s, T) = g_c^\alpha(c, T) [1 - h(s)] + g_c^\beta(c, T) h(s) + W_c^{\alpha \leftrightarrow \beta}(T) g^2(s), \quad (21.8)$$

where $W_c^{\alpha \leftrightarrow \beta}(T)$ is an energy barrier originating in the latent heat during $\alpha \leftrightarrow \beta$ structural phase transition. In the phase-field method the function $g(s)$ is usually defined by

$$g(s) \equiv s(1 - s). \quad (21.9)$$

As for the function $h(s)$, two different definitions have mainly been employed in the phase-field method, that is

$$h(s) = \frac{\int_0^s g(s') ds'}{\int_0^1 g(s') ds'} = s^2(3 - 2s) \quad (21.10)$$

and

$$h(s) = \frac{\int_0^s g^2(s') ds'}{\int_0^1 g^2(s') ds'} = s^3 (10 - 15s + 6s^2). \quad (21.11)$$

It seems that there is no significant effect on the simulation result as to whether (21.10) or (21.11) is employed. Clearly recognized from (21.10) and (21.11), the function $h(s)$ shows an S-shaped curve, the value of which ranges from 0 to 1. The function $g^2(s)$ is 0 when $s = 0$ and $s = 1$, and a maximum value at $s = 0.5$. Equation (21.8) constructs the energy surface connecting the chemical free energy curves of the α and β phase smoothly using function $h(s)$. The physical meaning of the third term in the right-hand side of (21.8) is the latent heat induced with a structural phase transition. (The detail for the formulation of a chemical free energy for each single phase is explained in Chap. 20.)

It should be noted that the free energy surface defined by (21.8) is a conveniently determined surface with no strict physical meaning. For instance, the atomic structure corresponding to the state of $s = 0.5$ is not defined in the phase-field method. (The same definition of atomic arrangement may be possible for $s = 0.5$, but the explicit image for the atomic arrangement is not needed because the phase-field method is a continuum model for microstructure calculation where only an energy is evaluated depending on the local order parameter values.)

The chemical free energy of the multicomponent and multiphase system is expressed as an extended form

$$\begin{aligned} & g_c(c_1, c_2, \dots, c_{N_c}, s_1, s_2, \dots, s_{N_s}, T) \\ &= \sum_{i=1}^{N_s} g_c^{\phi_i}(c_1, c_2, \dots, c_{N_c}, T) h(s_i) \\ &+ \frac{1}{2} \sum_{i=1}^{N_s} \sum_{j=1}^{N_s} W_c^{\phi_i \leftrightarrow \phi_j}(T) g(s_i, s_j), \end{aligned} \quad (21.12)$$

where N_c and N_s are the number of components and phases considered. The function $g_c^{\phi_i}(c_1, c_2, \dots, c_{N_c}, T)$ is a chemical free energy of ϕ_i phase denoted by i . In this case, since $s_i = s_i(\mathbf{r}, t)$ is a phase-field variable indicating the probability to find the ϕ_i phase at

position \mathbf{r} and time t , the condition $\sum_{i=1}^{N_s} s_i(\mathbf{r}, t) = 1$ must be satisfied. The function $g(s_i, s_j)$ is defined by $g(s_i, s_j) \equiv (1 - \delta_{ij})s_i^2 s_j^2$ and $g(s_i, s_j) \equiv (1 - \delta_{ij})s_i s_j$ for a binary system and the other multicomponent system, respectively, where δ_{ij} is Kronecker's delta, i. e., $\delta_{ij} = 1$ for $i = j$ and $\delta_{ij} = 0$ for $i \neq j$. This distinction is to avoid the appearance of a concave region on the free energy curve constructed by order parameters s_i .

21.2.2 Gradient Energy

A gradient energy F_{grad} [21.29–34] is given by a gradient squire approximation for the order parameter profile in the phase-field method, which is expressed as

$$F_{\text{grad}} = \int_{\mathbf{r}} \left[\frac{1}{2} \sum_{i=1}^{N_c} \kappa_c (\nabla c_i)^2 + \frac{1}{2} \sum_{i=1}^{N_s} \kappa_s |\nabla s_i|^2 \right] d\mathbf{r}, \quad (21.13)$$

where symbols κ_c and κ_s are the gradient energy coefficients.

It is sometimes treated that a gradient energy is same as an interfacial energy. Strictly speaking, this is not correct. The interfacial energy where the interface is defined by the diffused order parameter profile not only includes the gradient energy but also the chemical free energy. Since the physical meaning of an interfacial energy is the total free energy at the interface, a gradient energy is different from an interfacial energy.

Equation (21.13) is derived by means of the Taylor expansion of a chemical free energy with respect to the gradient and curvature of the order parameter profile and with the higher order terms removed. The key idea is that the gradient and the curvature of the order parameter profile are treated as invariant variables except for the order parameter itself. The physical meaning of this equation is explained as follows.

In order to make the argument simple, we only consider the composition field $c(\mathbf{r})$ for the A–B binary alloy system, and focus on $c(\mathbf{r}_1) = 0.5$ at arbitrary position \mathbf{r}_1 . When we only consider the chemical free energy for the total free energy at \mathbf{r}_1 , the total free energy value is not changed even if the gradient and curvature of the composition profile at \mathbf{r}_1 is altered. But when the composition profile is extremely sharp, such that it is observed in the modulated structure during spinodal decomposition, the number of A–A, B–B, and A–B atom pair at \mathbf{r}_1 will depend on the shape of the composition profile across the position \mathbf{r}_1 . This deviation is evaluated by considering the com-

position field information $c(\mathbf{r}_1 \pm \Delta\mathbf{r})$ around \mathbf{r}_1 , i. e., the deviation is described using the gradient and the curvature of the composition profile as an invariant variable. Therefore, the composition gradient energy is the excess energy induced from the spatial fluctuation of composition field, and in this case, the chemical free energy is the mean field energy without composition fluctuation.

The Orientation Dependence of Gradient Energy

The interface between phases with different crystal structure and orientation is often considered in the phase-field method, and commonly, the orientation dependence is introduced into the gradient energy coefficient [21.1, 2] in (21.13). Therefore, the variation calculation for the gradient energy is significantly influenced in this case. For simplicity, we consider the composition field of the A–B binary alloy system, and a two-dimensional calculation is supposed. Under this condition, the composition gradient energy coefficient is defined by $\kappa_c \equiv \varepsilon^2(\theta)$, where ε is a function of the orientation θ . Then the composition gradient energy is given as

$$F_{\text{grad}} = \frac{1}{2} \int_{\mathbf{r}} \varepsilon^2(\theta) (\nabla c)^2 d\mathbf{r}. \quad (21.14)$$

We consider the phase separated microstructure, and let \mathbf{n} be a unit normal at the interface between precipitate and matrix. The relations among \mathbf{n} , θ , and $c(\mathbf{r}, t)$ are given by

$$\begin{aligned} \mathbf{n} &= (n_1, n_2) = (\cos \theta, \sin \theta) \\ &= -\frac{\nabla c}{|\nabla c|} = -\frac{1}{\sqrt{c_{tx}^2 + c_{ty}^2}} (c_{tx}, c_{ty}), \\ \therefore \tan \theta &= \frac{n_2}{n_1} = \frac{c_{ty}}{c_{tx}} \rightarrow \theta = \tan^{-1} \frac{c_{ty}}{c_{tx}}, \end{aligned} \quad (21.15)$$

where c_{tx} and c_{ty} are defined by $c_{tx} \equiv \partial c / \partial x$ and $c_{ty} \equiv \partial c / \partial y$, respectively. It is worth noting that (21.15) insists θ and $c(\mathbf{r}, t)$ are not independent. Since the orientation of θ at the interface is a function of a composition gradient, the composition gradient energy coefficient κ_c is also a function of a composition gradient. Therefore, the variation calculation should be performed in (21.14) not only for the gradient squared part but also for the composition gradient energy coefficient itself. The explicit form of the variation calculation is written in the

form:

$$\begin{aligned}
 \frac{\delta F_{\text{grad}}}{\delta c} &= -\frac{d}{dx} \left(\frac{\partial f_{\text{grad}}}{\partial c_{ix}} \right) - \frac{d}{dy} \left(\frac{\partial f_{\text{grad}}}{\partial c_{iy}} \right) \\
 &= \frac{d}{dx} \left(\varepsilon \varepsilon' c_{iy} - \varepsilon^2 c_{ix} \right) \\
 &\quad - \frac{d}{dy} \left(\varepsilon \varepsilon' c_{ix} + \varepsilon^2 c_{iy} \right) \\
 &= -\varepsilon^2 (c_{ixx} + c_{iyy}) - (\varepsilon'^2 + \varepsilon \varepsilon'') \\
 &\quad \times (\theta_{iy} c_{ix} - \theta_{ix} c_{iy}) - 2\varepsilon \varepsilon' (\theta_{ix} c_{ix} + \theta_{iy} c_{iy}), \quad (21.16)
 \end{aligned}$$

where $f_{\text{grad}} \equiv (1/2)\varepsilon^2(\theta)(\nabla c)^2$, $\varepsilon' \equiv \partial \varepsilon / \partial \theta$, $\varepsilon'' \equiv \partial^2 \varepsilon / \partial \theta^2$, $c_{ixx} \equiv \partial^2 c / \partial x^2$, $c_{iyy} \equiv \partial^2 c / \partial y^2$, $c_{ixy} \equiv \partial^2 c / (\partial x \partial y)$, $\theta_{ix} \equiv \partial \theta / \partial x$, and $\theta_{iy} \equiv \partial \theta / \partial y$.

The diffusion potential concerning the composition gradient energy has to be calculated by (21.16), when the composition gradient energy coefficient has an orientation dependence. In the case when a facet interface is observed, further modification is required in (21.16), the detail of this modification is discussed by Eggleston et al. [21.35].

Gradient Energy Expression for Multicomponent and Multiphase Systems

We first consider the composition field for the $N_c + 1$ component system ($i = 0 \sim N_c$). The composition gradient energy in this case is obtained by

$$\begin{aligned}
 F_{\text{grad}} &= \frac{1}{2} \kappa_c \int_r \sum_{i=0}^{N_c} (\nabla c_i)^2 dr \\
 &= \frac{1}{2} \kappa_c \int_r \sum_{i=1}^{N_c} \sum_{j=1}^{N_c} (\delta_{ij} + 1) (\nabla c_i) (\nabla c_j) dr, \quad (21.17)
 \end{aligned}$$

where the condition $\sum_{i=0}^{N_c} c_i = 1$ is used and we assume κ_c to be a constant. δ_{ij} is Kronecker's delta. As for the ternary alloy system, (21.17) is reduced to

$$F_{\text{grad}} = \kappa_c \int_r \left[(\nabla c_1)^2 + (\nabla c_2)^2 + (\nabla c_1)(\nabla c_2) \right] dr. \quad (21.18)$$

Note that the cross-term $(\nabla c_1)(\nabla c_2)$ appears.

On the other hand, in the case for the multiphase system where the number of phases is $i = 1 \sim N_\phi$, the phase-field order parameter ϕ_i , ($0 \leq \phi_i \leq 1$) is intro-

duced, and the gradient energy is given by

$$\begin{aligned}
 F_{\text{grad}} &= \frac{1}{2} \int_r \sum_{i=1}^{N_\phi} \sum_{j=1}^{N_\phi} \kappa_\phi |\phi_j \nabla \phi_i - \phi_i \nabla \phi_j|^2 dr, \\
 \sum_{i=1}^{N_\phi} \phi_i &= 1. \quad (21.19)
 \end{aligned}$$

This is an irreducible expression for the gradient energy [21.36].

How to Derivate the Equation of Composition Gradient Energy

As a typical example for the derivation of a gradient energy equation, the formulation of the composition gradient energy that was proposed in the spinodal theory is explained [21.28, 29]. We concretely derive the composition gradient energy equation for the A–B binary alloy system and the solute composition of B component is referred to $c(\mathbf{r}, t)$ that is a function of local position \mathbf{r} and time t . In this formulation, since we employ the composition gradient ∇c and the curvature $\nabla^2 c$ as invariant variables, the chemical free energy is expanded in Taylor series form as follows:

$$\begin{aligned}
 g_c(c, \nabla c, \nabla^2 c) &= g_c(c, 0, 0) + K_0(c)(\nabla c) \\
 &\quad + K_1(c)(\nabla^2 c) + K_2(c)(\nabla c)^2 \\
 &\quad + K_3(c)(\nabla^2 c)^2 + K_4(c)(\nabla c)(\nabla^2 c) + \dots \\
 &\cong g_c(c, 0, 0) + K_0(c)(\nabla c) \\
 &\quad + K_1(c)(\nabla^2 c) + K_2(c)(\nabla c)^2, \quad (21.20)
 \end{aligned}$$

where we ignored the higher order terms in the Taylor series. $K_i(c)$ is an expansion coefficient and a function of composition. A function $g_c(c, 0, 0)$ corresponds the chemical free energy with no composition fluctuation (i.e., homogeneous single phase state). Expression (21.20) is the chemical free energy of the inhomogeneous system including the information of the composition profile shape.

Here, we focus on the free energy at position x_0 of the one dimensional composition profile with arbitrary shape. The chemical free energy at x_0 should be written as $g_c\{c(x_0), \nabla c(x_0), \nabla^2 c(x_0)\}$. When the coordinate conversion of a flip horizontal is performed to the function g_c around x_0 , i.e., it corresponds to the case that the point x_0 is looked at from back, the chemical free energy at x_0 is given as $g_c\{c(x_0), -\nabla c(x_0), \nabla^2 c(x_0)\}$.

Since energy must be invariant with the coordinate conversion because energy is a scalar quantity, it is necessary to satisfy the following relation:

$$g_c\{c(x_0), \nabla c(x_0), \nabla^2 c(x_0)\} = g_c\{c(x_0), -\nabla c(x_0), \nabla^2 c(x_0)\}. \quad (21.21)$$

Substituting (21.20) into (21.21), we obtain

$$\begin{aligned} & g_c\{c(x_0), 0, 0\} + K_0\{c(x_0)\}\{\nabla c(x_0)\} \\ & + K_1\{c(x_0)\}\{\nabla^2 c(x_0)\} + K_2\{c(x_0)\}\{\nabla c(x_0)\}^2 \\ & = g_c\{c(x_0), 0, 0\} - K_0\{c(x_0)\}\{\nabla c(x_0)\} \\ & + K_1\{c(x_0)\}\{\nabla^2 c(x_0)\} + K_2\{c(x_0)\}\{-\nabla c(x_0)\}^2, \\ & \therefore K_0\{c(x_0)\}\{\nabla c(x_0)\} = 0 \rightarrow K_0\{c(x_0)\} = 0. \end{aligned}$$

Hence $K_0(c)$ must be 0 identically because (21.21) should be satisfied at any position x_0 . Therefore, the chemical free energy for an inhomogeneous system has to be written as

$$g_c(c, \nabla c, \nabla^2 c) = g_c(c, 0, 0) + K_1(c)(\nabla^2 c) + K_2(c)(\nabla c)^2. \quad (21.22)$$

Therefore, the excess term originating in the composition fluctuation is expressed as

$$\begin{aligned} F_{\text{grad}} &= \int_V [K_1(c)(\nabla^2 c) + K_2(c)(\nabla c)^2] dV \\ &= \int_V K_1(c)(\nabla^2 c) dV + \int_V K_2(c)(\nabla c)^2 dV. \end{aligned} \quad (21.23)$$

F_{grad} is a composition gradient energy. Furthermore, the first term of the right-hand side of (21.23) is transformed as:

$$\begin{aligned} & \int_V K_1(c)(\nabla^2 c) dV \\ &= \int_S K_1(c) \{(\nabla c) \cdot \mathbf{n}\} dS - \int_V (\nabla K_1) \cdot (\nabla c) dV \\ &= \int_S K_1(c) \{(\nabla c) \cdot \mathbf{n}\} dS - \int_V \frac{\partial K_1}{\partial c} (\nabla c)^2 dV \\ &= - \int_V \frac{\partial K_1}{\partial c} (\nabla c)^2 dV, \end{aligned} \quad (21.24)$$

where the divergence theorem of Gauss, $\int_V f \nabla \cdot \mathbf{g} dV = \int_S f \mathbf{g} \cdot \mathbf{n} dS - \int_V \nabla f \cdot \mathbf{g} dV$, is utilized and \mathbf{n} is a unit

normal at the surface of the object. The reason the term for the surface integral in (21.24) has been eliminated is that the integrated value over the whole surface of the object becomes 0 statistically. Therefore, (21.23) is rewritten as

$$\begin{aligned} F_{\text{grad}} &= \int_V K_1(c)(\nabla^2 c) dV + \int_V K_2(c)(\nabla c)^2 dV \\ &= \int_V \left[K_2(c) - \frac{\partial K_1}{\partial c} \right] (\nabla c)^2 dV. \end{aligned} \quad (21.25)$$

Defining $\kappa(c)$ by

$$\kappa(c) = K_2(c) - \frac{\partial K_1}{\partial c}, \quad (21.26)$$

finally, we obtain

$$F_{\text{grad}} = \int_V \kappa(c)(\nabla c)^2 dV, \quad (21.27)$$

where $\kappa(c)$ is the so-called composition gradient energy coefficient. From (21.26), strictly speaking, $\kappa(c)$ is a function of a composition, but $\kappa(c)$ is often assumed to be constant and given by $\kappa = k\Omega d^2$, where Ω is an atomic interchange energy, d is the interatomic distance, and k is a phenomenological constant.

21.2.3 Elastic Strain Energy

In this section, the evaluation for the elastic strain energy of the coherent two-phase microstructure in A–B binary alloy system is explained as a simple example [21.37, 38]. The steps for evaluating the elastic strain energy is as follows:

Step 1 The eigenstrain [21.38] $\varepsilon_{ij}^0(\mathbf{r})$ is expressed as a function of the local composition $c(\mathbf{r})$, where \mathbf{r} is a position vector. The subscripts i and j take the integer values 1, 2, and 3.

Step 2 The total strain $\varepsilon_{ij}^c(\mathbf{r})$ is divided into two parts: $\varepsilon_{ij}^c(\mathbf{r}) = \bar{\varepsilon}_{ij}^c + \delta\varepsilon_{ij}^c(\mathbf{r})$, where $\bar{\varepsilon}_{ij}^c$ is the spatial average of $\varepsilon_{ij}^c(\mathbf{r})$, and $\delta\varepsilon_{ij}^c(\mathbf{r})$ is the deviation from $\bar{\varepsilon}_{ij}^c$. Therefore, the following relations should be satisfied:

$$\bar{\varepsilon}_{ij}^c = \int_{\mathbf{r}} \varepsilon_{ij}^c(\mathbf{r}) d\mathbf{r}, \quad \int_{\mathbf{r}} \delta\varepsilon_{ij}^c(\mathbf{r}) d\mathbf{r} = 0.$$

Step 3 The equation to calculate the displacement, that is initially an unknown quantity, is deduced from the mechanical equilibrium equation using the $\varepsilon_{ij}^0(\mathbf{r})$ as a boundary condition, then $\delta\varepsilon_{ij}^c(\mathbf{r})$ is calculated from $u_i(\mathbf{r})$ directly.

Step 4 The elastic strain energy is written as a function of $\varepsilon_{ij}^c(\mathbf{r})$ and $\varepsilon_{ij}^0(\mathbf{r})$.

Step 5 $\bar{\varepsilon}_{ij}^c$ is determined from a constraint condition for the whole body.

Utilizing steps 1 to 5, we are able to evaluate the elastic strain energy of the coherent two-phase microstructure. When we try to calculate the elastic strain energy, it is important to distinguish the known variables and the unknown ones. In this case, the given variable is $\varepsilon_{ij}^0(\mathbf{r})$ that is calculated directly from the composition field $c(\mathbf{r})$, and the unknown variable is $\varepsilon_{ij}^c(\mathbf{r})$. The following formulation of elastic strain energy may look complicated, but the basic idea is simple. We evaluate the unknown variable using the known one through the mechanical equilibrium equation and the boundary conditions. Detail of the evaluation method is explained along the lines of step 1 to 5 as follows.

Step 1

When the lattice parameter a is a linear function of the composition, i. e., the Vegard's law is satisfied, a is given by

$$a(\mathbf{r}) = a_0 + \frac{da}{dc} c(\mathbf{r}), \quad (21.28)$$

where $c(\mathbf{r})$ is a local solute composition of component B at position \mathbf{r} , and a_0 is the lattice parameter for pure A component. In this case, the eigenstrain is defined by

$$\begin{aligned} \varepsilon_{ij}^0(\mathbf{r}) &\equiv \frac{a(\mathbf{r}) - a_0}{a_0} = \eta c(\mathbf{r}) \delta_{ij}, \\ \eta &\equiv \frac{1}{a_0} \frac{da}{dc}, \end{aligned} \quad (21.29)$$

where η is a lattice mismatch that is calculated from the lattice parameters of pure A and B metals. Since the lattice parameters of pure component and the composition field $c(\mathbf{r})$ are given in advance, the spatial distribution of the eigenstrain $\varepsilon_{ij}^0(\mathbf{r})$ in the microstructure is easily calculated from (21.29).

Step 2

Next, the total strain $\varepsilon_{ij}^c(\mathbf{r})$ is defined by

$$\varepsilon_{ij}^c(\mathbf{r}) \equiv \bar{\varepsilon}_{ij}^c + \delta \varepsilon_{ij}^c(\mathbf{r}), \quad (21.30)$$

$$\int_r \delta \varepsilon_{ij}^c(\mathbf{r}) d\mathbf{r} = 0, \quad (21.31)$$

where $\bar{\varepsilon}_{ij}^c$ is a volume average of $\varepsilon_{ij}^c(\mathbf{r})$, $\delta \varepsilon_{ij}^c(\mathbf{r})$ is the deviation from $\bar{\varepsilon}_{ij}^c$, and is defined using the displacement

vector $u_i(\mathbf{r})$ as

$$\delta \varepsilon_{kl}^c(\mathbf{r}) \equiv \frac{1}{2} \left(\frac{\partial u_k(\mathbf{r})}{\partial r_l} + \frac{\partial u_l(\mathbf{r})}{\partial r_k} \right). \quad (21.32)$$

The elastic strain $\varepsilon_{ij}^{\text{el}}(\mathbf{r})$ is defined by

$$\varepsilon_{ij}^{\text{el}}(\mathbf{r}) \equiv \varepsilon_{ij}^c(\mathbf{r}) - \varepsilon_{ij}^0(\mathbf{r}). \quad (21.33)$$

On the basis of the linear elasticity theory, the stress is evaluated based on Hook's law,

$$\sigma_{ij}^{\text{el}}(\mathbf{r}) = C_{ijkl} \varepsilon_{kl}^{\text{el}}(\mathbf{r}) = C_{ijkl} \left[\varepsilon_{kl}^c(\mathbf{r}) - \varepsilon_{kl}^0(\mathbf{r}) \right], \quad (21.34)$$

where C_{ijkl} is an elastic constant.

Step 3

The mechanical equilibrium equation is expressed as

$$\sigma_{ij,j}^{\text{el}}(\mathbf{r}) = \frac{\partial \sigma_{ij}^{\text{el}}(\mathbf{r})}{\partial r_j} = 0, \quad (21.35)$$

where the no body force condition is assumed. Substituting (21.29), (21.32), and (21.34) into (21.35) yields

$$C_{ijkl} \frac{\partial^2 u_k}{\partial r_j \partial r_l} = C_{ijkl} \eta \delta_{kl} \frac{\partial c}{\partial r_j}. \quad (21.36)$$

The functions $c(\mathbf{r})$, u_i and $\delta \varepsilon_{ij}^c(\mathbf{r})$ are expressed in the form of a Fourier integral as follows:

$$c(\mathbf{r}) = \int_{\mathbf{k}} \hat{c}(\mathbf{k}) \exp(i\mathbf{k} \cdot \mathbf{r}) \frac{d\mathbf{k}}{(2\pi)^3} \quad (21.37)$$

$$u_i(\mathbf{r}) = \int_{\mathbf{k}} \hat{u}_i(\mathbf{k}) \exp(i\mathbf{k} \cdot \mathbf{r}) \frac{d\mathbf{k}}{(2\pi)^3} \quad (21.38)$$

$$\delta \varepsilon_{ij}^c(\mathbf{r}) = \int_{\mathbf{k}} \delta \hat{\varepsilon}_{ij}^c(\mathbf{k}) \exp(i\mathbf{k} \cdot \mathbf{r}) \frac{d\mathbf{k}}{(2\pi)^3}, \quad (21.39)$$

where $\mathbf{k} = (k_1, k_2, k_3)$ is a reciprocal wave vector in Fourier space. Substituting (21.37–21.39) into (21.36) and focusing on the amplitude part of the Fourier expression, we obtain

$$C_{ijkl} k_j k_l \hat{u}_k(\mathbf{k}) = -i C_{ijkl} \eta \delta_{kl} k_j \hat{c}(\mathbf{k}). \quad (21.40)$$

This is a Fourier expression of the mechanical equilibrium equation. (Note that the upright i is the imaginary number, not an index for vector or tensor.) Here, we define the following equations:

$$G_{ik}^{-1}(\mathbf{k}) \equiv C_{ijkl} k_j k_l, \quad (21.41)$$

$$\sigma_{ij} \equiv C_{ijkl} \eta \delta_{kl}. \quad (21.42)$$

Using (21.41) and (21.42) in (21.40), the $\hat{u}_k(\mathbf{k})$, that is a Fourier transform of $u_k(\mathbf{r})$, is given by

$$\begin{aligned}\hat{u}_k(\mathbf{k}) &= -iG_{ik}(\mathbf{k})C_{ijkl}\eta\delta_{kl}k_j\hat{c}(\mathbf{k}) \\ &= -iG_{ik}(\mathbf{k})\sigma_{ij}k_j\hat{c}(\mathbf{k}).\end{aligned}\quad (21.43)$$

Since the Fourier transform of (21.32) is

$$\delta\hat{\varepsilon}_{kl}^c(\mathbf{k}) = i\frac{1}{2}[\hat{u}_k(\mathbf{k})k_l + \hat{u}_l(\mathbf{k})k_k], \quad (21.44)$$

substituting (21.43) into (21.44) yields

$$\begin{aligned}\delta\hat{\varepsilon}_{kl}^c(\mathbf{k}) &= i\frac{1}{2}[\hat{u}_k(\mathbf{k})k_l + \hat{u}_l(\mathbf{k})k_k] \\ &= i\hat{u}_k(\mathbf{k})k_l \\ &= -iiG_{ik}(\mathbf{k})k_jk_l\sigma_{ij}\hat{c}(\mathbf{k}) \\ &= G_{ik}(\mathbf{k})k_lk_jC_{ijmn}\eta\delta_{mn}\hat{c}(\mathbf{k}).\end{aligned}\quad (21.45)$$

The values of the elastic constant C_{ijkl} and the lattice mismatch η are given from the materials parameters in advance. Since the composition field $c(\mathbf{r})$ is given beforehand, $\hat{c}(\mathbf{k})$ is calculated by the first Fourier transform of $c(\mathbf{r})$ numerically. Therefore, $\delta\hat{\varepsilon}_{kl}^c(\mathbf{k})$ is directly calculated based on (21.45) and obtained as a function of \mathbf{k} , then $\delta\varepsilon_{kl}^c(\mathbf{r})$ is calculated through the inverse first Fourier transform of $\delta\hat{\varepsilon}_{kl}^c(\mathbf{k})$ numerically.

Step 4

The elastic strain energy is given as

$$\begin{aligned}E_{\text{str}} &= \frac{1}{2} \int_{\mathbf{r}} C_{ijkl} \varepsilon_{ij}^{\text{el}}(\mathbf{r}) \varepsilon_{kl}^{\text{el}}(\mathbf{r}) d\mathbf{r} \\ &= \frac{1}{2} \int_{\mathbf{r}} \left[C_{ijkl} \left[\bar{\varepsilon}_{ij}^c + \delta\varepsilon_{ij}^c(\mathbf{r}) - \varepsilon_{ij}^0(\mathbf{r}) \right] \right. \\ &\quad \left. \times \left[\bar{\varepsilon}_{kl}^c + \delta\varepsilon_{kl}^c(\mathbf{r}) - \varepsilon_{kl}^0(\mathbf{r}) \right] \right] d\mathbf{r},\end{aligned}\quad (21.46)$$

where the elastic strain is defined by

$$\begin{aligned}\varepsilon_{ij}^{\text{el}}(\mathbf{r}) &\equiv \varepsilon_{ij}^c(\mathbf{r}) - \varepsilon_{ij}^0(\mathbf{r}) \\ &= \bar{\varepsilon}_{ij}^c + \delta\varepsilon_{ij}^c(\mathbf{r}) - \varepsilon_{ij}^0(\mathbf{r})\end{aligned}\quad (21.47)$$

and we are able to rewrite (21.46) using (21.47) as

$$E_{\text{str}} = \frac{1}{2} \int_{\mathbf{r}} \left[C_{ijkl} \left[\bar{\varepsilon}_{ij}^c + \delta\varepsilon_{ij}^c(\mathbf{r}) - \varepsilon_{ij}^0(\mathbf{r}) \right] \right. \\ \left. \times \left[\bar{\varepsilon}_{kl}^c + \delta\varepsilon_{kl}^c(\mathbf{r}) - \varepsilon_{kl}^0(\mathbf{r}) \right] \right] d\mathbf{r}$$

$$\begin{aligned}&= \frac{1}{2} \int_{\mathbf{r}} C_{ijkl} \bar{\varepsilon}_{ij}^c \bar{\varepsilon}_{kl}^c d\mathbf{r} + \frac{1}{2} C_{ijkl} \bar{\varepsilon}_{ij}^c \int_{\mathbf{r}} \delta\varepsilon_{kl}^c(\mathbf{r}) d\mathbf{r} \\ &\quad - \frac{1}{2} C_{ijkl} \bar{\varepsilon}_{ij}^c \int_{\mathbf{r}} \varepsilon_{kl}^0(\mathbf{r}) d\mathbf{r} \\ &\quad + \frac{1}{2} C_{ijkl} \bar{\varepsilon}_{kl}^c \int_{\mathbf{r}} \delta\varepsilon_{ij}^c(\mathbf{r}) d\mathbf{r} \\ &\quad + \frac{1}{2} \int_{\mathbf{r}} C_{ijkl} \delta\varepsilon_{ij}^c(\mathbf{r}) \delta\varepsilon_{kl}^c(\mathbf{r}) d\mathbf{r} \\ &\quad - \frac{1}{2} C_{ijkl} \int_{\mathbf{r}} \delta\varepsilon_{ij}^c(\mathbf{r}) \varepsilon_{kl}^0(\mathbf{r}) d\mathbf{r} \\ &\quad - \frac{1}{2} C_{ijkl} \bar{\varepsilon}_{kl}^c \int_{\mathbf{r}} \varepsilon_{ij}^0(\mathbf{r}) d\mathbf{r} \\ &\quad - \frac{1}{2} \int_{\mathbf{r}} C_{ijkl} \varepsilon_{ij}^0(\mathbf{r}) \delta\varepsilon_{kl}^c(\mathbf{r}) d\mathbf{r} \\ &\quad + \frac{1}{2} \int_{\mathbf{r}} C_{ijkl} \varepsilon_{ij}^0(\mathbf{r}) \varepsilon_{kl}^0(\mathbf{r}) d\mathbf{r} \\ &= \frac{1}{2} C_{ijkl} \bar{\varepsilon}_{ij}^c \bar{\varepsilon}_{kl}^c \int_{\mathbf{r}} d\mathbf{r} - C_{ijkl} \bar{\varepsilon}_{ij}^c \int_{\mathbf{r}} \varepsilon_{kl}^0(\mathbf{r}) d\mathbf{r} \\ &\quad + \frac{1}{2} C_{ijkl} \int_{\mathbf{r}} \varepsilon_{ij}^0(\mathbf{r}) \varepsilon_{kl}^0(\mathbf{r}) d\mathbf{r} \\ &\quad - C_{ijkl} \int_{\mathbf{r}} \delta\varepsilon_{ij}^c(\mathbf{r}) \varepsilon_{kl}^0(\mathbf{r}) d\mathbf{r} \\ &\quad + \frac{1}{2} \int_{\mathbf{r}} C_{ijkl} \delta\varepsilon_{ij}^c(\mathbf{r}) \delta\varepsilon_{kl}^c(\mathbf{r}) d\mathbf{r} \\ &= \frac{1}{2} C_{ijkl} \bar{\varepsilon}_{ij}^c \bar{\varepsilon}_{kl}^c - C_{ijkl} \bar{\varepsilon}_{ij}^c \delta_{kl} \eta \int_{\mathbf{r}} c(\mathbf{r}) d\mathbf{r} \\ &\quad + \frac{1}{2} C_{ijkl} \delta_{ij} \delta_{kl} \eta^2 \int_{\mathbf{r}} \{c(\mathbf{r})\}^2 d\mathbf{r} \\ &\quad - \frac{1}{2} C_{ijkl} \int_{\mathbf{r}} \delta\varepsilon_{ij}^c(\mathbf{r}) \varepsilon_{kl}^0(\mathbf{r}) d\mathbf{r} \\ &= \frac{1}{2} C_{ijkl} \bar{\varepsilon}_{ij}^c \bar{\varepsilon}_{kl}^c - C_{ijkl} \bar{\varepsilon}_{ij}^c \delta_{kl} \eta c_0 \\ &\quad + \frac{1}{2} C_{ijkl} \delta_{ij} \delta_{kl} \eta^2 \overline{\{c(\mathbf{r})\}^2} \\ &\quad - \frac{1}{2} \int_{\mathbf{k}} n_i \sigma_{ij} \Omega_{jk}(\mathbf{n}) \sigma_{kl} n_l |\delta\hat{c}(\mathbf{k})|^2 \frac{d\mathbf{k}}{(2\pi)^3},\end{aligned}\quad (21.48)$$

where \mathbf{n} is a unit vector in the \mathbf{k} direction, $\mathbf{n} \equiv \mathbf{k}/|\mathbf{k}|$, and $\Omega_{ik}^{-1}(\mathbf{n}) \equiv C_{ijkl}n_j n_l$. The following equations

$$\begin{aligned} \int_{\mathbf{r}} \delta \varepsilon_{ij}^c(\mathbf{r}) d\mathbf{r} &= 0, \\ \int_{\mathbf{r}} \varepsilon_{ij}^0(\mathbf{r}) d\mathbf{r} &= \delta_{ij} \eta \int_{\mathbf{r}} c(\mathbf{r}) d\mathbf{r} = \delta_{ij} \eta c_0, \\ \int_{\mathbf{r}} C_{ijkl} \delta \varepsilon_{ij}^c(\mathbf{r}) \varepsilon_{kl}^0(\mathbf{r}) d\mathbf{r} &= \int_{\mathbf{r}} C_{ijkl} \delta \varepsilon_{ij}^c(\mathbf{r}) \delta \varepsilon_{kl}^c(\mathbf{r}) d\mathbf{r}, \end{aligned}$$

are used for formulation of (21.48). The last relation of the above equations is obtained as follows:

$$\begin{aligned} \int_S \delta \sigma_{ij}^c(\mathbf{r}) u_i(\mathbf{r}) n_j dS - \int_{\mathbf{r}} \delta \sigma_{ij,j}^c(\mathbf{r}) u_i(\mathbf{r}) d\mathbf{r} &= 0, \\ \left[\because \delta \sigma_{ij}^c(\mathbf{r}) n_j = 0, \quad \delta \sigma_{ij,j}^c(\mathbf{r}) = 0 \right], \\ \int_{\mathbf{r}} \delta \sigma_{ij}^c(\mathbf{r}) \delta \varepsilon_{ij}^c(\mathbf{r}) d\mathbf{r} &= 0, \\ \int_{\mathbf{r}} C_{ijkl} \delta \varepsilon_{ij}^c(\mathbf{r}) \{ \delta \varepsilon_{kl}^c(\mathbf{r}) - \varepsilon_{kl}^0(\mathbf{r}) \} d\mathbf{r} &= 0, \\ \therefore \int_{\mathbf{r}} C_{ijkl} \delta \varepsilon_{ij}^c(\mathbf{r}) \varepsilon_{kl}^0(\mathbf{r}) d\mathbf{r} &= \int_{\mathbf{r}} C_{ijkl} \delta \varepsilon_{ij}^c(\mathbf{r}) \delta \varepsilon_{kl}^c(\mathbf{r}) d\mathbf{r}, \end{aligned}$$

where $\delta \sigma_{ij}^c(\mathbf{r}) = C_{ijkl} \{ \delta \varepsilon_{kl}^c(\mathbf{r}) - \varepsilon_{kl}^0(\mathbf{r}) \}$ and the Gauss integral is used. Furthermore, the mechanical equilibrium equation and the force balance at the body surface, i. e., the pressure on the surface is assumed to be 0, are considered.

Step 5

In the final stage of evaluating the elastic strain energy, the average value of the total strain $\bar{\varepsilon}_{ij}^c$ is determined. $\bar{\varepsilon}_{ij}^c$ is commonly evaluated by one of the following four types of boundary conditions:

1. The surface of the body is rigidly constrained and there is no external stress field.
Since the surface is fixed, the average of the total strain should be 0, i. e.,

$$\bar{\varepsilon}_{ij}^c = 0. \quad (21.49)$$

2. The body is constrained under homogeneous external strain $\bar{\varepsilon}_{ij}^a$.
In this case, the average total strain is the same as $\bar{\varepsilon}_{ij}^a$, i. e.,

$$\bar{\varepsilon}_{ij}^c = \bar{\varepsilon}_{ij}^a, \quad (21.50)$$

where the $\bar{\varepsilon}_{ij}^a$ is a known variable given by the boundary condition.

3. The surface of the body is unfixed and there is no external stress.

In this case, since the object can be expanded or contracted freely, the average total strain under a stable state should satisfy the condition:

$$\frac{\partial E_{\text{str}}}{\partial \bar{\varepsilon}_{ij}^c} = 0. \quad (21.51)$$

Substituting (21.48) into (21.51), we obtain the following relation:

$$\begin{aligned} \frac{\partial E_{\text{str}}}{\partial \bar{\varepsilon}_{ij}^c} &= C_{ijkl} \bar{\varepsilon}_{kl}^c - C_{ijkl} \delta_{kl} \eta c_0 = 0, \\ \therefore \bar{\varepsilon}_{kl}^c &= \delta_{kl} \eta c_0. \end{aligned} \quad (21.52)$$

4. The surface of the body is unfixed and the external stress σ_{ij}^a is applied.

In this case, the Gibbs energy is given as

$$G = E_{\text{str}} - \sigma_{ij}^a \bar{\varepsilon}_{ij}^c. \quad (21.53)$$

Since the average of total strain under the stable state should satisfy the condition:

$$\frac{\partial G}{\partial \bar{\varepsilon}_{ij}^c} = 0, \quad (21.54)$$

substituting (21.53) and (21.48) into (21.54) yields

$$\begin{aligned} \frac{\partial G}{\partial \bar{\varepsilon}_{ij}^c} &= C_{ijkl} \bar{\varepsilon}_{kl}^c - C_{ijkl} \delta_{kl} \eta c_0 - \sigma_{ij}^a = 0, \\ \therefore \bar{\varepsilon}_{kl}^c &= C_{ijkl}^{-1} \sigma_{ij}^a + \delta_{kl} \eta c_0, \end{aligned} \quad (21.55)$$

where C_{ijkl}^{-1} is an elastic compliance, i. e., an inverse matrix of C_{ijkl} .

It is worth noting that the elastic strain is expressed using (21.52) as

$$\begin{aligned} \varepsilon_{ij}^{\text{el}}(\mathbf{r}) &= \varepsilon_{ij}^c(\mathbf{r}) - \varepsilon_{ij}^0(\mathbf{r}) \\ &= \bar{\varepsilon}_{ij}^c + \delta \varepsilon_{ij}^c(\mathbf{r}) - \eta \delta_{ij} c(\mathbf{r}) \\ &= \delta_{ij} \eta c_0 + \delta \varepsilon_{ij}^c(\mathbf{r}) - \eta \delta_{ij} c(\mathbf{r}) \\ &= \delta \varepsilon_{ij}^c(\mathbf{r}) - \eta \delta_{ij} [c(\mathbf{r}) - c_0]. \end{aligned} \quad (21.56)$$

This equation means that the phrases *the mechanical equilibrium condition of the uniform strain is considered* and *the eigenstrain is redefined as $\varepsilon_{ij}^0(\mathbf{r}) \equiv \eta \delta_{ij} [c(\mathbf{r}) - c_0]$* are equivalent.

As for the multicomponent and multiphase system, the eigenstrain is expressed as a linear function of the order parameters ϕ_p as

$$\varepsilon_{ij}^0(\mathbf{r}, t) = \sum_p \varepsilon_{ij}^{00}(p) \phi_p(\mathbf{r}, t), \quad (21.57)$$

where ϕ_p corresponds to the composition field c and the squire of crystal structure field s^2 . $\varepsilon_{ij}^{00}(p)$ is a lattice mismatch concerning the order parameter ϕ_p . The derivation of elastic strain energy in this case is straightforward.

The evaluation of E_{str} mentioned above is for the homogeneous case, i.e., the elastic constant does not depend on the local order parameter. The elastic strain energy calculation in inhomogeneous case has been proposed and discussed in [21.39, 40].

21.2.4 Free Energy for Ferromagnetic and Ferroelectric Phase Transition

The order parameter used to describe ferromagnetic phase transition is a magnetization moment M , and the polarization moment P is employed as an order parameter for representing the ferroelectric phase transition in dielectric materials. In order to describe the ferromagnetic or ferroelectric domain microstructure formation in the phase-field method, the order parameters, M and P , are defined as a function of position \mathbf{r} and time t .

Since a description of the energy for the ferromagnetic and ferroelectric phase transition has a quite similar formulation, we explain the total free energy description for a ferroelectric phase transition during the structural phase transformation from cubic to tetragonal along the line of Wang's analysis [21.20].

In this field, the Landau-type bulk free energy density is commonly expressed by a six-order polynomial of the spontaneous polarization:

$$\begin{aligned} g_c = & \alpha_1(P_1^2 + P_2^2 + P_3^2) + \alpha_2(P_1^4 + P_2^4 + P_3^4) \\ & + \alpha_3(P_1^2 P_2^2 + P_2^2 P_3^2 + P_3^2 P_1^2) \\ & + \alpha_4(P_1^6 + P_2^6 + P_3^6) \\ & + \alpha_5[P_1^4(P_2^2 + P_3^2) + P_2^4(P_3^2 + P_1^2) \\ & \quad + P_3^4(P_1^2 + P_2^2)] \\ & + \alpha_6 P_1^2 P_2^2 P_3^2, \end{aligned} \quad (21.58)$$

where three variants are considered, and α_i are constant coefficients. The subscripts $i = 1, 2$, and 3 ; indicate a variant number. In the Ginzburg–Landau theory, the free energy function also depends on the gradient of the order parameter (that is, corresponding to the gradient energy). For ferroelectric materials, the polarization gradient energy represents the ferroelectric domain wall energy. For simplicity, the lowest order of the gradient

energy density takes the form:

$$\begin{aligned} f_{\text{grad}} = & \frac{1}{2} \kappa_1 (P_{1,1}^2 + P_{2,2}^2 + P_{3,3}^2) \\ & + \kappa_2 (P_{1,1} P_{2,2} + P_{2,2} P_{3,3} + P_{3,3} P_{1,1}) \\ & + \frac{1}{2} \kappa_3 [(P_{1,2} + P_{2,1})^2 + (P_{2,3} + P_{3,2})^2 \\ & \quad + (P_{1,3} + P_{3,1})^2] \\ & + \frac{1}{2} \kappa_4 [(P_{1,2} - P_{2,1})^2 + (P_{2,3} - P_{3,2})^2 \\ & \quad + (P_{1,3} - P_{3,1})^2], \end{aligned} \quad (21.59)$$

where κ_i are gradient energy coefficients and $P_{i,j}$ denotes the derivative of the i th component of the polarization vector P_i with respect to the j th coordinate.

In the phase-field simulations, each element is represented by an electric dipole with its strength of the dipole being given by a local polarization vector P_i . The multiple dipole–dipole electric interactions play a crucial role in calculating the morphology of a domain structure and in the process of domain switching as well. The multiple dipole–dipole electric interaction energy density is calculated by

$$f_d(\mathbf{r}) = -\frac{1}{2} f_{\text{dip}}(\mathbf{r}) \cdot \mathbf{P}(\mathbf{r}), \quad (21.60)$$

where

$$\begin{aligned} f_{\text{dip}}(\mathbf{r}) = & -\frac{1}{4\pi\epsilon} \int_{\mathbf{r}'} \left\{ \frac{\mathbf{P}(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|^3} \right. \\ & \left. - \frac{3(\mathbf{r} - \mathbf{r}')\mathbf{P}(\mathbf{r}') \cdot (\mathbf{r} - \mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|^5} \right\} d\mathbf{r}' \end{aligned} \quad (21.61)$$

is the electric field at point \mathbf{r} induced by all dipoles. When there is an externally applied electric field E_a , an additional electrical energy:

$$f_a = -E_i^e P_i \quad (21.62)$$

should be taken into account in the simulations. The spontaneous strains are associated with spontaneous polarizations. The eigenstrains are linked to the polarization components in the following form:

$$\begin{aligned} \varepsilon_{11}^0 &= Q_{11} P_1^2 + Q_{12} (P_2^2 + P_3^2), \\ \varepsilon_{22}^0 &= Q_{11} P_2^2 + Q_{12} (P_1^2 + P_3^2), \\ \varepsilon_{33}^0 &= Q_{11} P_3^2 + Q_{12} (P_1^2 + P_2^2), \\ \varepsilon_{12}^0 &= \varepsilon_{21}^0 = Q_{44} P_1 P_2, \\ \varepsilon_{23}^0 &= \varepsilon_{32}^0 = Q_{44} P_2 P_3, \\ \varepsilon_{31}^0 &= \varepsilon_{13}^0 = Q_{44} P_1 P_3, \end{aligned} \quad (21.63)$$

where Q_{ij} are the electrostrictive coefficients. When a dipole is among other dipoles with different orientations, there exist multiple dipole–dipole elastic interactions. The multiple dipole–dipole elastic interactions play an essential role in the determination of a domain structure. A twin-like domain structure is formed when the multiple dipole–dipole elastic interactions predominate.

Due to the constraint of the surroundings, the polarization-related strains include two parts: the elastic strain and the eigenstrain. The elastic strain related to polarization and/or polarization switching is given by

$$\varepsilon_{ij}^{\text{el}} = \varepsilon_{ij}^{\text{c}} - \varepsilon_{ij}^0. \quad (21.64)$$

When there exists an externally applied homogeneous stress σ_{kl}^{a} , using the superposition principle, we have the total elastic strains of the system:

$$\varepsilon_{ij}^{\text{el}} = \varepsilon_{ij}^{\text{c}} - \varepsilon_{ij}^0 + S_{ijkl}\sigma_{kl}^{\text{a}}, \quad (21.65)$$

where S_{ijkl} is the elastic compliance matrix. Finally, the elastic strain energy density under the cubic approximation is given by

$$e_{\text{str}} = \frac{1}{2}C_{11} \left[\left(\varepsilon_{11}^{\text{el}} \right)^2 + \left(\varepsilon_{22}^{\text{el}} \right)^2 + \left(\varepsilon_{33}^{\text{el}} \right)^2 \right] + C_{12} \left(\varepsilon_{11}^{\text{el}}\varepsilon_{22}^{\text{el}} + \varepsilon_{22}^{\text{el}}\varepsilon_{33}^{\text{el}} + \varepsilon_{33}^{\text{el}}\varepsilon_{11}^{\text{el}} \right)$$

$$+ 2C_{44} \left[\left(\varepsilon_{12}^{\text{el}} \right)^2 + \left(\varepsilon_{23}^{\text{el}} \right)^2 + \left(\varepsilon_{31}^{\text{el}} \right)^2 \right]. \quad (21.66)$$

As described above, the elastic strain energy is a function of polarization and applied stresses. An applied electric field can change the polarization and consequently vary the elastic strain energy density. On the other hand, an applied stress field can also change the polarization and thus change the electric energy density.

Integrating the free energy density over the entire volume of a simulated ferroelectric material yields the total free energy, F_{ele} , under externally applied electrical and mechanical loads, E_i^{e} and σ_{kl}^{a} . Mathematically, we have

$$F_{\text{ele}} = \int_r \left[g_{\text{c}}(P_i) + f_{\text{grad}}(P_{i,j}) + e_{\text{str}}(P_i, \sigma_{kl}^{\text{a}}) \right] d\mathbf{r}. \quad (21.67)$$

As for the energy description for a ferromagnetic phase transition, the order parameter is changed from P to M . The bulk Landau free energy density, in this case, corresponds the magnetocrystalline anisotropy energy. The formulation of another parts is almost the same and straightforward.

21.3 Solidification

21.3.1 Pure Metal

The interface between a liquid phase and a solid one is expressed by the continuum scalar function ϕ , which is called a phase-field variable and takes values from 0 (liquid phase) to 1 (solid phase) as illustrated in Fig. 21.1. The variable ϕ is a function of spatial position $\mathbf{r} = (x, y, z)$ and time t , and then the solidification process is represented by a temporal development of the ϕ field. Indicating the interface using ϕ , we are able to treat the complex changes of interface shapes such as a dendrite. The conditions of the interface curvature and temperature distribution around the interface are automatically satisfied by employing the parameters obtained from the physical properties at the interface.

The total free energy of the pure metal during solidification is given by

$$F = \int_V \left[f(\phi, T) + \frac{1}{2}\varepsilon^2 |\nabla\phi|^2 \right] dV, \quad (21.68)$$

where $f(\phi, T)$ is a chemical free energy defined by

$$f(\phi, T) \equiv h(\phi)f^{\text{s}}(T) + [1 - h(\phi)]f^{\text{l}}(T) + Wg(\phi). \quad (21.69)$$

Functions $f^{\text{s}}(T)$ and $f^{\text{l}}(T)$ are the chemical free energy for the solid and the liquid phase, respectively, given as a function of temperature T . The function $h(\phi)$ is a monotonic increasing function satisfying the constraint $h(0) = 0$ and $h(1) = 1$. The product $Wg(\phi)$ in the right-hand side of (21.69) is the energy barrier term, which takes a maximum value W within $0 < \phi < 1$ and $g(0) = g(1) = 0$, and is introduced in order to not mix the solid and liquid phases. The second term inside the integral of the right-hand side in (21.68) is a gradient energy that corresponds to the interfacial energy, and ε^2 is the gradient energy coefficient. When orientation dependence on the interfacial energy is considered, ε is assumed as a function of orientation.

In the phase-field method, the temporal and spatial development of the ϕ field is assumed to be proportional to the variation of the total free energy F with respect to ϕ , therefore the following differential evolution

Fig. 21.1 Schematic illustration of the one-dimensional profile of phase-field order parameter ϕ across the interface. The variable ϕ is commonly defined as a function of spatial position \mathbf{r} and time t , and the field dynamics, such as a solidification process, is represented by a temporal development of the field $\phi(\mathbf{r}, t)$

equation

$$\frac{\partial \phi}{\partial t} = -M_{\phi} \frac{\delta F}{\delta \phi}, \quad (21.70)$$

is employed, where M_{ϕ} is a mobility of the interface motion. As for the temporal and spatial changes of a temperature field, the thermal diffusion equation

$$\frac{\partial T}{\partial t} = D \nabla^2 T - p(\phi) \frac{L}{C_p} \frac{\partial \phi}{\partial t} \quad (21.71)$$

is applied. The second term of the right-hand side of (21.71) means the diverging term of heat produced from latent heat during solidification. Symbols D , L , and C_p are thermal diffusivity, latent heat, and specific heat, respectively. A function $p(\phi)$ satisfies the conditions $\int_0^1 p(\phi) d\phi = 1$ and $p(0) = p(1) = 0$, which is often defined by $p(\phi) \equiv \partial h / \partial \phi$ using the function $h(\phi)$. The phase-field method for the solidification simulation in a pure metal is calculated based on (21.70) and (21.71). The parameters M_{ϕ} , W , and ε are determined from the interface thickness 2λ (see Fig. 21.1) and the interfacial energy density σ . The relations between them are summarized as

$$M_{\phi} = \frac{T_m \mu \sigma}{\varepsilon^2 L}, \quad \sigma = \frac{\varepsilon \sqrt{W}}{3\sqrt{2}}, \quad 2\lambda = 2.2\sqrt{2} \frac{\varepsilon}{\sqrt{W}}. \quad (21.72)$$

T_m is the melting temperature, and μ is the kinetic coefficient determined by $v_n / \mu = f^L - f^S - 2\sigma / R$ that is an

equation of the sharp interface motion, where v_n and R are an interface velocity and a curvature at the interface. The numerical technique to solve the nonlinear differential equations is commonly a finite difference simulation. Since the calculation method is mathematically equivalent to that solving the differential equation describing temporal field dynamics, we can utilize many techniques developed in the field of the computational fluid dynamics.

The result of a two-dimensional simulation of dendrite growth in pure metal is shown in Fig. 21.2. The black and white parts are the solid and liquid phase, respectively. Note that the complex morphological change of the realistic dendrite growth is quite reasonably calculated.

Since the width of the solid–liquid interface in the solidification process commonly has the length of an atomic scale, the temperature field causes numerical errors in the gradual interface as shown in Fig. 21.1, if the numerical difference calculation is performed using coarse difference dividing cells. Since the parameter M is derived assuming the temperature is constant within the interface, a small calculation mesh size is required to neglect the temperature change though the interface region in the numerical simulation. Hence, the interface width should be negligibly small as compared to the capillary length and theoretically at the sharp interface limit. However, the value of the interface width is sometimes selected as large beyond the restriction for the computational efficiency.

This made the limit of the phase-field method at an early stage when this simulation method was proposed, but the new technique (called the thin interface limit model) of amending the point mentioned above has already been proposed. For example, *Karma* and *Rappel* [21.10] derived the phase-field mobility in the thin interface limit to relax the restriction of the interface

Fig. 21.2a–c Two-dimensional phase-field simulation of a dendrite growth process in pure metal is represented from (a)–(c). The black and white parts represent a solid and liquid phase, respectively

width and expressed it as follows:

$$M^{-1} = \frac{\varepsilon^2 L}{T_m \sigma} \left(\frac{1}{\mu} + \frac{\delta L}{4 D C_p} K \right)^{-1},$$

$$K = \int_0^1 \frac{h(\phi) [1 - h(\phi)]}{\phi(1 - \phi)} d\phi. \quad (21.73)$$

This thin interface limit model not only improves computer efficiency but also removes the limitation for the kinetic coefficient. They showed that the numerical calculation of the dendrite shape using the phase-field model agreed well with the solvability theory in both 2-D and 3-D. Therefore, we should emphasize that the idea that the phase-field method always physically requires a smooth interface is a mistake, and the phase-field method can be applied to the sharp interface with one atomic layer.

21.3.2 Alloy

In the phase-field model for alloy solidification, the local solute composition c is also employed as one of the phase-field order parameters and the gradient energy term for the solute composition field is introduced into the total free energy functional. But when the interface region is small relative to the entire microstructure simulated, a similar problem explained for the temperature field in the above section arises for the composition field. The thin interface model considering the composition field was proposed by Kim et al. [21.11]. They defined the interface as a fraction weighted mixture of the solid and liquid with different compositions and free energy, where the compositions of solid and liquid at the interface are determined to have the same chemical potential μ , i. e., the local equilibrium is assumed to be:

$$\begin{aligned} f^s &= c_S f_B^s(T) + (1 - c_S) f_a^s(T), \\ f^L &= c_L f_B^L(T) + (1 - c_L) f_a^L(T), \\ c &= h(\phi) c_S + [1 - h(\phi)] c_L, \\ \mu^s(c_S) &= \mu^L(c_L). \end{aligned} \quad (21.74)$$

The local solute composition of the solid phase and the liquid one is denoted by c_S and c_L , respectively. This model is called the **KKS** model (Kim–Kim–Suzuki model) [21.11], where a solute diffusion equation is solved simultaneously as

$$\frac{\partial c}{\partial t} = \nabla \cdot \left(\frac{D_c(\phi)}{f_{cc}} \nabla f_c \right), \quad (21.75)$$

Fig. 21.3a,b The change in dendrite shape of steel due to a ternary alloying element is demonstrated for (a) Fe-0.5 mol % C; and (b) Fe-0.5 mol % C-0.001 mol % P [21.12]. The simulation results show that a small addition of phosphorus changes the secondary arm spacing significantly even when it does not significantly change the interface velocity

where D_c is the solute diffusivity and f_c and f_{cc} are the first and the second derivatives of the chemical free energy density. The parameters, ε and W , are the same as the ones in the pure material solidification case defined by (21.72). The mobility M in the thin interface limit was also derived by Kim et al. as

$$\begin{aligned} M^{-1} &= \frac{\varepsilon^2}{\sigma} \left[\frac{RT}{V_m} \frac{1 - k^e}{m^e} \frac{1}{\mu} + \frac{\varepsilon}{D_L \sqrt{2W}} \zeta(c_S^e, c_L^e) \right], \\ \zeta(c_S^e, c_L^e) &= f_{cc}^s(c_S^e) f_{cc}^L(c_L^e) (c_L^e - c_S^e)^2 \\ &\times \int_0^1 \frac{h(\phi) [1 - h(\phi)]}{[1 - h(\phi)] f_{cc}^s(c_S^e) + h(\phi) f_{cc}^L(c_L^e)} \frac{1}{\phi(1 - \phi)} d\phi, \end{aligned} \quad (21.76)$$

where D_L is a diffusion coefficient of liquid phase, k^e and m^e are a partition coefficient and a gradient of liquidus line on the corresponding phase diagram, respectively. V_m is a molar volume and the superscript e indicates that the parameter is in a local equilibrium state.

The phase-field simulation of the dendrite shape changes performed by Suzuki et al. for Fe-0.5 mol % C binary alloy and 0.5 mol % C-0.001 mol % P ternary alloy at 1780 K is shown in Fig. 21.3 [21.12]. The secondary arms develop well and the arm spacing becomes narrow with a small addition of phosphorus because the phosphorus is likely to enrich the interface and reduce the interface stability. The simulation results show that a small addition of phosphorus changes the secondary arm spacing significantly even when it does not significantly change the interface velocity.

21.4 Diffusion-Controlled Phase Transformation

21.4.1 Cahn–Hilliard Diffusion Equation

Since the relation between the kinetics and the thermodynamics of phase transformations is plainly formulated in the diffusion theory treating an interdiffusion, the diffusion controlled phase decomposition in solid–solid phase transformations is a very good example for explaining the relation between energetics and dynamics in microstructure evolution. In this section, the basis of the diffusion equation concerning phase decomposition is explained [21.41].

From a physical viewpoint, atom diffusion in solids is formulated based on the equation of the friction. Because the diffusion of the atom inside the solid corresponds to the movement of the object in the medium with a very strong viscosity, the inertia term in the equation of motion (the so-called Ranjuban equation) attenuates exponentially and only the friction term will remain. We consider the case where atom A moves with speed v_1 and a thermodynamic driving force to move this atom is assumed to be F_1 . The F_1 is defined by

$$f_1 = -\nabla\mu_1, \quad (21.77)$$

where μ_1 is the chemical potential of component A. Thus, the velocity of atom A, v_1 , is given by the equation of the friction:

$$v_1 = M_1 f_1 = -M_1 \nabla\mu_1, \quad (21.78)$$

where M_1 is the mobility for atom A diffusion, which is a parameter indicating the easiness of atom movement and is physically equivalent to the reciprocal of the friction coefficient. M_1 is, exactly, a function of the local composition around the atom A in diffusing, but it is often assumed to be constant for simplicity. Using (21.78), we obtain the diffusion flow of component A, J_1 , which is induced by a driving force F_1 , as

$$J_1 = c_1 v_1 = -M_1 c_1 \nabla\mu_1, \quad (21.79)$$

where c_1 is a local composition of component A.

Next, we derive the equation of interdiffusion for the diffusion couple of A–B binary system. Henceforth, the element names A and B are referred to as 1 and 2, respectively, at the symbol subscript. The equation describing the interdiffusion is derived by eliminating v_0 in the right-hand side of the following equations, which are the governing equations for a macroscopic flux flow of the solute element:

$$\begin{aligned} J_1 &= -c_1 M_1 \nabla\mu_1 + v_0 c_1, \\ J_2 &= -c_2 M_2 \nabla\mu_2 + v_0 c_2, \end{aligned} \quad (21.80)$$

where v_0 is a macroscopic flux flow of the solute element, for instance, in the diffusion couple, it corresponds to the macroscopic velocity of coupling interface. According to the conservation law, the diffusion equation is defined as

$$\begin{aligned} \frac{\partial c_1}{\partial t} &= -\nabla \cdot J_1 = \nabla \cdot (c_1 M_1 \nabla\mu_1 - v_0 c_1), \\ \frac{\partial c_2}{\partial t} &= -\nabla \cdot J_2 = \nabla \cdot (c_2 M_2 \nabla\mu_2 - v_0 c_2). \end{aligned} \quad (21.81)$$

Therefore, the relation:

$$\begin{aligned} \frac{\partial(c_1 + c_2)}{\partial t} &= \nabla \cdot (c_1 M_1 \nabla\mu_1 + c_2 M_2 \nabla\mu_2 - v_0) = 0 \\ \therefore c_1 M_1 \nabla\mu_1 + c_2 M_2 \nabla\mu_2 - v_0 &= C : \text{const} \end{aligned}$$

is obtained by considering $c_1 + c_2 = 1$. Furthermore, if we assume $\nabla\mu_1 = 0$, $\nabla\mu_2 = 0$ and $v_0 = 0$ at the position far from the coupling interface, the value of C should be 0. Because C is a constant and independent of position. Therefore, the velocity of the coupling interface is given by

$$v_0 = c_1 M_1 \nabla\mu_1 + c_2 M_2 \nabla\mu_2. \quad (21.82)$$

Substituting (21.82) into (21.81), we obtain the interdiffusion equation as a form of

$$\begin{aligned} J_1 &= -(c_2 M_1 + c_1 M_2) c_1 \nabla\mu_1 \\ &= -(c_2 M_1 + c_1 M_2) c_1 c_2 \nabla(\mu_1 - \mu_2) \\ &= -(c_2 M_1 + c_1 M_2) c_1 c_2 \nabla \left(\frac{\partial g_c}{\partial c_1} \right) \\ &= -(c_2 M_1 + c_1 M_2) c_1 c_2 \left(\frac{\partial^2 g_c}{\partial c_1^2} \right) \nabla c_1, \\ J_2 &= -(c_2 M_1 + c_1 M_2) c_2 \nabla\mu_2 \\ &= -(c_2 M_1 + c_1 M_2) c_1 c_2 \nabla(\mu_2 - \mu_1) \\ &= -(c_2 M_1 + c_1 M_2) c_1 c_2 \nabla \left(\frac{\partial g_c}{\partial c_2} \right) \\ &= -(c_2 M_1 + c_1 M_2) c_1 c_2 \left(\frac{\partial^2 g_c}{\partial c_2^2} \right) \nabla c_2. \end{aligned} \quad (21.83)$$

In the formulation of (21.83), the Gibbs–Duhem relations

$$\begin{aligned} c_1 d\mu_1 + c_2 d\mu_2 &= 0, \\ \rightarrow c_1 d\mu_1 + c_2 d\mu_1 &= c_2 d\mu_1 - c_2 d\mu_2, \\ \therefore d\mu_1 &= c_2 d(\mu_1 - \mu_2) \end{aligned}$$

and

$$\begin{aligned}\frac{\partial g_c}{\partial c_1} &= \mu_1 - \mu_2 + c_1 \frac{\partial \mu_1}{\partial c_1} + c_2 \frac{\partial \mu_2}{\partial c_1} \\ &= \mu_1 - \mu_2, \\ \frac{\partial g_c}{\partial c_2} &= \mu_2 - \mu_1,\end{aligned}$$

are used, where g_c is a chemical free energy density. According to (21.83), the interdiffusion coefficient is expressed as follows:

$$\begin{aligned}\tilde{D}_1 &= (c_2 M_1 + c_1 M_2) c_1 c_2 \left(\frac{\partial^2 g_c}{\partial c_1^2} \right), \\ \tilde{D}_2 &= (c_2 M_1 + c_1 M_2) c_1 c_2 \left(\frac{\partial^2 g_c}{\partial c_2^2} \right).\end{aligned}\quad (21.84)$$

In particular, when g_c is a chemical free energy for an ideal solid solution, we find the relation $\partial^2 g_c / \partial c_1^2 = \partial^2 g_c / \partial c_2^2 = RT / (c_1 c_2)$ and entering this into (21.84), we have

$$\tilde{D}_1 = \tilde{D}_2 = c_2 M_1 RT + c_1 M_2 RT = c_2 D_1^* + c_1 D_2^*, \quad (21.85)$$

where $D_1^* = M_1 RT$ and $D_2^* = M_2 RT$ are the Einstein's relations, R is the gas constant and T is the absolute temperature, and D_i^* is a self-diffusion coefficient.

On the other hand, the phenomenological equation for the generalized Fick's first law is defined as

$$\begin{aligned}J_1 &= -L_{11} \nabla \mu_1 - L_{12} \nabla \mu_2, \\ J_2 &= -L_{21} \nabla \mu_1 - L_{22} \nabla \mu_2,\end{aligned}\quad (21.86)$$

where L_{ij} is the Onsager coefficient, which should satisfy the relation

$$L_{11} + L_{21} = 0, \quad L_{12} + L_{22} = 0, \quad L_{12} = L_{21}. \quad (21.87)$$

The above relation is derived from the restriction of solute conservation law and the condition of the detailed balance of local equilibrium. Considering (21.87) in (21.86), we get

$$\begin{aligned}J_1 &= -L_{11} \nabla (\mu_1 - \mu_2), \\ J_2 &= -L_{22} \nabla (\mu_2 - \mu_1).\end{aligned}\quad (21.88)$$

Since (21.83) and (21.88) should be the same equation, the Onsager coefficient is given by

$$\begin{aligned}L_{11} &= L_{22} = (c_2 M_1 + c_1 M_2) c_1 c_2, \\ L_{12} &= L_{21} = 0.\end{aligned}\quad (21.89)$$

An important point is that the interdiffusion and Onsager coefficients are obtained using (21.84) and (21.85), if a self-diffusion coefficient and a chemical free energy function g_c are experimentally determined.

Although we considered the chemical free energy g_c in the formulation mentioned above, the more general evolution equation that is able to describe the microstructure changes in the diffusion controlled phase transformation can be deduced using the total free energy of the microstructure G_{sys} instead of the chemical free energy g_c . For instance, the diffusion flux J_2 is expressed as

$$J_2 = -(c_2 M_1 + c_1 M_2) c_1 c_2 \nabla \frac{\delta G_{\text{sys}}}{\delta c_2}. \quad (21.90)$$

By comparing (21.83) and (21.90), the mobility M_c should be written as

$$M_c(c_2) = (c_2 M_1 + c_1 M_2) c_1 c_2. \quad (21.91)$$

Therefore, the nonlinear diffusion equation describing diffusion-controlled phase transformations is given as

$$\frac{\partial c_2}{\partial t} = \nabla \cdot \left[M_c(c_2) \nabla \frac{\delta G_{\text{sys}}}{\delta c_2} \right], \quad (21.92)$$

where the composition fluctuation term (i. e., the random noise term) is ignored.

This equation is a general form for the diffusion equation, and the Cahn–Hilliard equation [21.29] is also constructed from this equation. In the spinodal theory, the total free energy, G_{sys} , of the phase decomposed inhomogeneous microstructure is expressed as

$$\begin{aligned}G_{\text{sys}} &= \frac{1}{L} \int_x \left[g_c(c) + \eta^2 Y_{<hkl>} (c - c_0)^2 + \kappa \left(\frac{\partial c}{\partial x} \right)^2 \right] dx, \\ &\quad (21.93)\end{aligned}$$

where the one-dimensional system (the one-dimensional spatial direction is denoted by x with a total length L) is considered for simplicity, and c is a local solute composition of element B in an A–B binary alloy system. The quantities η , $Y_{<hkl>}$, and κ are the lattice mismatch, the function of the elastic constants, and the composition gradient energy coefficient, respectively. The first, second, and third terms in the integral at the right-hand side of (21.93) correspond to a chemical free energy, an elastic strain energy, and a composition gradient energy, respectively. If F is defined by the sum of these three terms and the variation principle is applied to F with

respect to the invariant variables c , x , and $(\partial c/\partial x)$, the variation $\delta G_{\text{sys}}/\delta c$ is given as

$$\begin{aligned}\frac{\delta G_{\text{sys}}}{\delta c} &= \frac{\partial F}{\partial c} - \frac{d}{dx} \left(\frac{\partial F}{\partial (\partial c/\partial x)} \right) \\ &= \frac{\partial g_c(c)}{\partial c} + 2\eta^2 Y_{\langle hkl \rangle} (c - c_0) - 2\kappa \left(\frac{\partial^2 c}{\partial x^2} \right),\end{aligned}\quad (21.94)$$

where the Euler equation is considered. $\delta G_{\text{sys}}/\delta c$ is commonly called as a diffusion potential. Substituting (21.94) into (21.92), we obtain the nonlinear diffusion equation:

$$\frac{\partial c}{\partial t} = \frac{\partial}{\partial x} \left[\tilde{D} \left(\frac{\partial c}{\partial x} \right) \right] - 2 \frac{\partial}{\partial x} \left[\tilde{K} \left(\frac{\partial^3 c}{\partial x^3} \right) \right], \quad (21.95)$$

where

$$\begin{aligned}\tilde{D} &\equiv M_c(c) \left(\frac{\partial^2 g_c(c)}{\partial c^2} + 2\eta^2 Y_{\langle hkl \rangle} \right), \\ \tilde{K} &\equiv M_c(c) \kappa.\end{aligned}\quad (21.96)$$

In many textbooks of spinodal decomposition, M_c is assumed to be a constant and \tilde{K} has been moved out beside the differentiation in the second term at the right-hand side in (21.95). The value \tilde{D} , defined by (21.96), is then the interdiffusion coefficient for the coherent phase decomposition.

In the practical viewpoint for the actual numerical simulation, it is effective to directly solve the equation

$$\frac{\partial c}{\partial t} = \frac{\partial}{\partial x} \left[M_c \left(\frac{\partial \mu_{\text{sys}}}{\partial x} \right) \right] \quad (21.97)$$

instead of (21.95). In order to solve (21.97), the diffusion potential $\mu_{\text{sys}} \equiv \delta G_{\text{sys}}/\delta c$ is first calculated as a function of local position x and time t , and then (21.97) is solved using a numerical simulation technique such as a finite difference method.

21.4.2 Spinodal Decomposition and Ostwald Ripening

Two-dimensional simulation of the spinodal decomposition in the Fe-40 at. % Mo alloy within bcc crystal structure during isothermal aging at 773 K is represented in Fig. 21.4 [21.14], where the Mo composition is indicated using grayscale, i. e., the black part corresponds to the Mo-rich region. The phase decomposition is clearly recognized to progress with aging. The lattice mismatch of the Fe–Mo alloy system is so large

Fig. 21.4 Two-dimensional simulation of the spinodal decomposition in the Fe-40 at. % Mo binary alloy with bcc crystal structure during isothermal aging at 773 K, where the Mo composition is indicated by grayscale, i. e., the black part corresponds to the Mo rich region. The lattice mismatch of the Fe–Mo alloy system is so large that a modulated structure, i. e., the microstructure with fine Mo-rich zones along the $\langle 100 \rangle$ directions, is produced by the mechanism of spinodal decomposition. Numerical values in the figure are the dimensionless aging time

Fig. 21.5 Three-dimensional phase field simulation for the spinodal decomposition of Fe-40 at. % Cr binary alloy at 773 K. The symbol t is a dimensionless normalized aging time. The precipitate phase is represented by an isocomposition surface of 40 at. % Cr

Fig. 21.6 Two-dimensional simulation of the spinodal decomposition of the ZrO_2 -8 mol % $\text{YO}_{1.5}$ partially stabilized zirconia at 1773 K. The calculation is performed on the two-dimensional plane of (110). The completely black and white regions indicate the composition of 16 mol % Y and 0 mol % Y, respectively. Numerical values in the figure are the aging time

that a modulated structure, i. e., the microstructure with fine Mo-rich zones along $\langle 100 \rangle$ directions, is produced by the mechanism of spinodal decomposition. Since the volume fraction of precipitates becomes higher, the encounter of precipitates happens so that the rod-shaped particles are temporarily produced in many places, as seen in Fig. 21.4d. However, with further aging particle-

splitting can be observed in Fig. 21.4f. This suggests that uniformity of particle size caused by elastic interactions becomes more energetically dominant than the usual particle coarsening controlled by the interfacial energy. Figure 21.4d–f clearly shows that the microstructure is self-regulated by the elastic interaction energy so as to produce a periodic microstructure with uniform particle size. The identical microstructures have experimentally been recognized in many real alloy systems such as Ni-base superalloys.

Figure 21.5 shows three-dimensional simulation of spinodal decomposition of Fe-40 at. % Cr alloy aged at 773 K. The precipitate is represented by an isocomposition surface of 40 at. % Cr. With aging, the fine microstructure coarsens according to the Ostwald ripening mechanism that is driven by the reduction of the interfacial energy.

Figure 21.6 demonstrates the two-dimensional simulation of the spinodal decomposition of the ZrO_2 -8 mol % $\text{YO}_{1.5}$ partially stabilized zirconia at 1773 K [21.42]. The calculation is performed on the two-dimensional plane of (110). The completely black and white regions indicate the composition of 16 mol % Y and 0 mol % Y, respectively. The orientation of the modulated microstructure is mainly controlled by elastic strain energy. Since the phase-field simulation is a continuum model, this simulation method is directly applicable for the phase transformation in ceramics and polymer materials.

21.5 Structural Phase Transformation

21.5.1 Martensitic Transformation

Figure 21.7 shows the simulation results of the cubic \rightarrow trigonal martensitic transformation in AuCd alloys calculated by Wang et al. [21.22]. For the cubic \rightarrow trigonal transformation, four lattice-correspondence variants are considered, i. e., four types of martensite orientation variants, with trigonal axes along the $[111]$, $[\bar{1}\bar{1}\bar{1}]$, $[\bar{1}\bar{1}1]$, and $[1\bar{1}\bar{1}]$ directions of the parent phase, are numbered 1, 2, 3, and 4, and are distinguished by shades of gray. The phase-field order parameter used in the simulation is the possibility of finding the trigonal martensite phase with variant i ($i = 1, 2, 3, 4$) at position \mathbf{r} and time t . The symbols τ and ζ indicate the reduced time and the ratio of the typical transformation strain energy to the chemical driving force, respectively.

The microstructures for $\zeta = 1$ and $\zeta = 5$ at $\tau = 30$ are presented in Fig. 21.7a and b, respectively. The effect of the contribution of elastic strain energy to the total free energy is demonstrated. Since the system with a higher value of ζ coarsens faster, Fig. 21.7a,b actually corresponds to the coarsening process of the domain structures. The microstructure is a herringbone type structure with coarsened domains. The schematic illustration of the arrangement of the domains in Fig. 21.7d is represented in Fig. 21.7c, which coincides with that observed in experiment of this alloy system [21.43].

21.5.2 Tweed-Like Structure and Twin Domain Formations

Figure 21.8 shows the calculated microstructure changes of the cubic (c) \rightarrow tetragonal (t) structural phase trans-

Fig. 21.7a–d Simulated three-dimensional microstructures in a single crystal computational volume faceted by the $\{100\}$ planes: (a) $\zeta = 1$ at $\tau = 30$; (b) $\zeta = 5$ at $\tau = 30$. (c) The schematic illustration of the herringbone structure shown in (d), where the numbers 1, 2, 3, and 4 represent the four types of variant domains [21.22]

formation in Ni_2MnGa during isothermal aging, where the final equilibrium state is a single t phase and the chemical driving force for $c \rightarrow t$ phase transition is assumed to be $\Delta G^{c \rightarrow t} = -40 \text{ J/mol}$ [21.44]. This driving force seems to be relatively small compared to that for the normal martensitic transformation, because we supposed the calculation condition of aging temperature to be just below the $c \rightarrow t$ phase transition temperature. This calculation is performed on the two-dimensional plane (001). The initial condition of the microstructure is a single c phase and the grayscale of the figure means the value of $s_1^2(\mathbf{r}, t)$, so the white part is t_1 phase (e.g., t phase with variant p is written as “ t_p phase”), and the black part corresponds to the t_2 phase. But only for Fig. 21.8a, cubic phase is also included in the black part. Numerical values in the figure are the dimensionless aging time (the time unit is described as s' not s).

At the initial stage of phase transformation, the tweed-like structure with $\langle 110 \rangle$ striation appears as shown in Fig. 21.8a,b. From Figs. 21.8c to e, t -phase domains grow gradually during aging, then a lamellar-shaped twin microstructure emerges (see Fig. 21.8e) and the straight twin domain with narrow width begins to

Fig. 21.8 Two-dimensional simulation result of the cubic \rightarrow tetragonal structural phase transformation in Ni_2MnGa during isothermal aging calculated on the two-dimensional plane of (001). The white part is the t_1 phase, e.g., the t phase with variant p is written as t_p phase, and black part corresponds to the t_2 phase ($\Delta G^{c \rightarrow t} = -40 \text{ J/mol}$). Numerical values in the figure are the dimensionless aging time

shrink by twin boundary motion (see Fig. 21.8f). The morphological changes of the microstructure are in very good agreement with the martensitic transformation induced by the weak first order structural phase transition that is observed, for instance, in the Fe-Pd system experimentally.

21.5.3 Twin Domain Growth under External Stress and Magnetic Field

Figure 21.9 shows the twin microstructure developments under external stress and magnetic fields [21.44]. The microstructure in Fig. 21.8f is employed as the initial condition for the simulation of Fig. 21.9, and the white and black parts in the figure correspond to the t_1 phase and t_2 phase, respectively. The microstructure changes from Figs. Fig. 21.9a to c demonstrate the twin domain growth with twin boundary motion under the condition of 1 MPa compressive applied stress along the vertical direction. It is recognized that the t_2 phase (black part) preferentially grows upwards. Because the c -axis of the unit cell for t_2 phase coincides with the direction along the y -axis (vertical direction) and the tetragonality of the t phase is less than unity, the compressive force makes the t_2 phase more stable. On the other hand, the microstructure changes under the external magnetic field along the x -axis (horizon-

Fig. 21.9a–f The twin microstructure developments under external stress and magnetic fields. The microstructure of Fig. 21.8f is employed as the initial condition for the simulation of Fig. 21.9, and the *white* and *black* parts in the figure correspond to t_1 phase and t_2 phase, respectively. ($\Delta G^{c \rightarrow t} = -40 \text{ J/mol}$). Numerical values in the figure are the dimensionless aging time

tal direction) without applied stress are demonstrated from Fig. 21.9c–f. In this case, the t_1 phase (white part) grows conversely. This is because t_1 phase has the c -axis, that is, the easy axis for magnetization, along the x -axis (horizontal direction), therefore, the magnetic energy of the t_1 phase is lower than that of t_2 phase.

21.6 Microstructure Evolution

21.6.1 Grain Growth and Recrystallization

In crystal grain growth dynamics, several phase-field models have been proposed with the first being proposed by *Chen and Yang* [21.16], in which the grains of different crystallographic orientations are represented by a set of nonconserved order parameter fields (multi-order parameter model). The temporal development of

the order parameter field is calculated by the Allen–Cahn equation [21.34].

On the other hand, an interesting phase-field model was recently proposed for studying the crystalline grain growth [21.17, 18]. It uses two order parameters to describe a polycrystal structure; one represents the crystalline order and the other indicates the value of the local orientation of the crystal. Whereas this model can also simulate grain rotation, which is absent from the multiorder parameter models, this order parameter is undefined in a disordered liquid state.

A typical example of the three-dimensional grain growth simulation by *Krill and Chen* [21.16] is shown in Fig. 21.10. It was obtained using a multiorder parameter free energy model with 25 order parameters. With increasing simulation time, the grains are eliminated by a mechanism of the grain boundary migration, and owing to the conservation of total volume, the average grain size increases steadily. The square of average grain size increases proportional to time, that is, expected for curvature-driven grain boundary migration.

Fig. 21.10a–d A typical grain evolution process obtained from a three-dimensional phase-field simulation of grain growth assuming isotropic grain boundary energy and isotropic boundary mobility [21.16]. The *white lines* show the grain boundary. With increasing simulation time from (a)–(d), the grains are eliminated by the mechanism of grain boundary migration and, owing to the conservation of total volume, the average grain size increases steadily

Fig. 21.11a,b Two-dimensional simulation of the recrystallization process. The microstructure changes of the upper and lower layer correspond to the case that the initial strain in the polycrystal is large and small, respectively. The *gray* parts are primary grain, and the *white* grains correspond to recrystallized ones. Numerical values in the figure are the dimensionless aging time

Figure 21.11 shows a two-dimensional simulation of the recrystallization process. The microstructure changes of upper and lower layer correspond to the case that the initial strain in the polycrystal is large and small, respectively. When the initial polycrystal is highly deformed, recrystallization frequently occurs in the place of grain growth, on the other hand, with less deformation, grain growth takes place sparsely.

21.6.2 Ferroelectric Domain Formation with a Dipole–Dipole Interaction

Figure 21.12 shows the temporal evolution of a dielectric domain structure without an external electric field. At the beginning of the evolution, a Gaussian random fluctuation was introduced to initiate the polarization evolution process. The shade regions imply the polarization domain and the orientation of polarization moment is indicated by the arrows in Fig. 21.12f. After $t = 4 \text{ s'}$ (the symbol s' means the dimensionless time unit), the polarization is still in the nucleation state. Figure 21.12b illustrates the polarization distribution after $t = 12 \text{ s'}$, where the 90° and 180° domain walls appear. Figure 21.12b–f demonstrate the temporal domain structure evolution, where the morphology of domain structure is changed by domain wall motion and the coarsening of domains is progressed.

Fig. 21.12a–f Temporal evolution of the domain structure development in dielectric materials without an external electric field. The *shaded* regions imply the polarization domain and the orientation of the polarization moment is indicated by *arrows* in (f). Numerical values in the figure are the dimensionless aging time

Figure 21.13a–f shows the temporal evolution of polarization switching when an external electric field is applied along the x -direction (rightward direction). Comparing Fig. 21.12 and Fig. 21.13 indicates that the applied electric field drives the domain walls to align their polarization moment along the applied field.

Fig. 21.13a–f Temporal evolution of the domain structure development in dielectric materials under external electric field in the x direction. Note that the applied electric field drives the domain walls to align their polarization moment along to the applied field. Numerical values in the figure are the dimensionless aging time

21.6.3 Modeling Complex Nanogranular Structure Formation

As a typical example of modeling complex microstructure evolution using the phase-field method, the FePt nanogranular microstructure formation during sputtering and the order–disorder phase transition of FePt nanoparticle in nanogranular thin films during subsequent annealing are demonstrated [21.45]. FePt nanogranular structure is well known as the candidate for the next generation of high-density recording media because of its large magnetocrystalline anisotropy. The simulation is performed on the nanostructure formation in FePt nanogranular thin film during sputtering and a subsequent phase transformation of FePt nanoparticles from A1 to L1₀ structure with isothermal aging.

Figure 21.14 shows the two-dimensional simulation result for the FePt nanogranular structure formation and

the ordering of FePt nanoparticles at 923 K [21.45]. The composition of the FePt phase is set at Fe-45 at. % Pt. The black and white regions with droplet shape are FePt nanoparticles, and the degree of white means the degree of L1₀ order. Therefore, a black particle is an FePt(A1) disordered phase, and a white particle is an FePt(L1₀) ordered phase. The matrix (gray part) is an amorphous alumina phase. Numerical values in the figure are normalized aging time.

At the initial stage (as-sputtered stage), as shown in Fig. 21.14a and b, the FePt phase takes a disordered state. With the aging progress, it is understood from Fig. 21.14c–e that ordering from A1 to L1₀ proceeds during coarsening of the FePt phase. It is noteworthy that the speed of ordering for a particle with small size seems to delay (see the left arrow in Fig. 21.14e). The antiphase boundary is also recognized in the FePt particle (see the right arrow in Fig. 21.14e). It is quite interesting that the degree of order decreases as the particle size becomes small (see the arrowed particle in Fig. 21.14g). This size dependence on ordering of FePt phase has already been observed experimentally by *Takahashi et al.* [21.46]. These microstructure changes agree well with features of FePt nanogranular structure formation experimentally observed.

We would like to emphasize that once the morphological shape of a microstructure is quantitatively obtained using phase-field modeling, it is possible to calculate magnetic properties such as a magnetic hysteresis based on the micromagnetics simulation [21.47, 48] using the calculated microstructure data as boundary conditions.

21.6.4 Dislocation Dynamics

A quite advanced phase-field modeling of the dislocation dynamics has been proposed by *Wang et al.* [21.26]. In order to describe a multidislocation system using a set of order parameters, they employed discontinuous relative displacements between the two lattice

Fig. 21.14a–h Two-dimensional simulation for the FePt nanogranular structure formation and the ordering of FePt (Fe-45 at. % Pt) nanoparticles at 923 K. The *black* and *white* regions with droplet shape are FePt nanoparticles, and the degree of white means the degree of L1₀ order. Therefore, a *black particle* is FePt(A1) disordered phase, and a *white particle* is FePt(L1₀) ordered phase, respectively. The matrix (*gray part*) is the amorphous-alumina phase. Numerical values in the figure are the dimensionless aging time

planes below and above the slip plane, measured in units of Burgers' vectors, as a phase-field order parameters. The temporal evolution of the order parameter fields is obtained by solving the governing equation for nonconserved order parameters. This model not only takes into account the stress-induced long-range interactions among individual dislocations but also automatically incorporates the effects of short-range interactions, such as multiplication and annihilation between dislocations.

Figure 21.15 shows a three-dimensional simulation of Frank–Read source calculated by Wang et al.. The periodic boundary condition is used and the rectangular shaped loop is introduced as the pinned source segments initially. In terms of inclusion formalism, a succession of dislocation generation through the Frank–Read mechanism should be interpreted as “sympathetic” nucleation of new thin lamellar inclusions.

Figure 21.16 shows an example from a phase-field simulation of plastic deformation of a model alloy under a uniaxial tensile stress imposed along vertical direction. The temporal dislocation generation during deformation was provided by randomly placed Frank–Read sources in the system. Figure 21.16a,b shows the dislocation microstructure at points a and b on the stress–strain curve. This model can be extended to the polycrystal and to systems where phase transformations and dislocation dynamics are simultaneously evolved.

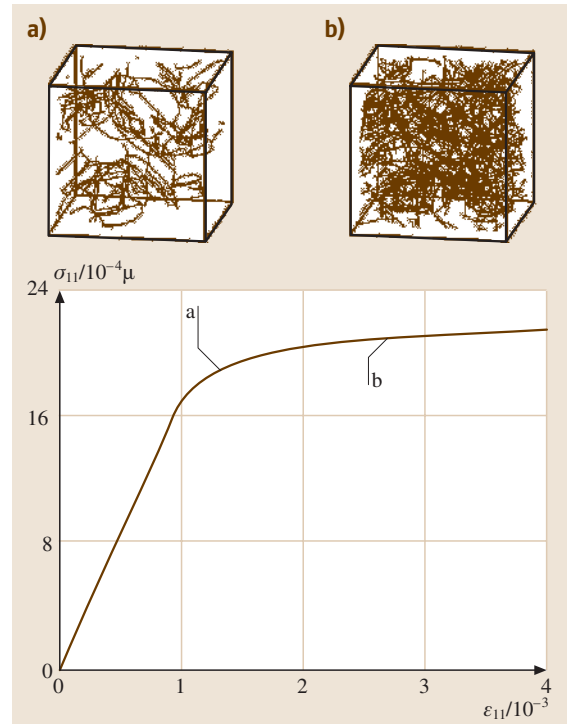

Fig. 21.16a,b The stress–strain curve obtained from a three-dimensional phase-field simulation of an *fcc* crystal under uniaxial loading [21.23]. The figures (a) and (b) show the dislocation microstructure at points a and b on the stress–strain curve

21.6.5 Crack Propagation

The phase-field simulation is also applicable to multicrock systems in polycrystalline materials if elastic isotropy is assumed [21.26]. In this case, the grain rotation does not change the components of the elastic modulus, and thus the polycrystal can be treated as an elastically homogeneous medium. However, the grain rotation in the polycrystal changes the crack propagation paths because it rotates the direction of permitted cleavage planes. Since the cleavage planes have different orientations in different grains, the crack picks up new energetically favored cleavage planes when it crosses the grain boundaries. The phase-field model explicitly takes into account this effect as well as the elastic coupling between cracks in different grains.

Figure 21.17 shows the phase-field simulation of crack propagation in a two-dimensional polycrystal calculated by Wang et al. [21.26]. The initial polycrystal is generated by the Voronoi tessellations under a peri-

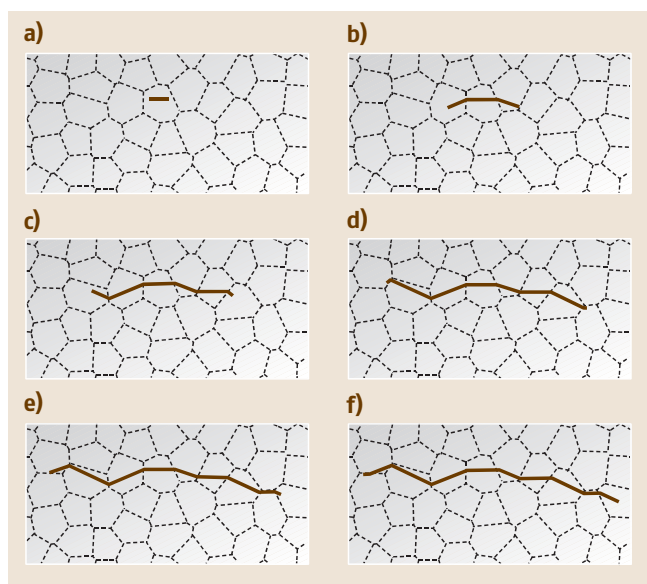

Fig. 21.17a–f Phase-field simulation of crack propagation in two-dimensional polycrystal. Under uniaxial stress in the y direction (vertical direction of the figure), the preexisting crack (a) starts to grow. When it crosses the grain boundary, the crack changes its original propagation path and picks up the energetically favored cleavage planes in the neighboring grains (b)–(f). The resultant meandering path is shown in (f) 21.26

(2) each point in the space belongs to the grain whose seed is the nearest to this point; and (3) a rotation angle is randomly assigned to each grain. The generated polycrystalline structure composed of 40 randomly oriented grains is shown as the dotted lines in Fig. 21.17. Two cleavage planes, (100) and (010), are assumed for each grain.

Uniaxial stress is applied to the polycrystal in the y direction (vertical direction), and as shown in Fig. 21.17a, a preexisting crack is introduced in one grain. The simulation results are shown in Fig. 21.17a–f. When the crack crosses through the grain boundary and enters the neighboring grain, the energetically favored cleavage plane is automatically picked up. This results in the meandering cleavage path, as shown in Fig. 21.17f.

odic boundary constraint. The simulation sequence is described briefly as follows: (1) 40 grain seeds are randomly positioned in the 512×256 computational cell;

Monte Carlo S

22. Monte Carlo Simulation

In the general overview on materials and their characteristics, outlined in chapter 3, it has been stated that *materials and their characteristics result from the processing of matter*. Thus, *condensed matter physics* is one of the fundamentals for the understanding of materials. The Monte Carlo Method, which is a powerful method in this respect, is presented in this final chapter of the Handbook's Part E on Modelling and Simulation Methods as follows:

First, the principles of this simulation technique are introduced

- Monte Carlo Method: the fundamentals
- Improved Monte Carlo algorithms
- Quantum Monte Carlo Method

Second, the application of the Monte Carlo Method is explained in considering selected areas of materials science:

- Electronic correlations: antiferromagnetism
- Perfect conductance of electricity: superconductivity
- Vortex states in condensed matter physics
- Quantum critical phenomena

22.1 Fundamentals of the Monte Carlo Method

In material science, we are always facing systems composed of a huge number of atoms or molecules, typically of order 10^{23} . Knowing the interactions among the particles, one can, in principle, predict the individual trajectories from a given initial configuration, specified by the positions and the velocities of the particles (for

quantum systems the initial wave functions), and thus know the destination of the system. However, even with the most advanced supercomputer, the system one can treat in this way is very much limited. On the other hand, in most cases, we are interested in the total, averaged behaviors of the system, such as density of gas

and magnetic polarization of a magnet, upon various external conditions such as temperature, pressure and magnetic field, instead of the detailed trajectories of individual particles. The statistical mechanics is such a disciplinary, which reveals simple rules governing systems of huge numbers of components. In many interesting cases, unfortunately, statistical mechanics cannot provide a final compact expression for the desired physical quantities because of the many-body effect of the interactions among components, although the bare interaction is two-body. Many approximate theories have been developed which make the field called condensed matter physics very rich. With the huge leaping of power of computers, the Monte Carlo approach based on the principle of statistical mechanics has been developed in the recent decades. This chapter is devoted to introducing the basic notions for the Monte Carlo method [22.1], with several examples of application.

22.1.1 Boltzmann Weight

According to the principle of statistical mechanics, the probability for a particular *microscopic* state appearing in an equilibrium system attached to a heat reservoir with temperature T is given by the Boltzmann weight

$$p_i = e^{-\beta E_i} / \sum_i e^{-\beta E_i} \equiv e^{-\beta E_i} / Z, \quad (22.1)$$

where $\beta = 1/k_B T$, E_i the energy of the system at the particular state, and Z the partition function. The expectation value of any physical quantity, such as the magnetic polarization of a magnet, can be evaluated by

$$\langle O \rangle = \frac{1}{Z} \sum_i O_i e^{-\beta E_i}. \quad (22.2)$$

The difficulty one meets in applications is: there are too many possible states such that it is practically unable to compute the partition function and the expectation values for desired physical quantities.

22.1.2 Monte Carlo Technique

The Monte Carlo techniques overcome this difficulty by choosing a subset of possible states, and approximate the expectation value of a physical quantity by the average within the subset of states of limited number. The way for picking up the subset of states can be specified by ourselves, and is very crucial to the accuracy of the estimation thus made. A successful Monte Carlo simulation thus relies heavily on the way of sampling.

Importance Sampling

One can regard the statistical expectation value as a time average over the states a system passes through the course of a measurement. This suggests that we can take a sample of the states of the system such that the possibility of any particular state being chosen is proportional to its Boltzmann weight. This importance sampling method is the simplest and most widely-used in Monte Carlo approaches. It is easy to see that the estimation for the desired expectation value is given simply by

$$\langle O \rangle_M = \sum_{i=1}^M O_i / M, \quad (22.3)$$

since the Boltzmann weight has been already involved into the process of sampling. This estimation is much more accurate than a simple sampling process, especially at low temperatures where the system spends the large portion of time in several states with low energies.

The implementation of the above importance sampling is achieved by Markov processes. A Markov process for Monte Carlo simulation generates a Markov chain of states: starting from the state a , it indicates a new one b , and upon inputting b it points the third one c , and so on. A certain number of the states at the head of these Markov chains are dropped, since they depend on initial state a . However, after running a sufficiently long time, the picked states should obey the Boltzmann distribution. This goal is guaranteed by the ergodicity property and the condition of detailed balance.

Ergodicity

This property requires that any state of the system can be reached via the Markov process from any other state supposing we run it sufficiently long. The importance of this condition is very clear since otherwise the missing states will have zero weight in our simulation which is not the case in reality. It is noticed that one still has room to set the *direct* transition probability from one state to many others to zero, as usually done in many algorithms.

Detailed Balance

This condition is slightly subtle and requires some consideration. For the desired distribution vector \mathbf{p} , with the components of the vector being the Boltzmann weight for each state, suppose we find an appropriate Markov process characterized by a set of transition probabilities among possible states such that

$$\sum_j p_i P(i \rightarrow j) = \sum_j p_j P(j \rightarrow i), \quad (22.4)$$

where p_i is the probability of the state i and $P(i \rightarrow j)$ the transition probability from i -state to j -state. The above condition is necessary since the desired distribution, namely the Boltzmann distribution, is the one for equilibrium state. However, the Markov process satisfying the above condition does not necessarily generate the desired distribution, even when the Markov chain is run long enough. Actually, it is possible that a dynamic limit cycle is realized as

$$\mathbf{p}'(t+n) = P^n \mathbf{p}'(t) \quad (22.5)$$

with $n > 1$, so that the desired distribution \mathbf{p} can never be reached. In order to avoid this situation, we set the detailed balance condition

$$p_i P(i \rightarrow j) = p_j P(j \rightarrow i). \quad (22.6)$$

It is easy to see that this condition eliminates the possibility of limit cycles. Then from the Perron-Frobenius theorem, it can be shown that the desired distribution \mathbf{p} is the only one that can be generated by the transition matrix P .

To be short, a Markov process satisfying the conditions (i) the ergodicity condition, (ii) $\sum_i P(i \rightarrow j) = 1$, and (iii)

$$P(i \rightarrow j)/P(j \rightarrow i) = p_j/p_i = e^{-\beta(E_j - E_i)}, \quad (22.7)$$

will generate the Boltzmann distribution at equilibrium.

Acceptance Ratio

There is still freedom when composing the transition probabilities. One can take a selection probability g and the acceptance ratio A such that

$$P(i \rightarrow j) = g(i \rightarrow j)A(i \rightarrow j). \quad (22.8)$$

For simplicity, one usually takes the constant selection probability for all possible states during the one-step transition. As for the acceptance ratio, we can take them as large as possible provided they satisfy the condition (22.7), which makes the Markov chain move more efficiently around the sampling space. It is easy to see that the acceptance ratio is given by

$$A(i \rightarrow j) = \begin{cases} e^{-\beta(E_j - E_i)}, & \text{for } E_j - E_i > 0; \\ 1, & \text{otherwise.} \end{cases} \quad (22.9)$$

This is the Metropolis algorithm [22.2].

With the selection probability and the acceptance ratio determined, a Monte Carlo simulation goes like the

following: from a given initial state we pick up a candidate for the next state out of the possible ones according to the selection probability; then we check if the candidate state is to be accepted according to the probability specified by the acceptance ratio. This routine is repeated for sufficiently long time before we insert a measurement step where we calculate physical quantities for the realized state.

It is then clear that the Markov chain of states thus generated is stochastic, which is the most important feature of the Monte Carlo techniques in comparison with other deterministic methods such as molecular dynamics. The rules which specify a particular simulation algorithm govern the distribution of the realized states when a large number of states are piled up.

22.1.3 Random Numbers

The stochastic property of Monte Carlo simulations comes in because one chooses a new state from the old one in a *random* fashion. This process is realized by random numbers. Therefore, generation of a sequence of random numbers is of crucial importance for accurate Monte Carlo simulations. Of course, as long as such a sequence is generated by a deterministic procedure written in a computer code, it cannot be really random. It is usually called *quasi* random provided it satisfies the following two conditions characteristic to *true* random numbers.

Condition I: The period of the quasi random numbers should be longer than the total length of simulations.

Condition II: The quasi random numbers should be k -dimensional equidistributed with large enough k . In other words, all possible sets consisting of k sequential numbers appear with the same frequency in a period, except the one of k zeros.

Classical Random Number Generators

The linear congruential sequence is given by

$$\mathbf{x}_{i+1} = a\mathbf{x}_i + b \mod 2^w, \quad i = 0, 1, \dots, \quad (22.10)$$

where w stands for the number of bits of random numbers \mathbf{x}_i , and a and b are suitable sets of numbers which maximizes the period of the quasi random numbers to 2^w . The merit of this sequence is its simplicity. However, it has several shortcomings. First, the period is not sufficiently long even with $w = 31$. Second, a random number is determined only by the previous one, and there exists strong correlation among sequential numbers. Third, the multiple operation is time consuming.

These shortcomings are overcome by the generalized feedback shift register (GFSR)

$$\mathbf{x}_{i+n} = \mathbf{x}_{i+m} \oplus \mathbf{x}_i, \quad i = 0, 1, \dots, \quad (22.11)$$

where \oplus denotes the exclusive-or logical operation. The two integers n and m are chosen so that $t^n + t^m + 1$ is an n -th order primitive polynomial of t . When the initial seeds x_0, x_1, \dots, x_{n-1} are prepared appropriately, the period of this sequence is $2^n - 1$. This period is due to the independence of each bit. Since each step only includes one logical operation, this algorithm is very fast. However, statistical properties of this family of random numbers is still not very satisfactory, as shown by large-scale Monte Carlo simulations of the two-dimensional Ising model [22.3] for which an exact solution is available.

Advanced Generators

In order to increase the period of the sequence of quasi random numbers, the twisted GFSR (TGFSR) has been introduced [22.4, 5]:

$$\mathbf{x}_{i+n} = \mathbf{x}_{i+m} \oplus \mathbf{x}_i A, \quad i = 0, 1, \dots, \quad (22.12)$$

where A is a $w \times w$ sparse matrix

$$A = \begin{pmatrix} 1 & & & & \\ & \ddots & & & \\ & & 1 & & \\ & & & 1 & \\ a_{w-1} & a_{w-2} & \cdots & a_1 & a_0 \end{pmatrix}. \quad (22.13)$$

Here a_{w-1}, \dots, a_0 take 1 or 0 so that $\varphi_A(t^n + t^m)$ is primitive with $\varphi_A(t)$ the characteristic polynomial of A . This operation mixes the information of all bits, and the period of each bit increases up to $2^{nw} - 1$. In order to accomplish the equidistribution property, tempering operations consisting of certain bitshift and bitmask logical operations are introduced in each step. Based on these two operations the so-called TT800 algorithm with $w = 32$, $n = 25$ and $m = 7$ exhibits the period $2^{800} - 1$ and 25-dimensional equidistribution.

A further improved generator known as the Mersenne Twister is proposed [22.6]:

$$\mathbf{x}_{i+n} = \mathbf{x}_{i+m} \oplus \left(\mathbf{x}_i^u | \mathbf{x}_{i+1}^l \right) A, \quad i = 0, 1, \dots, \quad (22.14)$$

where the matrix A is determined similarly to the TGFSR. The key point is to use the incomplete array, with $(\mathbf{x}_i^u | \mathbf{x}_{i+1}^l)$ standing for the operation to combine

the upper $(w-r)$ bits of \mathbf{x}_i and the lower r bits of \mathbf{x}_{i+1} . This operation drops the information of the lower r bits of \mathbf{x}_0 , and consequently the period is reduced from $2^{nw} - 1$ to $2^p - 1$, with $p = nw - r$. On the other hand, if the period can be chosen as a prime number, there exists an algorithm which evaluates the characteristic polynomial $\varphi_A(t)$ with $O(p^2)$ computations. Then, the period can be extended thanks to the r degrees of freedom. Taking $w = 32$, $n = 624$, $m = 397$ and $r = 31$ results in a Mersenne prime number $p = 19937$, namely the MT19937 algorithm has the period $2^{19937} - 1$ and 623-dimensional equidistribution. Owing to such an astronomical period and good statistical property on a rigorous mathematical basis, this algorithm is now becoming the standard quasi random number generator both in academic and commercial uses [22.7].

22.1.4 Finite-Size Effects

In the thermodynamic limit, many physical quantities diverge at the phase transition. Although all of them take finite values in a finite system, diverging properties can be evaluated from the scaling behavior of a series of finite-size systems.

First-order Phase Transition

In a first-order phase transition, divergence of physical quantities at the transition temperature is δ -function like in the thermodynamic limit. The size dependence of the divergent quantity and the transition temperature in finite systems should be

$$Q(L, T_c(L)) = Q_0 + C_1 L^d, \quad (22.15)$$

$$T_c(L) = T_c(\infty) + C'_1 L^{-d} + \dots, \quad (22.16)$$

Note that the constant term Q_0 is continuous from outside the transition regime, and thus is important physically as the divergent term.

Second-order phase transition

In a second-order phase transition, physical quantities diverge in a wide range around the critical temperature in the thermodynamic limit as

$$Q(T) \sim |T - T_c|^{-\varphi}, \quad (22.17)$$

where φ is the critical exponent of quantity Q . A typical example is the susceptibility of a ferromagnet. Correlations between order parameters develop in the following

Fig. 22.1 Schematic figure of non-equilibrium relaxation of order parameter from a fully polarized configuration for (a) $T > T_c$, (b) $T = T_c$ and (c) $T < T_c$

way

$$\langle m_i m_j \rangle - \langle m_i \rangle^2 \sim \frac{e^{-|i-j|/\xi}}{|i-j|^{d-2+\eta}}, \quad (22.18)$$

$$\xi \sim |T - T_c|^{-\nu}, \quad (22.19)$$

where m_i stands for the order parameter at position i , and ν and η are the critical exponents for the correlation length and critical correlation function. While the critical temperature T_c depends on details of systems such as lattice structures, the critical exponents are not changed by such details, a property known as the universality of critical phenomena.

In a finite system, phase transition is supposed to take place at the temperature where a correlated cluster becomes as large as the system size, namely $\xi \sim L$. Finite-size scaling theory claims that physical quantities around the critical temperature can be expressed as a function of L/ξ in the following fashion

$$Q(L, T) \sim L^{\varphi/\nu} f_{sc}[L^{1/\nu}(T - T_c)], \quad (22.20)$$

where $f_{sc}(x)$ is a scaling function.

Several statements can be derived from the finite-size scaling form (22.20): (1) At $T = T_c$, this form

is reduced to $Q(L, T_c) \sim L^{\varphi/\nu}$, which stands for the power-law size dependence at the critical temperature. (2) When $L^{-\varphi/\nu} Q(L, T)$ is plotted versus $L^{1/\nu}(T - T_c)$, the curves for different L should collapse to each other in the vicinity of T_c provided T_c , ν and φ are known. Alternatively, one can use this so-called finite-size scaling plot to evaluate the critical point and critical exponents.

22.1.5 Non-equilibrium Relaxation Method

As discussed above, measurement of physical quantities should be made after equilibration of the system. However, the relaxation process also contains valuable information of equilibrium state, such as the transition point and critical exponents. As an example, we consider the magnetic polarization of a ferromagnet, which presuming nonvanishing value only below the transition temperature as $m(T) \sim (T_c - T)^\beta$. If one starts from a fully polarized configuration, the order parameter m decays exponentially to zero as MC update proceeds for $T > T_c$; it converges to a finite value for $T < T_c$, as shown in Fig. 22.1. The dynamical scaling form [22.8,9] in the thermodynamic limit is given by

$$m(T; t) \sim t^{-\beta/(z\nu)} F_{sc}[t^{1/(z\nu)}(T - T_c)], \quad (22.21)$$

where z is the dynamical critical exponent. At $T = T_c$, (22.21) reduces to

$$m(T_c; t) \sim t^{-\beta/(z\nu)}. \quad (22.22)$$

Therefore, it is possible to evaluate the critical temperature T_c and a combination of critical exponents $\beta/(z\nu)$ [22.10–13]. Another combination of critical exponents $1/(z\nu)$ is evaluated from the “finite-time” scaling of eq.(22.21). Extensions to quantum systems [22.14–16] and Kosterlitz-Thouless [22.17] and first-order [22.18] phase transitions are possible.

22.2 Improved Algorithms

The conventional Monte Carlo algorithm explained above suffers from the problem of slow relaxation in cases such as nucleation process in first-order phase transitions, critical slowing down in the vicinity of second-order phase transitions, and complex free-energy landscape of random and/or frustrated systems. Several improved algorithms are proposed and shown to

be very efficient. Readers can refer to Ref. [22.19] for a well-written review.

22.2.1 Reweighting Algorithms

Suppose the number of states between E and $E + dE$ is given by $D(E)dE$ with the density of states (DOS)

$D(E)$, the probability for the system presuming energy E is $P(E, T) \sim D(E)e^{-\beta E}$, known as the canonical distribution. If the canonical distribution at a temperature β_0 is given, that at β is obtained by the reweighting formula [22.20]:

$$P(E; T) = \frac{e^{-(\beta-\beta_0)E} P(E; T_0)}{\int e^{-(\beta-\beta_0)\epsilon} P(\epsilon; T_0) d\epsilon}. \quad (22.23)$$

Since the histogram $P(E; T_0)$ has a sharp peak around the averaged energy of the system at T_0 , $P(E; T)$ can be evaluated from $P(E; T_0)$ with small enough statistical errors only if T is close enough to T_0 . This limitation can be overcome by taking data for several temperatures around the target one [22.21, 22].

The essential point of the histogram method is to notice that the probability distribution used in simulations can be different from that used for evaluating thermal averages of physical quantities, namely the Boltzmann distribution. In the multicanonical method [22.23, 24], the simulated probability distribution is taken as $P(E; T) \approx 1/E_0(T)$, where $E_0(T)$ stands for the range of the energy covered in simulations at temperature T . The reason that the multicanonical simulation works efficiently can be seen taking the example of a first-order phase transition. Since the canonical distribution has a sharp peak around the equilibrium energy, nucleation processes governed by the two free-energy minima with finite separation results in slow relaxation. This difficulty is overcome by the broad energy range covered by the multicanonical weight.

Since the DOS $D(E)$ is not known *a priori*, it should be evaluated in preliminary runs, and the approximate DOS $D_0(E; T)$ is utilized in simulations. The probability distribution

$$P_{MC}(E; T) = D_0^{-1}(E; T)D(E)/E_0(T) \quad (22.24)$$

does not have to be completely flat, and the reweighting formula is given by

$$P(E; T) = \frac{e^{-\beta E} D_0(E; T) P_{MC}(E; T)}{\int e^{-\beta\epsilon} D_0(\epsilon; T) P_{MC}(\epsilon; T) d\epsilon}. \quad (22.25)$$

From a practical point of view, construction of the flat histogram (or precise estimation of the DOS) is the crucial point of the multicanonical method, and various algorithms have been proposed [22.25–30] after the original one. In all these algorithms, the DOS is evaluated by accumulating the entry number of a random walk in the energy space. As the system size increases, the deviation of the DOS grows exponentially, and the

estimation within limited preliminary runs by simple accumulation becomes difficult.

In order to overcome this difficulty, a new algorithm [22.31, 32] was proposed based on a “biased” random walk in the energy space:

0. Set $i = 0$, $D(E) \equiv 1$ and $n = 1$.
1. Select a site at random and measure the initial energy E_b .
2. Choose a Monte Carlo move to the state with energy E_a by the transition probability $p(E_b \rightarrow E_a) = \min[D(E_b)/D(E_a), 1]$.
3. Update the DOS at the energy of the chosen state as $D(E) \rightarrow D(E)f_i$, with a modification factor $f_i > 1$.
4. If $n < N$, set $n \rightarrow n + 1$ and go to step 1.
5. If $n = N$, set $f_i \rightarrow f_{i+1}(< f_i)$, $i \rightarrow i + 1$, $n = 1$, rescale the DOS and go to step 1.
6. Continue this process until $f_i \rightarrow 1$.

The essential point of this algorithm is the introduction of the modification factor f_i . When f_0 and N are taken so that f_0^N is comparable to the total number of states, the deviation of the DOS is reproduced in the early stage of the iteration. Of course, $f_i > 1$ means that the detailed balance condition is not satisfied (in this sense this algorithm does not belong to Monte Carlo ones), and the DOS during the iteration has a systematic discrepancy from the equilibrium one. The true DOS is obtained at the final stage of the iteration, where $f_i = 1$ eventually holds.

The reweighting algorithm discussed above has a bonus that some physical quantities not available in conventional Monte Carlo algorithm can be treated by this method. For example, the energy dependence of the free-energy landscape can be evaluated [22.33, 34], which is suitable for the analysis of the first-order phase transition.

22.2.2 Cluster Algorithm and Extensions

In the vicinity of the critical temperature T_c of a second-order phase transition, the correlation time τ of a physical quantity Q defined in

$$\langle Q(t_0)Q(t_0+t) \rangle \sim e^{-t/\tau}, \quad (22.26)$$

diverges as $\tau \sim (T - T_c)^{-z\nu}$, where z is a dynamical critical exponent. The critical slowing down makes computer simulations around the critical point very time consuming. In order to overcome this difficulty, the cluster algorithm (Swendsen-Wang (SW) algorithm) was proposed [22.35].

Here we explain this algorithm using the Ising model,

$$-\beta\mathcal{H} = K \sum_{(i,j)} \sigma_i \sigma_j, \quad \sigma_i = \pm 1. \quad (22.27)$$

First, we consider the Hamiltonian $\mathcal{H}_{l,m}$ in which the interaction between sites l and m are removed. Then, we define the conditional partition functions $Z_{l,m}^P$ and $Z_{l,m}^{AP}$ for $\sigma_l \sigma_m = +1$ and -1 by

$$Z_{l,m}^P = \text{Tr}_\sigma e^{-\beta\mathcal{H}_{l,m}} \delta_{\sigma_l \sigma_m, 1}, \quad (22.28)$$

$$Z_{l,m}^{AP} = \text{Tr}_\sigma e^{-\beta\mathcal{H}_{l,m}} \delta_{\sigma_l \sigma_m, -1}. \quad (22.29)$$

The partition function is expressed as

$$Z = \text{Tr}_\sigma e^{-\beta\mathcal{H}} = e^K Z_{l,m}^P + e^{-K} Z_{l,m}^{AP}. \quad (22.30)$$

Using

$$Z_{l,m} = \text{Tr}_\sigma e^{-\beta\mathcal{H}_{l,m}} = Z_{l,m}^P + Z_{l,m}^{AP}, \quad (22.31)$$

we can rewrite (22.29) as

$$Z = e^K \left[(1 - e^{-2K}) Z_{l,m}^P + e^{-2K} Z_{l,m} \right]. \quad (22.32)$$

This expression can be interpreted as: “If the spins at sites l and m are parallel, create a bond with the probability $p = 1 - e^{-2K}$.” When this procedure is repeated for all nearest-neighbor pairs of spins, each spin is assigned to one of the clusters. The system is now mapped on a percolation problem with N_c clusters [22.36, 37]

$$Z = \text{Tr} p^b (1 - p)^n 2^{N_c}, \quad (22.33)$$

where b is the number of bonds and n is the number of interactions which do not form bonds, and the trace is taken for all possible configurations of clusters. In each Monte Carlo step, we assign a new Ising variable for each cluster independently. This nonlocal update using percolation clusters reduces significantly the relaxation time.

It was then proposed [22.38] that one can flip a single cluster in one step which is grown from a randomly chosen site. This process improves the efficiency of the SW cluster algorithm [22.39].

The algorithm discussed above can be applied to the Heisenberg model [22.38],

$$-\beta\mathcal{H} = K \sum_{\langle ij \rangle} \mathbf{S}_i \cdot \mathbf{S}_j, \quad \mathbf{S}_i^2 = 1, \quad (22.34)$$

using an operator $R(\mathbf{r})$ with respect to a randomly chosen unit vector \mathbf{r} in the spin space,

$$R(\mathbf{r})\mathbf{S} = \mathbf{S} - 2(\mathbf{S} \cdot \mathbf{r})\mathbf{r}, \quad (22.35)$$

and a spin cluster is formed in the procedure: “If the spins at sites l and m satisfies $M \equiv (\mathbf{S}_l \cdot \mathbf{r})(\mathbf{S}_m \cdot \mathbf{r}) > 0$, create a bond with the probability $p = 1 - e^{-2KM}$.” This rule is a natural extension of the SW algorithm in the Ising model (22.27), and \mathbf{r} is updated in each Monte Carlo step. A similar extension has been made to the six-vertex model [22.40]. Since this model is a classical counterpart of the quantum Heisenberg model, this extension enabled the cluster-update version of quantum Monte Carlo simulations, as will be discussed later.

Further developments of the cluster algorithm took place in connection with percolation theories. The invaded cluster algorithm [22.41, 42] which automatically tunes physical parameters to the critical point is a typical example. It turns out that a simple algorithm to tune the probability p directly until critical percolation is observed [22.43] works better.

Another important progress is the worm algorithm [22.44], which enables accelerated dynamics as fast as the cluster update within the local update. Although this algorithm is based on the closed-path configurations appearing in high-temperature expansions, it shares the fundamental concept with the cluster algorithm, namely Monte Carlo simulations in alternative representations of original systems. Since this algorithm exhibits its merits more clearly in quantum Monte Carlo simulations, it will be explained later in this chapter.

22.2.3 Hybrid Monte Carlo Method

As far as the ergodicity and detailed balance condition are satisfied, any kind of update process can be adopted in a certain Monte Carlo algorithm. Then, it is interesting to hybridize Monte Carlo and molecular dynamics (MD) simulations. Since MD process corresponds to a forced particle move on an equal-energy surface, it is expected to be effective in frustrated systems at low temperatures. An implementation in this direction is formulated for the Heisenberg spin glass model [22.45, 46]:

$$\mathcal{H} = \sum_{\langle ij \rangle} J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j, \quad \mathbf{S}_i^2 = 1, \quad (22.36)$$

with the equation of motion

$$\hbar \frac{d\mathbf{S}_i}{dt} = \mathbf{S}_i \times \mathbf{H}_i, \quad \mathbf{H}_i = \frac{\partial \mathcal{H}}{\partial \mathbf{S}_i} = \sum_j J_{ij} \mathbf{S}_j. \quad (22.37)$$

The MD treatment for all spins is inserted in each Monte Carlo step for certain time intervals.

22.2.4 Simulated Annealing and Extensions

In complex free-energy landscapes of random and/or frustrated systems as shown in Fig. 22.2, conventional Monte Carlo algorithms result in trapping to a metastable state. Applications of the multicanonical and cluster algorithms brought some progress but the results were not so satisfactory, since for example frustrations suppress the formation of large clusters. One therefore needs special treatments for this class of problems.

Fig. 22.2 Schematic figure of a complex free-energy landscape

Fig. 22.3 Deep valleys of the free-energy landscape at low temperatures (at the bottom) can be bypassed with high-temperature configurations (upper ones correspond to higher temperatures)

The simulated annealing [22.47] was originally proposed for optimization problems, namely searching the state which minimizes a cost function. The cost function can be taken as the energy of a physical system. One can then introduce an auxiliary *temperature*, and define a *free energy* at finite temperatures. The benefit is that one can then search the global energy minimum via some passes activated naturally by finite temperatures. The simulation is started from a high temperature, and the system is cooled down gradually.

Simulated Tempering

In the simulated tempering [22.48, 49] the inverse temperature β is treated as a dynamical variable, such that both the cooling and heating processes are implemented in the algorithm. The reason this algorithm works well is explained in Fig. 22.3. The probability distribution of the original system,

$$P(\mathbf{x}) = \frac{e^{-\beta \mathcal{H}(\mathbf{x})}}{Z(\beta)}, \quad Z(\beta) = \sum_{\mathbf{x}} e^{-\beta \mathcal{H}(\mathbf{x})}, \quad (22.38)$$

is extended to a larger parameter space of \mathbf{x} and $\{\beta_m\}$ ($m = 1, 2, \dots, M$) as

$$P(\mathbf{x}, \beta_m) = \frac{e^{-\beta_m \mathcal{H}(\mathbf{x})}}{Z(\beta_m)} \tilde{\pi}_m, \quad (22.39)$$

$$\tilde{\pi}_m \propto \exp[g_m + \log Z(\beta_m)], \quad \sum_m \tilde{\pi}_m = 1. \quad (22.40)$$

One choice of the function g_m is $g_m = -\log Z(\beta_m)$, which results in $\tilde{\pi}_m = 1/M$. That is, all β_m are visited equally.

Choosing several discrete inverse temperatures can make the simulation efficient, and the optimal number and distribution of $\{\beta_m\}$ are estimated as follows [22.49, 50]. First, the acceptance ratio of the flip between different temperatures is given by

$$\begin{aligned} & \exp[-(\beta_m \mathcal{H}(\mathbf{x}_m) - \beta_{m+1} \mathcal{H}(\mathbf{x}_{m+1}))] \\ & \approx \exp[-(\Delta\beta)^2 d \mathcal{H} / d\beta] \\ & = \exp[-(\Delta\beta)^2 NC / \beta_m^2], \end{aligned}$$

where N and C are the number of particles and the specific heat, respectively. In order to keep the acceptance ratio independent of the system size, $\Delta\beta \sim N^{-1/2}$ or $M \sim N^{1/2}$ should be satisfied. If C diverges at the critical temperature, one should take $M \sim N^{[1+\alpha/(d\nu)]/2}$, with the critical exponent α of C and the space dimension d .

Next, each β_m is determined iteratively in preliminary runs. A new set $\{\beta'_m\}$ is constructed from the old

set $\{\beta_m\}$ as

$$\beta'_1 = \beta_1, \quad (22.41)$$

$$\beta'_m = \beta'_{m-1} + (\beta_m - \beta_{m-1}) \frac{p_m}{c} \quad (m = 2, \dots, M), \quad (22.42)$$

$$c = \frac{1}{M-1} \sum_{m=2}^M p_m, \quad (22.43)$$

with $\beta_1 < \beta_2 < \dots < \beta_M$. The acceptance ratio p_m at β_m is also evaluated during preliminary runs. The above procedure arrives at equilibrium when all values of $\{p_m\}$ become equal, which is consistent with the initial choice of g_m .

Monte Carlo simulations are performed using the above sets of $\{\beta_m\}$ and $\{g_m\}$. Since g_m only depends on β_m , update without changing β_m is the same as the standard one, and the weight for update of β_m is proportional to $e^{-\beta_m \mathcal{H} + g_m}$. Measurements on physical quantities are made similarly to the conventional Monte Carlo algorithm at each β_m .

Exchange Monte Carlo

Instead of treating one system as in the simulated tempering, the exchange Monte Carlo method [22.50] takes M replicated systems at β_m ($m = 1, 2, \dots, M$), and exchanges the configurations between replicas of close temperatures. The optimal distribution of β_m is evaluated similarly to that in the simulated tempering as given in (22.41–22.43). Update in a replica is the same as the conventional one, and exchange of replicas at β_m and β_{m+1} is introduced by comparison of the weights $\exp[-\beta_m \mathcal{H}(\mathbf{x}_m) - \beta_{m+1} \mathcal{H}(\mathbf{x}_{m+1})]$ and $\exp[-\beta_m \mathcal{H}(\mathbf{x}_{m+1}) - \beta_{m+1} \mathcal{H}(\mathbf{x}_m)]$. This algorithm can be regarded as a parallelized version of the simulated tempering, and is often called parallel tempering.

This algorithm has several advantages compared with the simulated tempering. First, it is unnecessary to introduce the nontrivial function g_m . Since determination of g_m (or equivalently $Z(\beta_m)$) is complicated and time consuming, this property simplifies the coding and accelerates simulations. Second, existence of fixed sets of β_m throughout simulations is suitable for observing the replica overlap, which is important in the study of spin glasses. Third, this algorithm fits very well with parallel coding. Most calculations can be done independently in each replica (i.e., in each CPU), and only information on exchange rates and temperatures have to be sent to other CPUs.

22.2.5 Replica Monte Carlo

The replica Monte Carlo [22.51] implemented for spin glass models can be regarded as a mixture of the exchange Monte Carlo and the cluster algorithm. Consider the Ising spin glass model

$$\mathcal{H} = - \sum_{\langle ij \rangle} \beta J_{ij} \sigma_i \sigma_j, \quad (22.44)$$

and take M replicas. The pair Hamiltonian of two close temperatures is defined as (for simplicity, $m = 1$)

$$\mathcal{H}_{\text{pair}}(\sigma^1, \sigma^2) = - \sum_{\langle ij \rangle} \left(\beta^1 J_{ij} \sigma_i^1 \sigma_j^1 + \beta^2 J_{ij} \sigma_i^2 \sigma_j^2 \right). \quad (22.45)$$

Using a new Ising variable $\tau_i^{(m)} = \sigma_i^{(m)} \sigma_i^{(m+1)}$, (22.45) is written as

$$\mathcal{H}_{\text{pair}}(\sigma^1; \tau^1) = - \sum_{\langle ij \rangle} \left(\beta^1 + \beta^2 \tau_i^1 \tau_j^1 \right) J_{ij} \sigma_i^1 \sigma_j^1. \quad (22.46)$$

The pair Hamiltonian is divided into clusters within which $\tau_i^1 \tau_j^1 = +1$ is satisfied. When each cluster is represented by an effective Ising variable $\eta_a^{(m)}$ with the index a of clusters, the pair Hamiltonian is expressed as

$$\mathcal{H}_{\text{cl}}(\eta^1) = - \sum_{\langle a, b \rangle} k_{a, b} \eta_a^1 \eta_b^1, \quad (22.47)$$

$$k_{a, b} = (\beta^1 - \beta^2) \sum_{\langle i \in a, j \in b \rangle} J_{ij} \sigma_i^1 \sigma_j^1. \quad (22.48)$$

The cluster update is introduced as Monte Carlo flips of the variable η_a^1 starting from configurations with all-up η_a^1 spins.

After the cluster flip, original Ising variables are changed as $\sigma_i^{1,2} \leftarrow \eta_a^1 \sigma_i^{1,2}$ for $i \in a$, and conventional Monte Carlo flips are performed in each replica to assure the ergodicity.

In the representation (22.46), the exchange Monte Carlo corresponds to a simultaneous flip of all $\tau^1 = -1$ clusters. Although the present algorithm was proposed as early as the cluster algorithm itself and much earlier than the exchange Monte Carlo, it has not been used so popularly to date due to complex coding and limited applicability in comparison with the exchange Monte Carlo. However, a recent study [22.52] showed that in two dimensions this algorithm is much faster than the exchange Monte Carlo.

22.3 Quantum Monte Carlo Method

The quantum Monte Carlo method is a powerful method to investigate both finite- and zero-temperature properties of quantum systems. The results are exact within error bars. This method can be applied to large-size systems in any dimensions. However, it has a problem when applied to the systems with large frustrations or strong correlations. In such systems, almost half of samples have negative weights, and Monte Carlo simulations do not work well. Hence, readers had better take care in using the quantum Monte Carlo method for such systems. The negative-sign problem is explained in Sect. 22.3.8.

There are several types of quantum Monte Carlo algorithms. Depending on the model, the most suitable algorithm should be chosen: For spin systems without magnetic fields, the cluster algorithm is effective (Sect. 22.3.3). Under magnetic fields, the worm algorithm or the directed-loop algorithm is better (Sect. 22.3.5). The continuous-time algorithm makes simulations efficient (Sect. 22.3.4). For electron systems, the auxiliary-field algorithm is appropriate, especially for the Hubbard model (Sect. 22.3.6). To investigate the ground-state properties, projection methods are suitable (Sect. 22.3.7).

There are other Monte Carlo methods to investigate quantum systems. Here, we only consider the quantum Monte Carlo algorithms by which results converge to the exact value in principle. Hence, approximate methods like variational Monte Carlo methods or fixed-node approximations are beyond our scope.

22.3.1 Suzuki-Trotter Formalism

Quantum Monte Carlo simulations in d -dimensional systems are generally performed through mapping to the corresponding $(d+1)$ -dimensional classical systems.

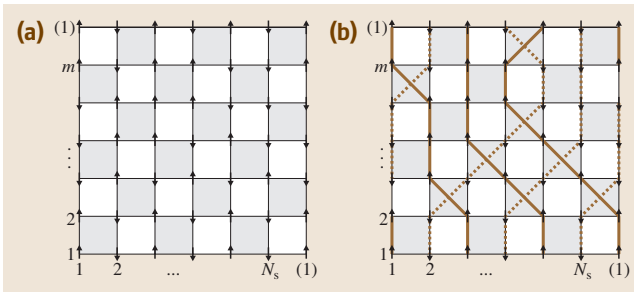

Fig. 22.4 (a) $(d+1)$ -dimensional space-time for N_s site quantum system. (b) World-line configuration. The vertical axis represents the Trotter axis, and m is the Trotter number

The Suzuki-Trotter transformation is the most typical procedure of this mapping using the Trotter formula. In order to explain the basics of quantum Monte Carlo methods, we review first the Suzuki-Trotter formalism [22.53].

The partition function of quantum systems is generally defined as

$$Z = \text{Tr} e^{-\beta \mathcal{H}}, \quad (22.49)$$

where β and \mathcal{H} are the inverse temperature and the Hamiltonian, respectively. Using the generalized Trotter formula, the exponential of quantum Hamiltonians can be decomposed into the product of exponentials in infinitesimal time-slices as

$$e^{\beta \mathcal{H}} = \lim_{n \rightarrow \infty} \left(\prod_i e^{-\Delta \tau \mathcal{H}_i} \right)^n, \quad (22.50)$$

where $\Delta \tau = \beta/n$, and \mathcal{H}_i is a local Hamiltonian that satisfies $\mathcal{H} = \sum_i \mathcal{H}_i$. Inserting complete sets between time slices, the partition function can be expressed in terms of local weights as

$$Z = \sum_A W(A), \quad W(A) = \prod_i w(a_i). \quad (22.51)$$

Here, A denotes a configuration such as shown in Fig. 22.4(a), and a is a local configuration on a plaquette. Their weights are represented by $W(A)$ and $w(a)$, respectively. Plaquette weights are defined on shaded plaquettes in Fig. 22.4(a).

In this way, the system is mapped onto a $(d+1)$ -dimensional classical system. This transformation is called the Suzuki-Trotter transformation [22.54, 55]. Quantum Monte Carlo simulations are performed through updates of configurations in the $(d+1)$ -dimensional space-time. For recent progress see Ref. [22.56, 57].

22.3.2 World-Line Approach

In order to explain how quantum Monte Carlo simulations are performed in the $(d+1)$ -dimensional space-time, we here review the world-line algorithm. As an example, we consider the spin-1/2 Heisenberg model, which is defined by the following Hamiltonian:

$$\mathcal{H} = J \sum_{\langle i, j \rangle} \mathbf{S}_i \cdot \mathbf{S}_j, \quad (22.52)$$

where the summation is taken over nearest-neighbor sites, and S_i denotes the spin operator at site i . All the possible local configurations and weights of plaquettes in a time-slice are listed in Table 22.1.

Up spins (or down spins) may be joined by lines as illustrated in Fig. 22.4(b). These lines are called world-lines [22.58]. In the world-line algorithm, world-line configurations are updated. One way to update them is the following: As illustrated in Fig. 22.5, we try to flip four spins (a, b, c, d), taking care so that the flip satisfies the conservation law of the model. The new world-line configuration is accepted with the probability

$$P = \frac{\rho'_1 \rho'_2 \rho'_3 \rho'_4}{\rho_1 \rho_2 \rho_3 \rho_4 + \rho'_1 \rho'_2 \rho'_3 \rho'_4}, \quad (22.53)$$

based on the heat-bath algorithm (or the Metropolis algorithm). In this way, world-lines are locally moved. This process is called a local flip. Since the ergodicity is not satisfied by this type of updates only [22.59], we need other types of flips. If up spins (or down spins) align in the imaginary time direction or in the diagonal directions, they can flip simultaneously. If up and down spins align alternately in the space direction, they can also flip simultaneously. These types of flips are called global flips [22.60]. Combining these two types of flips, world-line configurations are updated. Physical quantities such as magnetization, susceptibilities, energy and specific heat can be measured using spin configurations, local weights and their derivatives in the $(d+1)$ -dimensional space-time [22.61–63].

In the world-line algorithm, the width of the time slice is finite. Hence, the extrapolation $\Delta\tau \rightarrow 0$ is necessary after simulations. The error due to the finite $\Delta\tau$ is systematic: It is proportional to $\Delta\tau^2$ or $\Delta\tau^4$, etc., depending on the way of decomposition in (22.50) [22.64, 65]. In the continuous-time algorithm, the discreteness of the Trotter slice is removed by taking $\Delta\tau \rightarrow 0$ in the definition of local probabilities as will be discussed later.

22.3.3 Cluster Algorithm

Spin configurations in the $(d+1)$ -dimensional space-time can be updated more efficiently by using the cluster algorithm. For the cluster algorithm in quantum systems [22.35, 40], readers may refer to excellent overviews in Ref. [22.66, 67]. In the cluster algorithm, spin configurations as in Fig. 22.4(a) are mapped onto graphs [22.68, 69]. The weights $V(G)$ of graph G are

Table 22.1 Local configurations and their weights

a	$w(a)$

defined in order to satisfy the following relation:

$$W(A) = \sum_G V(G) \Delta(A, G), \quad (22.54)$$

where $\Delta(A, G)$ is one if spin configuration A is compatible with graph G , and otherwise zero. Similarly, it is possible to define the local version of (22.54) as

$$w(a) = \sum_g v(g) \delta(a, g). \quad (22.55)$$

For the Heisenberg model defined in (22.52), $\delta(a, g)$ is chosen as shown in Table 22.2.

The probability $P(g|a)$ of assigning graph g to configuration a is given by

$$P(g|a) = \frac{\delta(a, g)v(g)}{w(a)}. \quad (22.56)$$

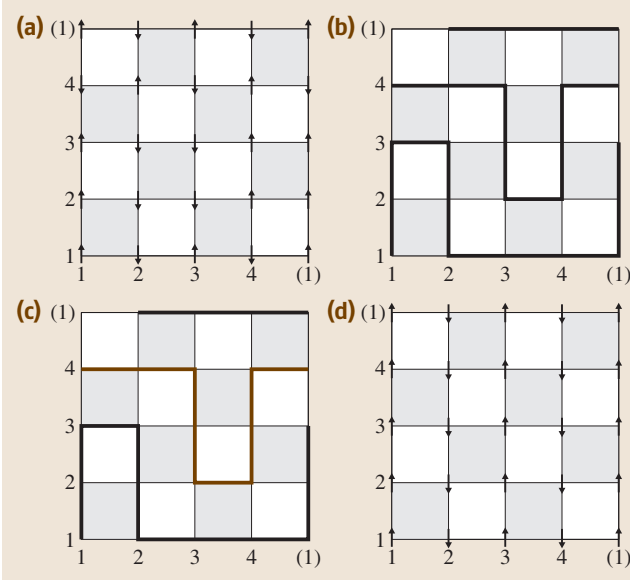

Fig. 22.6 Update of spin configurations through graph representation. See text for details

The updating procedure in the cluster algorithm is illustrated in Fig. 22.6: For a spin configuration (a), graphs are assigned as in (b) with probability given in (22.56), which results in clusters (or loops). The clusters are flipped with probability 1/2. If the graph shown in a red line in (c) is flipped, the spin configuration becomes as in (d). In the cluster algorithm, a large number of spins flip simultaneously. Hence, the auto-correlation time is greatly reduced compared with the world-line algorithm [22.40,70,71]. Also, it is easy to take the limit of $\Delta\tau \rightarrow 0$ [22.72]. For isotropic Heisenberg models and XXZ models with XY -anisotropy, clusters form loops. Hence, the cluster algorithm for these models are called the loop algorithm [22.40].

The cluster algorithm is also applied to the models with general spin S [22.73]. Since spin- S operators can

Table 22.3 Local configurations and their weights in the limit of $\Delta\tau \rightarrow 0$

a	$w(a)$
$\begin{pmatrix} \uparrow & \uparrow \\ \uparrow & \uparrow \end{pmatrix}, \begin{pmatrix} \downarrow & \downarrow \\ \downarrow & \downarrow \end{pmatrix}$	$1 - \frac{\Delta\tau J}{4}$
$\begin{pmatrix} \uparrow & \downarrow \\ \uparrow & \downarrow \end{pmatrix}, \begin{pmatrix} \downarrow & \uparrow \\ \downarrow & \uparrow \end{pmatrix}$	$1 + \frac{\Delta\tau J}{4}$
$\begin{pmatrix} \uparrow & \downarrow \\ \downarrow & \uparrow \end{pmatrix}, \begin{pmatrix} \downarrow & \uparrow \\ \uparrow & \downarrow \end{pmatrix}$	$-\frac{\Delta\tau J}{2}$

be represented by $2S$ spin-1/2 operators, simulations in the N_s -site system with spin S can be performed by mapping the system onto the $2SN_s$ -site system with spin-1/2 operators under the special boundary condition in the imaginary-time direction [22.74]. The boundary condition is set in order to project out the unphysical states with $S_i^2 < S(S+1)$.

Simulations under the magnetic field (H) can be performed by the cluster algorithm, replacing the flipping probability with

$$P_{\text{flip}} = \frac{e^{\beta H M_{\text{new}}}}{e^{\beta H M_{\text{new}}} + e^{\beta H M_{\text{old}}}}, \quad (22.57)$$

where M_{new} and M_{old} are the magnetizations of the cluster in the new and old configurations, respectively. We should be careful about the use of it in the low-temperature regime under high magnetic fields, because in such situations the flipping probability defined in (22.57) becomes exponentially small [22.75]. Hence, in this case, other algorithms such as the worm algorithm [22.76,77] or the directed-loop algorithm [22.78] are suitable.

22.3.4 Continuous-Time Algorithm

Based on the cluster algorithm, the limit of $\Delta\tau \rightarrow 0$ is taken [22.72]. The local weights in Table 22.1 become as in Table 22.3 in the limits of $\Delta\tau \rightarrow 0$. The probability of assigning graphs $P(g|a)$ is given in Table 22.4, using (22.56). The positions of new vertices are statistically determined in the continuous time. According to Table 22.4, the probability that a new vertex is created during the interval τ_L between antiparallel spins is $1 - e^{-\frac{\tau_L J}{2}}$. The procedure of the continuous-time loop algorithm is illustrated in Fig. 22.7: For a spin configuration (a), graphs are assigned as in (b) with probabilities given in Table 22.4. The loops are flipped with probability 1/2. If the graphs shown in red lines in (c) are flipped, the spin configuration becomes as in (d).

Table 22.4 Probability $P(g|a)$ of assigning graphs to configurations in the limit of $\Delta\tau \rightarrow 0$.

$\begin{matrix} \diagdown & g \\ a & \diagup \end{matrix}$	$ $	$=$
$\begin{pmatrix} \uparrow & \uparrow \\ \uparrow & \uparrow \end{pmatrix}, \begin{pmatrix} \downarrow & \downarrow \\ \downarrow & \downarrow \end{pmatrix}$	1	0
$\begin{pmatrix} \uparrow & \downarrow \\ \uparrow & \downarrow \end{pmatrix}, \begin{pmatrix} \downarrow & \uparrow \\ \downarrow & \uparrow \end{pmatrix}$	$1 - \frac{\Delta\tau J}{2}$	$\frac{\Delta\tau J}{2}$
$\begin{pmatrix} \uparrow & \downarrow \\ \downarrow & \uparrow \end{pmatrix}, \begin{pmatrix} \downarrow & \uparrow \\ \uparrow & \downarrow \end{pmatrix}$	0	1

Physical quantities are calculated in the same way as in the discrete-time loop algorithm. Since in the continuous-time algorithm, the limit of $\Delta\tau \rightarrow 0$ is already taken, it is unnecessary to extrapolate data to $\Delta\tau \rightarrow 0$. Another merit is that the memory cost is generally smaller than the discrete-time loop algorithm.

The stochastic series expansion (SSE) algorithm [22.79–81] is an alternative quantum Monte Carlo algorithm which does not depend on the Trotter formula and can produce exact results within error bars without extrapolations at finite temperatures. In the SSE algorithm, the partition function defined in (22.49) is expressed as

$$Z = \sum_{n=0}^{\infty} \frac{(-\beta)^n}{n!} \text{Tr} \mathcal{H}^n. \quad (22.58)$$

This expansion converges exponentially for $n \sim N_s \beta$. Here, a truncation at $n = L$ of this order is imposed. The number L is adjusted during equilibration so that the highest value of n appearing in the simulation does not exceed L . In this case, truncation errors become completely negligible. Using this L , the partition function is rewritten as

$$Z = \sum_{S_L} \frac{\beta^m (L-m)!}{L!} \text{Tr} \prod_{i=1}^L \mathcal{H}_{a_i, b_i}, \quad (22.59)$$

where S_L denotes a sequence of operator indices: $S_L = [a_1, b_1], [a_2, b_2], \dots, [a_L, b_L]$, with $a_i \in \{1, 2\}$ and $b_i \in \{1, \dots, M\}$ (M : the number of bonds), or $[a_i, b_i] = [0, 0]$. Here, $\mathcal{H}_{1,j}$ and $\mathcal{H}_{2,j}$ denote diagonal and off-diagonal parts of the local Hamiltonian on bond j , respectively. (A positive constant is added to $\mathcal{H}_{1,j}$ in order to make all matrix elements positive, if necessary.) The operator $\mathcal{H}_{0,0}$ is defined as the unit operator: $\mathcal{H}_{0,0} = 1$. The number of non-[0,0] elements in S_L is denoted by m . Simulations are performed in the $N_s L$ site system in the $(d+1)$ -dimensional space-time. Spin configurations are updated through updates of indices at vertices $[1,b] \leftrightarrow [0,0]$ or $[1,b_i][1,b_j] \leftrightarrow [2,b_i][2,b_j]$. The latter process is improved by the operator-loop update [22.82], which is naturally extended to the directed-loop algorithm [22.78].

22.3.5 Worm Algorithm

In the cluster algorithm, it is difficult to investigate properties in the low-temperature regime under high magnetic fields, because the flipping probability of clusters becomes exponentially small. This difficulty can be removed by taking the effects of magnetic fields

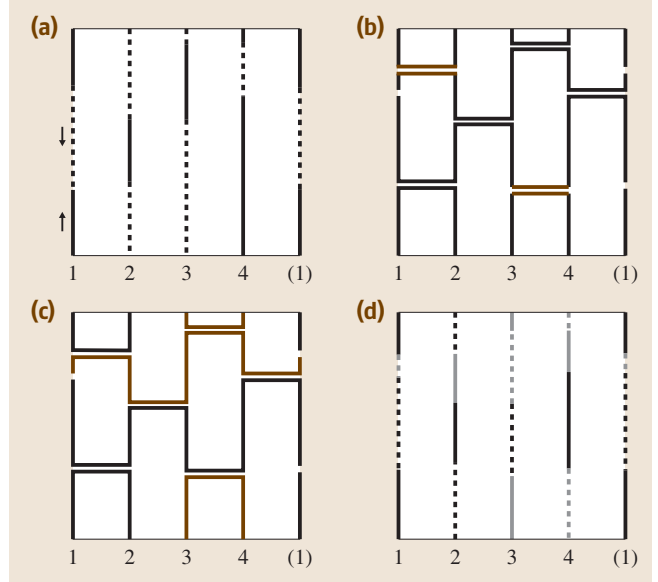

Fig. 22.7a–d Update of spin configurations through graph representation in the limit of $\Delta\tau \rightarrow 0$. In (a) and (d), up and down spins are represented by solid and dotted lines, respectively. In (b), new vertices are joined by red lines. See text for details

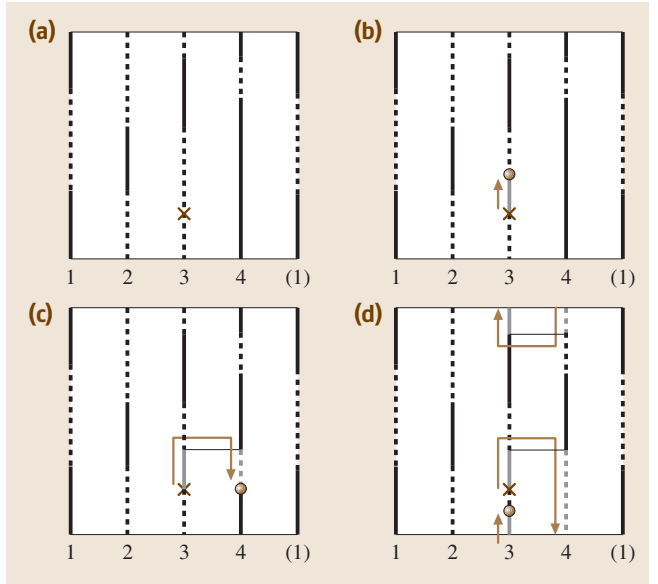

Fig. 22.8 Update of spin configurations by the directed-loop algorithm

into account in the process of loop formations, as in the worm algorithm [22.76, 77] and the directed-

loop algorithm [22.78]. The updating procedure of the directed-loop algorithm is illustrated in Fig. 22.8: A starting point is randomly chosen in the $(d+1)$ -dimensional space-time as in (a). From this starting point, the worm moves in one of the two directions as in (b). The worm can hop to another site stochastically as in (c). Reaching a vertex, the worm jumps to the other site as in (d) with the probability one. These motions are continued until the worm goes back to the starting point. (The worm may turn back at vertices, if probabilities are defined to allow such processes.) The trajectory of the worm forms a loop as in the loop algorithm. In the worm algorithm, two worms (or the head and tail of a worm) are created randomly at nearby times in the $(d+1)$ -dimensional space-time. Then, the worms move randomly until they meet again. The off-diagonal correlations like $\langle S^+ S^- \rangle$ can also be calculated by using the worms [22.76, 77].

22.3.6 Auxiliary Field Approach

The basic strategy of the auxiliary field quantum Monte Carlo algorithm is the following: Auxiliary fields are introduced in the path integral representation. Quantum (fermionic) degrees of freedom are integrated exactly, and the remaining degrees of freedom for (classical) auxiliary fields are integrated by Monte Carlo techniques. There is a powerful auxiliary field algorithm for the Hubbard model [22.83–86]. We consider the Hubbard model defined by the following Hamiltonian:

$$\mathcal{H} \equiv \mathcal{H}_t + \mathcal{H}_U, \quad (22.60)$$

$$\mathcal{H}_t \equiv -t \sum_{\langle i,j \rangle, \sigma} (c_{i\sigma}^\dagger c_{j\sigma} + c_{j\sigma}^\dagger c_{i\sigma}), \quad (22.61)$$

$$\mathcal{H}_U \equiv U \sum_i n_{i\uparrow} n_{i\downarrow}, \quad (22.62)$$

where $c_{i\sigma}$ and $n_{i\sigma}$ denote the annihilation operator and the number operator with spin σ at site i , respectively. The partition function defined in (22.49) can be decomposed as

$$\text{Tr} e^{-\beta \mathcal{H}} = \lim_{n \rightarrow \infty} \text{Tr} (e^{-\Delta \tau \mathcal{H}_t} e^{-\Delta \tau \mathcal{H}_U})^n, \quad (22.63)$$

where $\Delta \tau = \beta/n$. The exponential of the U -term can be expressed in terms of auxiliary fields s_i as [22.87]

$$e^{-\Delta \tau U n_{i\uparrow} n_{i\downarrow}} = \frac{1}{2} \sum_{s_i = \pm 1} e^{(2as_i - \frac{\Delta \tau U}{2})n_{i\uparrow}} \times e^{(-2as_i - \frac{\Delta \tau U}{2})n_{i\downarrow}}, \quad (22.64)$$

where $\cosh 2a = e^{\frac{\Delta \tau U}{2}}$. Since the U -term is decomposed into up- and down-spin parts as

$$e^{-\Delta \tau \mathcal{H}_U} = \frac{1}{2^{N_s}} \sum_{s_1, \dots, s_{N_s}} e^{-\Delta \tau \mathcal{H}_U^\uparrow(s_1, \dots, s_{N_s})} \times e^{-\Delta \tau \mathcal{H}_U^\downarrow(s_1, \dots, s_{N_s})}, \quad (22.65)$$

the partition function becomes

$$Z = \lim_{n \rightarrow \infty} \frac{1}{2^{N_s n}} \sum_{\{s\}} \text{Tr} \prod_{\sigma} \prod_{l=1}^n \left(e^{-\Delta \tau \mathcal{H}_t^\sigma} e^{-\Delta \tau \mathcal{H}_U^\sigma(\{s_l\})} \right) = \lim_{n \rightarrow \infty} \frac{1}{2^{N_s n}} \sum_{\{s\}} W^\uparrow(\{s\}) W^\downarrow(\{s\}), \quad (22.66)$$

where $\{s\} = s_{i,l}$ ($i = 1, \dots, N_s, l = 1, \dots, n$), $\{s_l\} = s_{i,l}$ ($i = 1, \dots, N_s$), and N_s denotes the number of sites. It should be noted that in this expression the interactions between up and down spins are removed in each auxiliary-field configuration. This reduces the problem to non-interacting fermions under local magnetic fields produced by auxiliary fields. It is easy to solve the non-interacting fermion problem. The effects of interactions are taken into account through Monte Carlo samplings for the auxiliary fields. By taking the trace over the fermionic degrees of freedom, the weight W^σ is obtained as

$$W^\sigma(\{s\}) = \det \left[I + \prod_{l=1}^n \left(e^{-\Delta \tau \mathcal{H}_t^\sigma} e^{-\Delta \tau \mathcal{H}_U^\sigma(\{s_l\})} \right) \right]. \quad (22.67)$$

Simulations are performed by updating auxiliary-field configurations in the $(d+1)$ -dimensional space-time.

The auxiliary-field Monte Carlo algorithm is also used to investigate ground-state properties, replacing the trace of the partition function in (22.49) by the expectation value of a trial state. This corresponds to a kind of projection method.

22.3.7 Projector Monte Carlo Method

The basic principle of the projection method is to extract the ground-state component by repeatedly applying the Hamiltonian many times to a trial state. In the process of multiplication of the Hamiltonian, configurations are generated by Monte Carlo techniques [22.88, 89]. Here, as an example, we take the Monte Carlo power method which is the simplest projection method.

Let us suppose that a trial state ($|\psi\rangle$) has finite overlap with the ground state ($|\phi_0\rangle$), i. e. $\langle\phi_0|\psi\rangle \neq 0$. Then, physical quantities in the ground state are evaluated as

$$\bar{O} = \lim_{p \rightarrow \infty} \bar{O}_p, \quad \bar{O}_p \equiv \frac{\langle\psi|\hat{\mathcal{H}}^p O \hat{\mathcal{H}}^p|\psi\rangle}{\langle\psi|\hat{\mathcal{H}}^{2p}|\psi\rangle}, \quad (22.68)$$

where $\hat{\mathcal{H}} \equiv \mathcal{H} - C$, and C is chosen such that $|E_0 - C| > |E_i - C|$. Here, E_0 is the ground-state energy, and E_i ($i = 1, 2, 3, \dots$) the energy of i -th excited state. In Monte Carlo simulations, the trial state is expanded in terms of the states which are used in Monte Carlo updates such as site representation as $|\psi\rangle = \sum_i a_i |i\rangle$. The denominator of \bar{O}_p is expressed as

$$\begin{aligned} \langle\psi|\hat{\mathcal{H}}^{2p}|\psi\rangle &= \sum_{i_0, i_1, \dots, i_{2p}} a_{i_{2p}}^* a_{i_0} \prod_{j=1}^{2p} \langle i_j | \hat{\mathcal{H}} | i_{j-1} \rangle \\ &= \sum_{i_0} |a_{i_0}|^2 \sum_{\text{path}} (WP)_{\text{path}}, \\ W &= \frac{a_{i_0}}{a_{i_{2p}}} \prod_{j=1}^{2p} \langle i_{j-1} | \hat{\mathcal{H}} | i_j \rangle, \\ P &= \prod_{j=1}^{2p} \frac{|a_{i_j}|^2}{|a_{i_{j-1}}|^2}. \end{aligned} \quad (22.69)$$

Similarly, the numerator of \bar{O}_p can also be expressed in terms of $|i\rangle$. Using Monte Carlo techniques, states are generated according to the distribution determined by $|a_{i_0}|^2$. From a configuration ($|i_0\rangle$), we choose one of the configurations which are reached by multiplying the Hamiltonian with probability $|a_{i_1}|^2/|a_{i_0}|^2$. This procedure is repeated $2p$ times to obtain the weight (W) of a path. \bar{O}_p is calculated as the ratio of $\langle\psi|\hat{\mathcal{H}}^p O \hat{\mathcal{H}}^p|\psi\rangle$ to $\langle\psi|\hat{\mathcal{H}}^{2p}|\psi\rangle$, which are approximately obtained as the average of weights over all paths produced by Monte Carlo samplings.

Monte Carlo updates for $|i_0\rangle$ are performed by the algorithm of the variational Monte Carlo method. In this sense, the Monte Carlo power method corresponds to the extension of the variational Monte Carlo method to make it possible to extract the ground-state component from the variational trial state. As is well known, the variational Monte Carlo method does not suffer from the negative-sign problem. However, the Monte Carlo power method does in general, because the weights W can be negative. If we use the trial state that has the same node structure with the ground state, the negative sign problem does not appear. If negative weights can be removed due to some special symmetry, the negative-sign problem can also be avoided. Improved algorithms

of the Monte Carlo power method have been proposed such as the power Lanczos method [22.90] which makes the convergence faster by adopting the principle of the Lanczos algorithm.

Here, we briefly review the ground-state version of the auxiliary-field quantum Monte Carlo algorithm. As a trial state, the state in the following form is used:

$$\begin{aligned} |\Phi\rangle &= |\Phi^\uparrow\rangle \otimes |\Phi^\downarrow\rangle, \\ |\Phi^\sigma\rangle &= \prod_{j=1}^M \left(\sum_{i=1}^{N_s} \Phi_{i,j}^\sigma c_{i,\sigma}^\dagger \right) |0\rangle, \end{aligned} \quad (22.70)$$

where M and N_s are the numbers of up- (or down-) spins and lattices, respectively. Using auxiliary fields, the expectation value of the exponentials of the Hamiltonian by the trial state is expressed as

$$\begin{aligned} \rho_n &= \langle\Phi| (e^{\Delta\tau\mathcal{H}})^n |\Phi\rangle \\ &= \sum_{\{s_1, \dots, s_n\}} W_\uparrow(\{s\}) W_\downarrow(\{s\}), \\ W_\sigma(\{s\}) &= \det \left[\Phi^\sigma \prod_{l=1}^n (U_\sigma^l(\{s_l\}) K^l) \Phi^\sigma \right], \end{aligned}$$

where U_σ^l is a diagonal matrix whose diagonal elements are $1/\sqrt{2} \exp(2as_{i,l}\sigma - (\Delta\tau U/2))/\sqrt{2}$, and $K^l = \exp(-\bar{K})$. Here, \bar{K} has non-zero matrix elements $-\Delta\tau t$ for (i, j) components, where i and j are the nearest neighbors. Updates for the auxiliary fields are performed in the same way as in the finite-temperature algorithm.

The stochastic reconfiguration method [22.91–93] is a projection method which is based on an extension [22.94,95] of the fixed-node approximation [22.96, 97]. In this method, configurations of walkers are rearranged so as not to increase negative weights under the condition that expectation values of some operators remain unchanged.

In principle, the ground state is obtained by projection methods through a large number of projection steps, if trial states have finite overlap with the ground state. However, special attention should be paid for the choice of trial states in practice. If the symmetry of the ground state is known, the trial state should be chosen to have the same symmetry as the ground state. Then, the simulations can be performed within the subspace of this symmetry, and the convergence becomes faster. Even though a trial state $|\phi_0\rangle$ has a lower energy than a state $|\phi_s\rangle$ which has the same symmetry as the ground state, the energy starting from $|\phi_s\rangle$ can become lower than that from $|\phi_0\rangle$ at finite projection steps. The symmetries of

the ground state that need to be taken into account commonly are, for example, the total spin $S = 0$ and total momentum $K = 0$. Such a trial state may be better than ordered states as an initial state of projection methods.

22.3.8 Negative-Sign Problem

In quantum Monte Carlo simulations, partial Boltzmann weights may be negative. Since the Markov process cannot be defined for negative weights, simulations are based on the absolute values of weights. The statistical average of a physical quantity is obtained by dividing the average of physical quantity with signs of weights by the average of signs. Generally, at low temperatures or in large systems, the average of signs becomes exponentially small, and its statistical error becomes exponentially large. This difficulty is called the negative-sign problem.

Here, we show a simple example that exhibits the negative-sign problem. We consider the Heisenberg model defined by (22.52) in a three-site cluster with the Trotter number three. There are three types of world-line configurations as shown in Fig. 22.9. Other world-line configurations can be obtained by inversion of spin directions or translations.

The weights of these configurations are

$$\begin{aligned} \text{a)} \quad & w \begin{pmatrix} \uparrow & \uparrow & \uparrow \\ \uparrow & \uparrow & \uparrow \end{pmatrix}^3, \\ \text{b)} \quad & w \begin{pmatrix} \downarrow & \uparrow & \uparrow \\ \downarrow & \uparrow & \uparrow \end{pmatrix} w \begin{pmatrix} \uparrow & \uparrow & \uparrow \\ \uparrow & \uparrow & \uparrow \end{pmatrix}^2 \text{ and} \end{aligned}$$

Fig. 22.9 World-line configurations for a three-site system

$$\text{c)} \quad w \begin{pmatrix} \uparrow & \downarrow \\ \downarrow & \uparrow \end{pmatrix}^3,$$

where local weights are defined in Table 22.1. Since $w \begin{pmatrix} \uparrow & \downarrow \\ \downarrow & \uparrow \end{pmatrix}$ is negative, the weight of (c) is negative. If we define the probability as in (22.53), the probability of (c) from (b) (or (b) from (c)) becomes negative. Thus, we decouple the weight W into the positive weight W' and the sign S as $W = W' \times S$. The probability is then redefined as $P = W'_{\text{new}} / (W'_{\text{new}} + W'_{\text{old}})$. The average of physical quantity Q is obtained as

$$\begin{aligned} \langle Q \rangle &= \frac{\sum_A W(A) Q(A)}{\sum_A W(A)} \\ &= \frac{\sum_A W'(A) S(A) Q(A)}{\sum_A W'(A) S(A)} \\ &= \frac{\sum_A W'(A) S(A) Q(A)}{\sum_A W'(A)} \\ &\quad / \frac{\sum_A W'(A) S(A)}{\sum_A W'(A)} \\ &= \frac{\langle SQ \rangle'}{\langle S \rangle'}, \end{aligned} \quad (22.71)$$

where $\langle \rangle'$ denotes the average with respect to W' . When the number of negative weights is as large as that of positive weights, $\langle S \rangle'$ becomes almost zero. Then, the statistical error becomes large. The negative sign problem is generally severe in the low-temperature regime.

Spin models without frustration do not suffer from the negative-sign problem, because all the weights can be chosen as positive by a gauge transformation. The Hubbard models on bipartite lattices with attractive interactions ($U < 0$) or those with repulsive interactions ($U > 0$) at half-filling do not have negative weights. One-dimensional electron systems with nearest-neighbor hopping also do not suffer from the negative-sign problem in general.

Even with frustrations or strong correlations, some models can be simulated without negative-sign problems by using special algorithms. For some frustrated Heisenberg chains, quantum Monte Carlo simulations can be performed free of negative-sign problems by the algorithm shown in Ref. [22.98]. In this algorithm, the representation basis is changed from the conventional S^z -basis to the dimer basis. Using this dimer basis, the system is described as a single chain where dimer units are connected with a single effective coupling. The

suppression of negative weights can be proved by a non-local unitary transformation with appropriate coupling constants.

Another algorithm which does not suffer from the negative-sign problem for strongly-correlated electron systems is shown in Ref. [22.99, 100]. This algorithm is based on a cluster algorithm and called the meron-cluster algorithm. The model considered here is the fermionic version of the spin-1/2 Heisenberg model without chemical potentials. For fermionic systems, there are two types of clusters, one changing their signs by a flip, and the other not. The former is called meron-clusters. Only the configurations without meron-clusters contribute to the average of the sign (Sign), since in the cluster algorithm without magnetic fields (which correspond to chemical potentials for fermionic systems), clusters flip independently with probability 1/2: Configurations with meron-clusters cancel signs by a flip $((+1-1)/2=0)$. For the calculation of susceptibilities $\chi = \langle O^2 \text{Sign} \rangle / \langle \text{Sign} \rangle$, only the configurations with zero or two meron-clusters contribute. Thus, updating configurations with the restriction that there are at most two meron-clusters, susceptibilities can be calculated with sufficient statistics.

22.3.9 Other Exact Methods

There are some methods which give exact results for large quantum systems in principle other than quan-

tum Monte Carlo methods. One is the high-temperature expansion method [22.101, 102]. In this method, the partition function is expanded in powers of the inverse temperature. Thus, this method gives exact results in the high-temperature limit and is applicable to any models in the thermodynamic limit. Properties in the low-temperature regime are investigated by extrapolating data using the Padé approximation.

The density-matrix renormalization group (DMRG) method also gives accurate results in large-size systems [22.103, 104]. In this method, the ground state is approximated by eigen states of the density matrix with large weights. The states are updated by adding or readjusting local sites. Hence, this method is effective for one-dimensional systems with open boundary conditions. This method has been extended to investigate finite-temperature properties [22.105–109].

In order to investigate electron systems without suffering from the negative-sign problem, the path-integral renormalization group (PIRG) method has been developed [22.110–112]. In this method, the ground state is approximated by a linear combination of non-orthogonal single-particle states in the form of (22.70). The states are selected so as to minimize the energy. Single-particle trial states are generated in the same way as in the auxiliary-field quantum Monte Carlo method. This method is applicable to the Hubbard models in any dimensions even with frustrations [22.113–115].

22.4 Bicritical Phenomena in O(5) Model

Several applications of the Monte Carlo techniques are reviewed in the remaining part of this chapter. The first one is for a classical O(5) model. The competition between antiferromagnetism (AF) and superconductivity (SC) is observed in high- T_c superconductors and several others including organic ones, where the effects of strong correlations among electrons are important. This feature has led to the SO(5) theory, where the U(1) symmetry of SC and SU(2) symmetry of AF is unified to a group of SO(5) [22.116, 117]. The SO(5) symmetry is achieved through the competition between the two orders at a bicritical point [22.118, 119] in the phase diagram. In general, however, the symmetry of a fixed point, or even its existence, depends on the dimensionality, the number of degrees of freedom, as well as biquadratic perturbations [22.120, 121]. In literature [22.122], the following picture for the stability of the multicritical point for 5 spin-components in three dimensions is

provided by the ϵ expansions of the renormalization group (RG) theory: for positively large, biquadratic AF-SC couplings, the normal(N)-AF and N-SC transitions switch from second to first order before the two critical lines touch because of thermal fluctuations, resulting in two tricritical points and a triple point in the phase diagram; the stable fixed point should be a decoupled, tetracritical point characterized by a negative biquadratic AF-SC coupling.

Our Monte Carlo (MC) simulations on the O(5) Hamiltonian in three dimensions [22.123, 124] indicate however that the bicritical point is stable as far as the biquadratic coupling is non-negative, and that for negative biquadratic couplings the biconical, tetracritical point takes the place, in contrast to the RG results. We have formulated a scaling theory on the order parameters, which provides a powerful tool for estimation of the bicritical point and the bicritical and crossover exponents.

22.4.1 Hamiltonian

The Hamiltonian is given by [22.123]

$$\mathcal{H} = - \sum_{\langle i,j \rangle} J_{ij}^{\text{AF}} \mathbf{s}_i \cdot \mathbf{s}_j - \sum_{\langle i,j \rangle} J_{ij}^{\text{SC}} \mathbf{t}_i \cdot \mathbf{t}_j + g \sum_i \mathbf{s}_i^2 + w \sum_i \mathbf{s}_i^2 \mathbf{t}_i^2, \quad (22.72)$$

on the simple cubic lattice. The couplings are limited to nearest neighbors. The vector $\mathbf{s}(\mathbf{t})$ of three(two) components is for the local AF(SC) order parameter, and $\mathbf{s}_i^2 + \mathbf{t}_i^2 = 1$. The Hamiltonian (22.72) is O(3) and O(2) symmetric with respect to the rotations in the two subspaces for \mathbf{s} and \mathbf{t} , respectively. The symmetries are broken spontaneously when temperature is below the corresponding critical points. The system enjoys a higher O(5) symmetry for $J_{ij}^{\text{AF}} = J_{ij}^{\text{SC}}$ and $g = w = 0$, while anisotropy in coupling constants breaks the O(5) symmetry. There are two other fields which break the symmetry: g field associated with the chemical potential of electrons and w field with the quantum effects of Gutzwiller projection of double occupancy of electrons [22.125, 126]. Higher-order terms are known to be irrelevant to critical phenomena and thus are omitted in our study.

In a typical MC simulation process, we generate a random configuration of superspins at a sufficiently high temperature, and then cool down the system gradually. The conventional Metropolis algorithm is adopted, with 50,000 MC steps for equilibration and 100,000 MC steps for statistics on each superspin at a given temperature. The system size for data shown here is $L^3 = 40^3$ with periodic boundary conditions. We have simulated up to $L^3 = 80^3$ and confirmed that finite-size effects do not change our results.

22.4.2 Phase Diagram

For the long-range order parameters of SC, we adopt the helicity modulus defined by

$$\Upsilon \equiv \lim_{\theta \rightarrow 0} \frac{F(\theta) - F(0)}{(\theta/L)^2 S}, \quad (22.73)$$

where the free energy $F(\theta)$ is for the system under a twist, for example, along x direction, $\varphi \rightarrow \varphi + \theta \times (1 - 2x/L)$ with $S = L^2$ for the cross section. For the long-range order parameter of AF, the staggered magnetization is used:

$$m = \frac{1}{N} \sqrt{\langle (\sum_i \mathbf{s}_i)^2 \rangle}. \quad (22.74)$$

Fig. 22.10 Temperature and g dependence of the helicity modulus for isotropic couplings and $w = 0$ [22.123, 124]

Fig. 22.11 Temperature and g dependence of the staggered magnetization for isotropic couplings and $w = 0$ [22.123, 124]

First we show the simulation results for the simplest case of $J_{ij}^{\text{AF}} = J_{ij}^{\text{SC}} (= J)$ and $w = 0$ in Figs. 22.10 and 22.11. The helicity modulus (staggered magnetization) is zero for $g < 0$ ($g > 0$).

Fig. 22.12 g - T phase diagram with a bicritical point for isotropic couplings and $w = 0$ [22.123, 124]

The phase diagram thus obtained is depicted in Fig. 22.12. The bicritical point is located at $[g_b, T_b] = [0, 0.845J/k_B]$, at which the two critical lines merge tangentially. We shall address the crossover phenomenon in Fig. 22.12 as $g \rightarrow 0$ later.

We have also turned on the anisotropy in the coupling constants: $J_c^{SC} = J/10$, namely the SC coupling along the c crystalline axis is 1/10 of other coupling constants, while keeping $w = 0$. The bicritical point is achieved at $[g_b, T_b] = [1.18J, 0.67J/k_B]$ [22.127]. It is interesting to observe that the O(5) symmetry broken by the coupling anisotropy is recovered by tuning the g field to the common tangent of the two critical lines starting from the bicritical point.

Next, we check the stability of the bicritical point upon introducing a positive w field. It is revealed that the Gutzwiller projection out of the double occupancy of electrons in high- T_c cuprates should result in a positive biquadratic AF-SC coupling [22.125, 126]. Without losing generality, let us set $w = 0.1J$ in Hamiltonian (22.72). For $g \geq 0.012J$ and $g \leq 0.010J$ we observe long-range SC and AF orders, respectively. At $g = 0.011J$ either AF or SC is realized depending on the initial random configuration and cooling process, same as at $g = g_b = 0$ for $w = 0$. No homogeneous coexistence between AF and SC can be observed, and all the phase transitions upon temperature reduction are

second order, and thus there is no fluctuation-induced first-order transition suggested by the RG ϵ expansions. The phase diagram for $w = 0.1J$ is the same as that in Fig. 22.12 for $w = 0$ except that the bicritical point shifts to $g_b = 0.011J$ [22.123].

We have increased the w field to $w = 0.5J$ supposing that it should result in stronger first-order N-AF and N-SC phase transitions in wider regimes, if any. Systems have also been enlarged up to $L^3 = 80^3$ in order to check possible finite-size effects. All we have observed are second-order N-AF and N-SC transition and a stable bicritical point.

For the negative biquadratic coupling $w = -0.1J$, we observe a biconical, tetracritical point at $g_t = -0.011J$ (of the same absolute value of g_b for $w = 0.1J$) as shown in Fig. 22.13. There is a region in the phase diagram where AF and SC coexist homogeneously.

22.4.3 Scaling Theory

For positively large enough g field, there is a sufficiently large temperature region above the SC critical line where AF fluctuations are irrelevant to the critical phenomenon. This critical region characterizing the O(2) symmetry breaking is, however, shrinking as g is reduced. This can be read from the temperature dependence of the helicity modulus in Fig. 22.10, and

Fig. 22.13 g - T phase diagram with a bicritical point for isotropic couplings and $w = -0.1J$ [22.123, 124]

Fig. 22.14 Scaling plot for estimation on the bicritical point and the ratio ν_5/ϕ according to (22.79) [22.123, 124]

can be understood easily, at least qualitatively, since in Hamiltonian (22.72) thermal fluctuations associated with the O(5) symmetry become more important as g decreases. Similar behaviors are observed for the Néel order parameter for $g < 0$.

In order to analyze the crossover phenomenon quantitatively, we develop the scaling theory for order parameters below the critical lines (see [22.128] for the scaling theory for the response functions above the critical lines):

$$\Upsilon(T; g) \simeq A g^{\nu_5/\phi} \times f\left((T/T_b - 1)/g^{1/\phi}\right), \quad (22.75)$$

with ν_5 for the bicritical singularity of $n = 5$ and ϕ the crossover exponent. For simplicity, we consider here the case of $g_b = 0$, noticing that extension to cases $g_b \neq 0$ is straightforward. The scaling function $f(x)$ should have the following properties:

$$f(x) \simeq \begin{cases} (-x)^{\nu_5}, & \text{as } x \rightarrow -\infty; \\ (B_2 - x)^{\nu_2}, & \text{as } x \rightarrow B_2 \end{cases}, \quad (22.76)$$

with B_2 defined by

$$B_2 g^{1/\phi} = T_c(g)/T_b - 1, \quad (22.77)$$

Fig. 22.15 Scaling plot for the data on helicity modulus in Fig. 22.10 according to (22.75) [22.123, 124]

which describes the SC critical line. With the properties (22.76), we can arrive at

$$\Upsilon(T; g) \simeq \begin{cases} A \times (1 - T/T_b)^{\nu_5}, & \text{for } g = 0; \\ A \times (1 - T/T_c(g))^{\nu_2}, & \text{for } g > 0. \end{cases} \quad (22.78)$$

This formulation of the bicritical scaling theory permits us to evaluate the bicritical and crossover exponents as well as the bicritical point in high precisions from the MC simulation results.

From the scaling ansatz (22.75), one should have

$$\Upsilon(T_b; \eta g)/\Upsilon(T_b; g) = \eta^{\nu_5/\phi}. \quad (22.79)$$

In order to fully utilize this relation, we plot in Fig. 22.14 the g and temperature dependence of $\Upsilon(T_b; \eta g)/\Upsilon(T_b; g)$ for $\eta = 1/2$. The two curves should cross at the point $[T_b, \eta^{\nu_5/\phi}]$ according to (22.79). Therefore, we estimate $T_b \simeq 0.8458 \pm 0.0005 J/k_B$ and $\nu_5/\phi \simeq 0.525 \pm 0.002$. Each point in Fig. 22.14 is obtained by 3 million MC steps on each superspin.

The crossover exponent ϕ can be evaluated from the slope $\kappa[\eta; g]$ of $\Upsilon(T; \eta g)/\Upsilon(T; g)$ with respect to temperature at the bicritical point T_b in Fig. 22.14:

$$\phi = \ln(g_2/g_1)/\ln(\kappa[\eta; g_1]/\kappa[\eta; g_2]). \quad (22.80)$$

In this way, we have $\phi = 1.387 \pm 0.030$ with the error bar estimated from those of the slopes. Finally, we arrive at $\nu_5 = 0.728 \pm 0.018$.

Fig. 22.16 Zoom in of Fig. 22.15 around the origin [22.123, 124]

With the estimates on the bicritical point and the bicritical, crossover exponents, we can plot the data in Fig. 22.10 in the scaled way described in (22.75). The result is depicted in Figs. 22.15 and 22.16, where we have $A \simeq 1.0$ and $B_2 \simeq 1/4$. The singularity at $x = B_2$ can be fitted very well by the critical exponent for the pure XY

model of O(2) symmetry $v_2 \simeq 0.67$ as in (22.78). To the best of our knowledge, the scaling theory for bicritical phenomena is verified in such a precise way for the first time.

The scaling analysis for the AF order parameters for $g < 0$ can be performed in the same way. Beside the critical exponents we have obtained the coefficient $B_3 \simeq 1/6$ which describes the critical line of AF order:

$$B_3(-g)^{1/\phi} = T_N(g)/T_b - 1. \quad (22.81)$$

The ratio $B_2/B_3 = 3/2$ is given by the inverse ratio of the two degrees of freedom and should be a universal constant for the competition between two orders of two and three components such as in the high- T_c superconductivity.

Since the helicity modulus is related to the London penetration depth $\Upsilon \sim 1/\lambda^2$, the scaling theory is expected to be useful for analyzing experimental results. Another interesting issue for the AF-SC competition is the magnetic-field effect. When we apply an external magnetic field, the long-range SC order is achieved in the form of the Abrikosov flux-line lattice. The N-SC transition becomes first order accompanied by the melting of flux-line lattice. Because the strong thermal fluctuations in the SC sector, the N-AF transition becomes first order nearby the AF-SC phase boundary. There is a tricritical point on the N-AF phase boundary where the N-AF transition is switched back to second order [22.129].

22.5 Superconductivity Vortex State

Superconductivity is one of the most fascinating physical phenomena, because of its perfect conductance of electricity. Its prominent character is however the peculiar magnetic property, namely the diamagnetism known as the Meissner effect. A deeply related phenomenon is the quantization of magnetic flux by superconductivity. There are two kinds of superconductors, type I and II. The superconductivity in type I samples is broken discontinuously by increasing magnetic field to a critical value. For type II superconductors, according to the mean-field theory by Abrikosov [22.130, 131], who shared the Nobel Prize of Physics in 2003 with Ginzburg and Leggett, there exist two critical magnetic fields: at the lower critical field H_{c1} quantized fluxes start to penetrate into the sample and form a triangular lattice of flux lines; at the upper critical field H_{c2} superconductivity is suppressed because of the overlapping of flux cores.

Both the translation and rotation symmetry associated with the spatial distribution of flux lines and the local U(1) gauge symmetry are broken at the upper critical field H_{c2} . In the mean-field theory, this phase transition is *second order*.

Although the theory by Abrikosov is ground breaking, thermal fluctuations are not treated sufficiently. The discovery of high- T_c superconductivity in cuprates makes the thermal-fluctuation regime accessible. A first-order melting of the flux-line lattice was proposed based on transport measurements, in which resistance drops discontinuously. Later on, experiments on thermodynamic quantities, such as magnetization and the specific heat, revealed clearly the first-order nature of the phase transition. For review articles, see Refs. [22.132–134].

A theoretical understanding toward the phase transition in vortex states beyond mean-field theory is not

easy. It is shown by the ϵ expansions of renormalization group (RG) that the superconductivity to normal phase transition should be *first order*, up to the lowest order of ϵ [22.135]. This result is natural since the melting of the flux-line lattice is understood to be similar to most other melting phenomena in reality ($d = 3$). However, the upper critical dimension for the superconductivity vortex state is $d_u = 6$, above which mean-field theory is correct, since thermal fluctuations in the two dimensions perpendicular to the magnetic field are cut off by the vortex spacing and thus cannot contribute to the long-range order, noticing $d_u = 4$ for superconductivity without magnetic field. The treatment on RG flows is therefore quite hard using quantities only to the lowest order of $\epsilon = d_u - d = 3$. As a matter of fact, the conclusion on the first-order melting transition of vortex lattice from RG was challenged by others.

22.5.1 Model Hamiltonian

This situation motivated many computer simulation works. As the melting temperature is much lower than $T_{c2}(B)$, where the Meissner effect sets on, it is a reasonable approximation to neglect fluctuations in the amplitude of the complex order parameter when the melting transition is concerned. In addition, the high- T_c superconductors are extremely type-II, in which the penetration length of magnetic field is much larger than the correlation length. This permits one to take the magnetic induction uniform and equal to the applied magnetic field.

With these two approximations we can derive the following three-dimensional frustrated XY model [22.136, 137] from the Ginzburg-Landau (GL) Lawrence-Doniach (LD) free-energy functional for layered superconductors [22.138, 139]:

$$H = - \sum_{\langle i, j \rangle} J_{ij} \cos(\varphi_i - \varphi_j - \frac{2\pi}{\phi_0} \int_i^j \mathbf{A} \cdot d\mathbf{r}). \quad (22.82)$$

Namely, the main effects of thermal fluctuations come from the phase degrees of freedom of superconductivity order parameter, which are defined on the simple cubic lattice in simulation. The couplings are limited to nearest neighbors and $J_{ij} = J$ with $J = \phi_0^2 d / 16\pi^3 \lambda_{ab}^2$ for links $\langle ij \rangle$ parallel to the superconducting layer while $J_{ij} = J/\Gamma^2$ for the perpendicular. The lattice constant along the c direction is the separation between neighboring CuO_2 layers d , while the lattice constant in the ab planes λ_{ab} can be taken in a range satisfying

$\xi_{ab} \ll \lambda_{ab} \ll \lambda_{ab}$. Then the anisotropy parameter should be given by the relation $\Gamma \lambda_{ab} = \gamma d$ if one wants to simulate a superconductor with anisotropy parameter $\gamma = \lambda_c / \lambda_{ab}$.

For magnetic fields parallel to the c axis, one can set $A_z = 0$. The strength of the magnetic field is given in a dimensionless way $f \equiv B l_{ab}^2 / \phi_0$. Vortices are figured out, including vorticity n , by counting the gauge invariant phase differences around any plaquette

$$\sum_{\langle i, j \rangle} [\varphi_i - \varphi_j - A_{ij}] = 2\pi(n - f). \quad (22.83)$$

In the ground state, the areal density of vortices should be equal to f .

In the above model, we assume a finite amplitude of *local* superconductivity order parameter on each site, which gives the coupling strength. At high temperatures, the phases fluctuate significantly and thus a coarse grain to any length scales larger than that given initially in the model will result in a vanishing amplitude of superconductivity order parameter. As for the long-range order of superconductivity, one needs to investigate the coherence of the phase degrees of freedom in the present system. The helicity modulus proportional to the rigidity of the system under an imposed phase twist as in (22.75) should be taken as the true *long-range* superconductivity order parameter.

22.5.2 First Order Melting

Here we present some of our results published in [22.140–142], with simulation techniques developed partially in early studies [22.143]. Similar results are reported by other groups [22.144–146]. For the convenience of simulation, we take $\Gamma = \sqrt{10}$ when modeling the moderately anisotropic high- T_c superconductor $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ of $\gamma = 8$. The magnetic field is $f = 1/25$. The system size is $L_{ab} \times L_{ab} \times L_c = 50 \times 50 \times 40$, where $N_v = 100$ vortices induced by the external magnetic field are contained in each ab plane. Periodic boundary conditions (PBCs) are set in all the directions. The conventional Metropolis algorithm is adopted. The number of MC sweeps at each temperature is 50,000 for equilibration and 100,000 for sampling. Around the transition temperature, we have simulated up to several million MC sweeps.

The Specific Heat

In Fig. 22.17 we display the temperature dependence of the specific heat per vortex line per length d evaluated

Fig. 22.17 Temperature dependence of the specific heat per vortex line per length d

via the fluctuation-dissipation theorem:

$$C = (\langle H^2 \rangle - \langle H \rangle^2) / k_B T^2. \quad (22.84)$$

A sharp spike is observed in the specific heat around the temperature $T_m \simeq 0.567 J/k_B$. Quantitatively, the specific heat is $C_+ \simeq 18.5 k_B$ just above T_m , $C_{\max} \simeq 23 k_B$ right on T_m , and $C_- \simeq 17.5 k_B$ just below T_m in a narrow regime of temperature.

Figure 22.18 displays the variation of the internal energy around the transition temperature T_m . A kink-like anomaly takes place, and from the two straight lines in Fig. 22.18 the latent heat is estimated as $Q \simeq 0.07 k_B T_m$ per flux per layer. The data on the specific heat and the latent heat indicate very clearly that a first-order phase transition occurs at T_m .

According to the finite-size scaling theory for a first-order phase transition [22.1], one has

$$C^{\max} = \frac{Q^2}{4k_B T_m^2} L_{ab}^2 L_c f + \frac{C_+ + C_-}{2}, \quad (22.85)$$

$$\Delta T = \frac{2k_B T_m^2}{Q L_{ab}^2 L_c f}, \quad (22.86)$$

providing that the system is already large enough such that the estimate of the latent heat in the way described in Fig. 22.18 is accurate enough. It has been checked that

Fig. 22.18 Temperature dependence of the internal energy per vortex line per length d

Fig. 22.19 Structure factors for vortex lattice at low temperature (left) and vortex liquid at high temperatures (right)

our data satisfy these two relations very well. Therefore, we can say that the present simulation results are statistically and thermodynamically correct.

Structure Factor

The correlation functions of vortices can be described by a structure factor defined by

$$S(\mathbf{q}_{ab}, z) = \frac{1}{N_v} \int_{-\infty}^{\infty} \frac{dq_c}{2\pi} e^{iq_c z} \langle n(\mathbf{q}) n(-\mathbf{q}) \rangle, \quad (22.87)$$

where $n(\mathbf{q}) = \sum_{\mathbf{r}} n(\mathbf{r}) \exp(-i\mathbf{q} \cdot \mathbf{r})$ and $n(\mathbf{r})$ is the vorticity in the c direction (i. e., along the magnetic field) at position \mathbf{r} . Two typical structure factors $S(\mathbf{q}_{ab}, z=0)$ for the in-plane correlation functions of vortices are de-

picted in Fig. 22.19. It becomes clear that the first-order phase transition is a melting transition of the vortex lattice of hexagonal symmetry into the isotropic vortex liquid.

Helicity modulus

The temperature dependence of the helicity modulus along the c axis

$$\begin{aligned} \Upsilon_c = & \frac{1}{L_{ab}^2 L_c} \left\langle \sum_{(i,j)} J_{ij} \cos(\varphi_i - \varphi_j) (\hat{e}_{ij} \cdot \hat{c})^2 \right\rangle \\ & - \frac{1}{k_B T L_{ab}^2 L_c} \left\langle \left[\sum_{(i,j)} J_{ij} \sin(\varphi_i - \varphi_j) (\hat{e}_{ij} \cdot \hat{c}) \right]^2 \right\rangle \\ & + \frac{1}{k_B T L_{ab}^2 L_c} \left\langle \sum_{(i,j)} J_{ij} \sin(\varphi_i - \varphi_j) (\hat{e}_{ij} \cdot \hat{c}) \right\rangle^2, \end{aligned} \quad (22.88)$$

is presented in Fig. 22.20. It increases from zero to a finite value $\Upsilon_c(T_m) \simeq 0.6 J/\Gamma^2$ in a narrow temperature region around T_m as the system is cooled down. Therefore, the phase transition at T_m is the normal to superconducting phase transition. The sharp onset of Υ_c is another indication of first-order transition. The helicity modulus in the ab plane remains zero even below the transition temperature T_m . Therefore, the system is superconducting only along the c axis even below T_m .

Fig. 22.20 Temperature dependence of the helicity modulus and the correlation length

The correlation length of phase variables along the c direction increases with cooling and reaches to $\xi_{\varphi,c} \simeq 10d$ at the melting temperature. We notice that our system size is $L_c = 40$ in units of d , and is therefore sufficient for simulating the true phase transition of the vortex system of the given parameters. If a smaller system of $L_c \leq 20$ was taken, the system would behave as if a long-range SC order had established at a temperature above the melting point, where the structure factor evolves from that of the liquid into the lattice. Then one would be led to two phase transitions, instead of the true single one.

Phase Diagram

By tuning the magnetic field, or equivalently the anisotropy parameter, we have mapped out the B - T phase diagram of the pancake vortices as shown in Fig. 22.21. The decreasing melting temperature with increasing magnetic field is consistent with the Clausius-Clapeyron relation

$$\Delta B = -4\pi \Delta s / (dB_m/dT), \quad (22.89)$$

where Δs is the entropy jump of unit volume. Taking into account the temperature dependence of the penetration depth, and thus that of the coupling strength in our model, we can [22.142] compare our numerical results with experiments. The agreement is quite satisfactory as in Table 22.5.

The hump in the specific heat at $T_v \simeq 1.1 J/k_B$ is produced by a huge number of thermal excitations of vortices in the form of closed loops. Even *local* superconductivity order parameters cannot survive at any

Fig. 22.21 B - T phase diagram [22.142]

Table 22.5 Comparison between our simulation results and experimental observations for $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$. ΔS denotes the entropy jump per flux line per length d

B=8 Tesla	T_m [K]	ΔS [k_B]	ΔB [G]
simulation	81	0.55	0.19
experiment	79	0.4	0.25

scale larger than the grid, which indicates $T_v = T_{c2}$. Therefore, treating thermal fluctuations successfully makes the mean-field phase transition at H_{c2} a crossover.

22.5.3 Continuous Melting: $B \parallel ab$ Plane

When the external magnetic field is applied parallel to the CuO_2 layers of a high- T_c superconductor, magnetic induction tends to penetrate the sample through the positions where superconductivity concentration is lower, namely the so-called block layers. Because of the Josephson couplings, magnetic induction is still quantized, the so-called interlayer Josephson vortices. A Josephson vortex is of a large size along the ab plane and squeezed in the c direction. The inter-vortex repulsion in this geometry is highly anisotropic, and meanwhile vortex lines feel strong layer pinning for motions along the c axis. In spite of much effort, which certainly makes the vortex physics very

rich [22.148–158], a unified picture for possible phases, phase transitions and phase diagrams is still not yet available. We have performed extensive Monte Carlo simulations of the frustrated XY model (22.82). The main prediction from computer simulation [22.147, 159] (see also [22.160, 161]) is that there is a multicritical point in the B - T phase. For magnetic fields above the critical value, there is an intermediate phase characterized by intraplane (2D) quasi-long-range crystalline order of vortex lines in between the liquid and the 3D lattice.

The model Hamiltonian is given in (22.82) with a gauge $A_{xy} = 0$. We take Γ as the anisotropy constant $\gamma = 8$ of the material $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$. The unit length of our grid is then d for all the three directions. For the convenience of simulation, we choose $f = 1/32$ and put the system size as $L_x = 384$, $L_y = 200$ and $L_z = 20$ with $N_v = 240$ flux lines in the system.

The Specific Heat

The specific heat is displayed in Fig. 22.22. There are sharp spikes in the specific heat for $\gamma = 8$ and 9 at $T_m \simeq 0.96 J/k_B$, which indicates a first-order melting. As the total latent heats are very small, we plot in Fig. 22.23 the expectation values for the cosine function of the gauge invariant phase difference between neighboring layers, which is proportional to the Josephson energy. There

Fig. 22.22 Temperature dependence of the specific heat for several anisotropy parameters [22.147]. Data for $\gamma = 8$ and 9 are shifted by constants

Fig. 22.23 Temperature dependence of the Josephson energy for several anisotropy parameters [22.147]. Data for $\gamma = 8$ and 9 are shifted by constants

Fig. 22.24 Structure factors for Josephson vortices $S(k_x, k_c, y=0)$ at $T = 0.65 J/k_B$ (left) and $T = 0.70 J/k_B$ (right). The panels are for wave numbers within $k_x \in [-25\pi/192d, 25\pi/192d]$ (horizontal) and $k_c \in [-2\pi/d, 2\pi/d]$ (vertical) [22.159]

are discontinuous jumps in this quantity for $\gamma = 8$ and 9, corresponding to the spikes in the specific heat.

However, the first-order melting transition is suppressed when the anisotropy parameter is increased to $\gamma = 10$, for which the spike in the specific heat and the discontinuous jump in the Josephson energy disappear as in Fig. 22.22 and Fig. 22.23. It is discussed in Ref. [22.147] that there is a critical value of $f\gamma$ above which the intralayer repulsion force becomes significantly stronger than the interlayer one, such that the intralayer order establishes first upon cooling. For a more careful discussion please refer to our original paper [22.159]. It is easy to see that this critical mag-

netic field should be above the following value when the anisotropy parameter γ is given (see also [22.153]):

$$B = \frac{1}{2\sqrt{3}\gamma d^2}. \quad (22.90)$$

To determine the value of the critical magnetic field demands a lot of simulation time, and has actually not yet been done. Nevertheless, the above relation seems to give a reasonable estimate for moderately anisotropic superconductors such as $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$.

Structure Factor

The above scenario has been verified by checking the vortex correlation function. In Fig. 22.24, we present the structure factors for $f = 1/32$ and $\gamma = 20$. For $T = 0.65 J/k_B$ there is a 3D long-range crystalline order characterized by the δ -function Bragg peaks; for $T = 0.7 J/k_B$ the Bragg spots smear out significantly in the k_c direction, corresponding to short-range correlation in the c direction.

The k_x profile for the Bragg spot at $(k_x, k_c) = (\pm 2f\pi/d, \pm\pi/d)$ is plotted in Fig. 22.25 for several temperatures, from which we found that the real-space correlation functions show power-law decay with exponents $1 \leq \eta \leq 2$. The cusp singularity in the k_x profiles is suppressed at $T \simeq 0.96 J/k_B$ where $\eta \simeq 1.97$. The suppression of the quasi long-range order upon

Fig. 22.25 k_x profiles for the Bragg spots [22.159]

Fig. 22.26 Temperature dependence of intensity of Bragg peaks [22.159]

heating should be a Kosterlitz-Thouless (KT) transition [22.159].

The temperature dependence of the intensity of Bragg peaks is displayed in Fig. 22.26 in such a fashion that for quasi long-range orders the intensity should be zero at the thermodynamics limit. As our system is finite, small values of normalized intensity can be seen for $\gamma = 20$ which increases very slowly with decreasing temperature in the region $0.7J/k_B \leq T \leq 0.95J/k_B$. Across $T_x \simeq 0.65J/k_B$ where the Bragg spots become δ -function like, the intensity increases noticeably. The onset of 3D long-range order is revealed as a second-order phase transition in the 3D XY universality class. In a sharp contrast, the intensity of Bragg peaks for $\gamma = 8$ increases very sharply with decreasing temperature as soon as they become observable at the melting point $T_m \simeq 0.96J/k_B$ as shown in Fig. 22.26.

22.6 Effects of Randomness in Vortex States

It is highly nontrivial whether the vortex lattice can survive when defects are introduced into the system. The answer depends on the dimensions of the space and the type of defects. In the elastic theory, the Hamiltonian of vortex states including point-like randomness is given by

$$\mathcal{H} = \frac{c}{2} \int [\nabla u(x)]^2 d^d x - \int V(x) \rho(x) d^d x, \quad (22.91)$$

where the first term stands for the simplified elastic energy associated with deviations of flux lines $u(x)$ from their equilibrium positions, and $V(x)$ and $\rho(x)$ denote the random potential and the density of flux lines, respectively. Larkin [22.163, 164] proposed an approximation to replace the second term by

$$\int V(x) \rho(x) d^d x \approx \int f(x) u(x) d^d x, \quad (22.92)$$

where $f(x)$ is the Gaussian random force.

Then, the situation becomes similar to Imry-Ma's argument [22.165] for the random-field model. Let us compare the energy between a polycrystal containing domains of the linear size $\sim L$ with the perfect vortex lattice. The elastic energy loss and the pinning energy gain are proportional to L^{d-2} and $L^{d/2}$, respectively. Since the second term is larger than the first one for large enough L in $d < 4$, the vortex lattice is unstable for infinitesimal randomness in $d < 4$. This simple consideration turns out to be insufficient and the picture

Right now experimental verifications of the multicritical point and the KT phase are carried on by several groups. For an estimate, we foresee the critical field at $H \sim 50$ Tesla for $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ of $\gamma = 8$ and $H \sim 2$ Tesla for $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\gamma}$ of $\gamma = 150$.

Since it is still not easy to simulate the vortex states of low vortex density, namely small magnetic field, the total phase diagram is not available merely by the computer simulation. Recently, using the density functional theory, we [22.162] find in certain magnetic field regimes below that given by (22.90) a smectic phase [22.154, 155], characterized by long-range correlation along the c axis and short-range correlations in the ab plane, that may exist in between the lattice and liquid phases. The melting is then two-step: first-order lattice-smectic and second-order smectic-liquid transitions.

of a Bragg glass is now established where the vortex correlations become quasi long ranged [22.166–170].

22.6.1 Point-Like Defects

Here our Monte Carlo simulations based on the frustrated XY model are reviewed. Modeling of point-like randomness is not unique in the frustrated XY model. One possible way is to introduce a Gaussian random variable ϵ_{ij} with $\langle \epsilon_{ij} \rangle = 0$ and $\langle \epsilon_{ij}^2 \rangle = 1$ as $J_{ij} = J + p\epsilon_{ij}$ [22.171]. In this definition, randomness is included in every bond, and the strength of randomness p can be treated as a continuous thermodynamic variable like temperature. On the other hand, the pinning force of these randomly-modulated interactions to vortices may be very weak.

We introduced [22.172] point defects as the plaquettes which consist of four weaker couplings and are randomly distributed in the xy plane with probability p . Couplings are given by $J_{ij} = (1 - \epsilon)J$ ($0 < \epsilon < 1$) on the point defects, and $J_{ij} = J$ elsewhere. This formulation of point defects is schematically drawn in Fig. 22.27. As will be seen later, most phases observed experimentally in vortex states are reproduced by this modeling.

Bragg Glass

Monte Carlo simulations are performed for $f = 1/25$, $\Gamma = 20$, $p = 0.003$, and various pinning strengths ϵ with the system size $L_x = L_y = 50$ and $L_c = 40$. The

Fig. 22.27 Modeling for point-like defects [22.172]

Fig. 22.28 ϵ - T phase diagram of vortex states with the point defects [22.172, 173]

Fig. 22.29 Modeling for columnar defects [22.174]

same algorithm for the clean system discussed previously is adopted. The $\epsilon - T$ phase diagram is displayed in Fig. 22.28.

The first-order melting transition between the Bragg glass (BrG) and vortex liquid (VL) phases is similar to

that of the vortex lattice and VL phases in pure systems as shown previously. As the strength of point-like defects ϵ increases, the melting temperature T_m decreases, which shows a sharp contrast to the case with columnar defects as will be discussed later.

The Bragg glass is destroyed when the pinning force becomes large enough even though temperature is low, and thus thermal fluctuations are not significant. This *randomness-induced* melting was first observed numerically in the random-field XY model [22.175] and the Lawrence-Doniach model [22.176]. The first-order nature of this phase transition is clarified in more detail by precise numerical studies on the phase boundary. We showed [22.172] that the latent heat on the boundary is one order smaller than that on the *thermal* melting line. It was also reported [22.171] that the latent heat is vanishing within error bars while discontinuity in other physical quantities remains observable on the phase boundary.

Possible Vortex Glass

As a possible thermodynamic phase above the BrG, the vortex glass (VG) phase [22.177, 178], where flux lines are tightly pinned by point-like defects, has been considered. In the early stage of numerical simulations, the VG-VL boundary was detected by the jump of the correlation time [22.179] or the deviation of flux lines [22.180]. In the frustrated XY model, the VG phase is characterized by finite helicity modulus along the c axis and vanishing Bragg peak [22.172]. Although the absence of the VG was once argued [22.171], stability of the VG phase without the screening has now been established [22.181–183]. It is noticed that the stability of VG phase including the screening is still unsettled [22.184, 185].

Vortex slush

There is a vortex slush phase [22.186–188] in the phase diagram Fig. 22.28. The vortex slush shares the same symmetry of the liquid. The two phases are separated by a first-order transition line characterized by the jump of the density of dislocations in the xy plane [22.189, 190]. As in the gas-liquid case, this transition line is terminated by a critical point as shown in Fig. 22.28. It is interesting to notice that even above the critical point, a step-like anomaly of the specific heat was reported [22.173, 191].

22.6.2 Columnar Defects

Columnar defects created by heavy-ion irradiation along the c axis work as strong correlated pinning centers to the

Fig. 22.30 p - T phase diagram for vortex states with the columnar defects [22.174]

vortex lines and produce new vortex states such as the Bose glass (BG) [22.192–194]. We introduced [22.174] columnar defects as the correlated plaquettes surrounded by four weak couplings $J_{ij} = (1 - \epsilon)J$ with probability p in the xy plane and $J_{ij} = J$ elsewhere, as shown in Fig. 22.29. Since the density of defects p plays an essential role in vortex states with columnar defects, we tune the parameter p while fixing ϵ . Parameters for simulation are $\Gamma = 5$, $f = 1/25$, $\epsilon = 0.1$, and $L_x = L_y = 50$ and $L_c = 80$.

Bose Glass

The p - T phase diagram obtained by Monte Carlo simulations is displayed in Fig. 22.30. When the number of columnar defects exceeds that of flux lines, the BG is stable at low temperatures. Here, we concentrate on small densities of columnar defects, ranging from the pure system with $p = 0$ to the matching case $p = f = 1/25$.

In order to evaluate the BG phase boundary, the tilt modulus c_{44} is evaluated. The Hamiltonian under the transverse field H^\perp is given by $\mathcal{H}' = \mathcal{H} - H^\perp m^\perp$ with the transverse magnetization m^\perp , and c_{44} is given [22.195] by

$$c_{44} \sim \left[\frac{\partial \langle m^\perp \rangle}{\partial H^\perp} \Big|_{H^\perp=0} \right]^{-1} \sim N_{\text{flux}} k_B T / \left\langle \left(m^\perp \right)^2 \right\rangle \Big|_{H^\perp=0}, \quad (22.93)$$

aside from a coefficient. The BG phase boundary is signaled by a large jump of c_{44} , which is expected to be infinite in the thermodynamic limit.

Interstitial Liquid

When the number of columnar defects is smaller than that of flux lines and the temperature is slightly higher than the BG transition temperature, columnar defects still trap some flux lines, while other interstitial flux lines can move around. This state is known as the interstitial liquid (IL) [22.196]. The helicity modulus along the c axis Υ_c takes a finite value as long as some of the flux lines are trapped by columnar defects. Therefore, the vanishing of the helicity modulus Υ_c corresponds to the boundary of the IL region.

Possibility of Bragg-Bose Glass

Similar to the BrG phase of vortex state with point-like defects, a Bragg-Bose glass (BBG) was proposed in the presence of columnar defects [22.197], which is characterized by quasi-long-range crystalline order and diverging tilt modulus. However, stability of this phase is not so trivial. At the ground state, flux lines are perfectly parallel to the magnetic field and the columnar defects. The system is then equivalent to the two-dimensional vortex states with point defects, where the absence of the BrG phase at $T = 0$ was shown numerically [22.198]. Therefore, the BBG (if exists) may be a kind of order caused by thermal fluctuations.

For small enough p and low enough temperatures, the structure factor shows sharp Bragg peaks, which is consistent with the BBG. As the temperature increases, the maximum value of the structure factor S_q^{max} drops just on the BG boundary with a narrow coexistence region, and the δ -function peak of the specific heat is observed. These facts indicate that the first-order melting transition of the BBG phase occurs just on the BG boundary at low density of columnar defects. The BBG at low temperature can be destroyed by introducing

Fig. 22.31a,b Density of vortices in the xy plane averaged along the c axis in the (a) BBG and (b) IL phases with the same configuration of columnar defects [22.174]. The defects are painted in yellow (no flux lines) to red (filled with flux lines), and other regions are painted in violet (no flux lines) to light blue (largest probability of flux lines)

more columnar defects, indicated by a sharp change of S_q^{\max} . It is found that the BBG-BG phase boundary is almost independent of temperature, as shown in Fig. 22.30.

As can be seen in Fig. 22.31(a) for BBG phase, all flux lines are localized and form a triangular lattice. There exist some unoccupied columnar defects (yellow dots). The defects far from stable positions of vortex lattice remain unoccupied in the BBG phase. On the other hand, in Fig. 22.31(b) for the IL phase, most defects are occupied unless other occupied ones are very close by chance. Owing to such *selected pinning* of flux lines in the BBG, introduction of more columnar defects to

certain density enhances energy gain by trapping more flux lines using defects close to stable positions of vortex lattice, without destroying the lattice structure. This results in increase of the melting temperature. When p becomes large enough, the vortex lattice will be destroyed by the overwhelming pinning energy and the BG phase becomes stable.

The above description is consistent with the simulations based on the boson model [22.199], while the simulations based on the density-functional theory results in a different picture characterized by the two-step melting transition with the “BrG phase” surrounded by the BG phase [22.200, 201].

22.7 Quantum Critical Phenomena

Here we show several examples investigated by quantum Monte Carlo simulations, which is helpful for understanding the methodology.

22.7.1 Quantum Spin Chain

It was naively expected that low-energy excitations of spin systems are described by spin waves. In the spin-wave approximation, low-energy excitations are always gapless, regardless of the length of spins. However, Haldane predicted that in one dimension

low-energy excitations have a finite gap for integer spin systems [22.203, 204]. This prediction was later confirmed by numerical simulations [22.205–207] and experiments [22.208–211]. Further, Affleck extended Haldane’s argument to bond-alternating systems and predicted that integer spin chains can have a gapless excitation with special values of the alternating strength [22.212–214].

Some compounds that can be regarded as spin $S=1$ bond-alternating Heisenberg chains have been found experimentally [22.215–219]. Among them, the susceptibility of $[\text{Ni}(333\text{-tet})(\mu\text{-N}_3)](\text{ClO}_4)_n$ [333-tet denotes tetraamine N,N' -bis(3-aminopropyl)-1,3-propanediamine] shows a gapless behavior [22.220]. In order to confirm whether this compound can really be described by an $S=1$ bond-alternating Heisenberg chain, numerical simulations have been performed [22.202]. Since the model is a non-frustrated Heisenberg model, quantum Monte Carlo simulations can be performed without negative-sign problems as explained in Sect. 22.3.8. Hence, the loop algorithm (Sect. 22.3.3) is applied to this system. The comparison between the result of the quantum Monte Carlo simulation and the experimental result is shown in Fig. 22.32. In the wide temperature range, numerical and experimental data agree well. This indicates that the magnetic properties of this compound are well described by the $S=1$ bond-alternating Heisenberg chain at the gapless point. Only in the very low temperature regime, data show a little difference which may be due to single-ion anisotropy of this compound.

It was also predicted that at the gapless point low-energy properties are described by the level $k=1$

Fig. 22.32 Uniform susceptibility $\chi(q=0; T)$ obtained by the quantum Monte Carlo simulation and experiments [22.202]

Fig. 22.33 Staggered susceptibility $\chi(q = \pi; T)$ obtained by the quantum Monte Carlo simulation [22.202]. S1BA and S1/2AH denote the $S = 1$ bond-alternating Heisenberg chain at the gapless point and the $S = 1/2$ Heisenberg chain, respectively

SU(2) Wess-Zumino-Witten (WZW) model [22.212–214], which is the same universality class as the $S = 1/2$ Heisenberg chain. The critical properties at the gapless point are also investigated by the quantum Monte Carlo simulation [22.202]. It is known that in the WZW universality class staggered susceptibility $\chi(q = \pi; T)$ and staggered structure factor $S(q = \pi; T)$ diverge toward the critical point [22.221, 222] as

$$\chi(q = \pi; T) \propto T^{-1} [\ln(T_\chi/T)]^{1/2}, \quad (22.94)$$

$$S(q = \pi; T) \propto [\ln(T_S/T)]^{3/2}. \quad (22.95)$$

Figures 22.33 and 22.34 show the numerical results for $\chi(q = \pi; T)$ and $S(q = \pi; T)$. The scaling properties of (22.94) and (22.95) are clearly observed.

In this way, quantum Monte Carlo simulations are powerful to investigate properties of spin systems. There are many other examples to show the power of quantum Monte Carlo simulations [22.66].

22.7.2 Mott Transition

It is widely believed that for the high- T_c superconductivity strong correlations near the Mott transition play an important role. In the insulating phase, there is a magnetic order and the spin and charge excitations

Fig. 22.34 Staggered structure factor $S(q = \pi; T)$ obtained by the quantum Monte Carlo simulation [22.202]

are separated. On the other hand, in the metallic phase, it is expected that spin and charge degrees of freedom are strongly coupled, and the excitations may be described by fermionic quasi particles at least in the low electron-density regime. The difficulty of approaching the Mott transition comes from the complexity of the transit of these two-types of states. Since the Hubbard and t - J models are known to be insulators at half filling and become metallic by doping, characteristic features of Mott transitions would be described by these models.

Properties near the metal-insulator transition have been numerically investigated by quantum Monte Carlo simulations. For the two-dimensional Hubbard model, Furukawa and Imada applied the auxiliary-field quantum Monte Carlo method (Sect. 22.3.6) and found non-trivial power-law behaviors toward the Mott transition point [22.223]: The compressibility κ and the spin structure factor $S(Q)$ diverge as

$$\kappa \propto \delta^{-1}, \quad (22.96)$$

$$S(Q) \propto \delta^{-1}, \quad (22.97)$$

where δ denotes the doping concentration. Equation (22.97) suggests that the antiferromagnetic correlation length ξ_m diverges as

$$\xi_m \propto \delta^{-1/2}, \quad (22.98)$$

assuming that the spin-spin correlations behave as $\langle S_0 S_r \rangle \propto e^{iQr} \cdot e^{-r/\xi_m}$. These features are observed by

Fig. 22.35 Scaling behavior of chemical potential μ as a function of doping δ for the two-dimensional t - J model [22.227]

experiments [22.224–226]. For the two-dimensional t - J model, a similar analysis has been made based on the numerical results obtained by a Monte Carlo power method (Sect. 22.3.7) [22.227] as shown in Figs. 22.35 and 22.36. The results are qualitatively the same as the Hubbard model. Here, compressibility κ behaves as $\kappa \propto \partial\delta/\partial\mu$.

Fig. 22.36 Scaling behavior of spin structure factor $S_{\max}(Q)$ as a function of doping δ for the two-dimensional t - J model [22.227]

Fig. 22.37 Magnetization process of the $S = 1/2$ XXZ model with Ising-like anisotropy on a square lattice [22.228]. Solid and dotted lines denote the magnetization jump determined by the Maxwell construction

These numerical simulations suggest that spin and charge fluctuations diverge toward the Mott transition point. There is a possibility that such large fluctuations may lead to the high- T_c superconductivity.

In this way, properties of strongly correlated electron systems can be investigated by quantum Monte Carlo simulations.

22.7.3 Phase Separation

Quantum Monte Carlo simulations can also be applied to investigate first-order phase transitions. For example, in the two-dimensional t - J model, the phase-separation boundary has been investigated by a Monte Carlo power method [22.227] (Sect. 22.3.7). In finite systems, the energy obtained in canonical ensembles as a function of the electron density becomes concave downward in the region of phase separation. In order to satisfy the thermodynamic requirement, a tangent has to be drawn based on the Maxwell construction. Thus, the phase-separation boundary can be estimated using quantum Monte Carlo data in finite clusters. Since very accurate simulations are necessary in order to determine the precise position of the phase-separation boundary in the very small doping regime for the two-dimensional t - J model, it is a subtle problem and still controversial [22.227, 229–239].

Fig. 22.38 Critical field H_c for the $S=1/2$ XXZ model with Ising-like anisotropy 22.228. Here, λ denotes the anisotropy parameter. At the isotropic point, $\lambda = 1$

A similar analysis has been made for the magnetization process of the $S=1/2$ XXZ models with Ising-like anisotropy in two and three dimensions by using the cluster algorithm [22.228] (Sect. 22.3.3). Magnetization curves (M - H curves) are obtained by the quantum Monte Carlo simulation in canonical ensembles in finite systems as shown in Fig. 22.37. This figure shows the non-monotonic behavior of magnetization M as a function of magnetic field H , indicating the phase separation (i.e., the magnetization jump). The phase-separation boundary determined by the Maxwell construction has little size effect as shown in Fig. 22.37.

Fig. 22.39 Magnetization jump M_s for the $S=1/2$ XXZ model with Ising-like anisotropy 22.228

The critical field H_c and the magnetization jump M_s are shown in Figs. 22.38 and 22.39. The results in two and three dimensions are quite different from the one-dimensional result. In one dimension, there is no region of the phase separation, and the critical field near $\lambda=1$ behaves as $H_c \propto \exp[-\pi^2/2\sqrt{2(\lambda-1)}]$ [22.240], where λ denotes the anisotropy parameter. (At the isotropic point, $\lambda=1$.)

It should be noted that the $S=1/2$ XXZ model can be mapped onto the Bose-Hubbard model with nearest-neighbor repulsions in the hard-core limit. Thus, numerical results for the $S=1/2$ XXZ model imply that the corresponding Bose-Hubbard model also shows the first-order transition.

Appendix – International Standards

Standardisation of materials characterisation methods is needed for various reasons, for example:

- To provide the basis for measurements and tests that can be compared confidently with those made by others around the world,
- To ensure that a material conforms to a technical specification of characteristics,
- To be used in the design of a component or structure
- To support investigations into the reasons for failures in service.

In addition, the results achieved from materials measurement and testing help guarantee the quality, safety and reliability of products, components, and technical systems.

The importance of measurement, testing and standardisation to science, technology, and economy was expressed as follows by the Commission of the European Union:

There is no science without measurements, no quality without testing and no global markets without standards.

Introducing the compilation of standards in the Appendix of this Handbook, some general remarks on standardisation in this field should be made.

Work on standardisation of materials measurement and test methods started between 1920 and 1930 for the various methods in the individual countries. Therefore, the National, European and ISO standards partly have contained different specifications. Whereas it is generally accepted to strive for a complete alignment of standards at all standardization levels, problems can arise from the interlining of existing national standards and new supranational standards (e.g. ISO/EN). When adopting a supranational standard as a national stan-

dard, it must be ensured that the supranational standard adopted e.g. as DIN EN ISO in no way contradict relevant national standards. In most cases the relevant national standard will be cancelled.

However, it might happen that the new EN ISO standard covers only a part of the existing national standard. In these cases it must be decided whether the part not covered by the new EN ISO standard can be abandoned or whether this part contains specifications that must be retained due to their relevance for the national economic region. In the latter case it will be maintained as a so-called “residual standard”.

A further important purpose of standardization work is to decrease the measurement uncertainty of the test methods and to give the users of standards guidelines to handle.

With the publication of EN ISO/IEC 17025 “General requirements for the competency of testing and calibrating laboratories”, the test or calibration certificates provided by the laboratories shall incorporate the measurement results received including the measurement uncertainty. From these data it shall be possible to gather that the metrological specifications have been fulfilled. Moreover, it shall be ensured that the measurement results are converted back to SI units using a metrological chain.

In this Appendix of the Springer Handbook of Materials Measurement Methods a collection of standards related to the different chapters of this Handbook is compiled. The chapter standard collections are selective and not complete; they differ in scope and volume and depend on the field and the state of the art of the pertinent standards’ developments.

The references listed comprise the symbol S for standard, the number of the chapter, the continued numbers (separate for each chapter), the name of the editing standards organization, the standards’ notation, the year of publication, and the title of the standard. For the abbreviations of the standards organizations see the following explanation including the internet address:

Part B Measurement Methods for Composition and Structure

Chapter 4 Chemical Composition

Chemical Separations (4.1.2)

S-4-1	ANSI/ASTM D 6042: 1996-00-00	Test Method for Determination of Phenolic Antioxidants and Erucamide Slip Additives in Polypropylene Homopolymer Formulations Using Liquid Chromatography (LC)
S-4-2	ANSI/ASTM D 6060: 2001-00-00	Practice for Sampling of Process Vents with a Portable Gas Chromatograph
S-4-3	ANSI/ASTM D 6159: 1997-00-00	Test Method for Determination of Hydrocarbon Impurities in Ethylene by Gas Chromatography/Note: reaffirmation of ANSI/ASTM D6159-1997
S-4-4	ANSI/ASTM D 6420: 2001-00-00	Test Method for Determination of Gaseous Organic Compounds by Direct Interface Gas Chromatography-Mass Spectrometry
S-4-5	ANSI/ASTM D 6733: 2001-00-00	Test Method for Determination of Individual Components in Spark Ignition Engine Fuels by 50 Meter Capillary High Resolution Gas Chromatography
S-4-6	ASTM D 4626: 1995-00-00	Standard Practice for Calculation of Gas Chromatographic Response Factors / Note: Reapproved 2000

S-4-7	ASTM D 5399: 1995-00-00	Standard Test Method for Boiling Point Distribution of Hydrocarbon Solvents by Gas Chromatography/ Note: Reapproved 2000
S-4-8	ASTM D 5917: 2002-00-00	Standard Test Method for Trace Impurities in Monocyclic Aromatic Hydrocarbons by Gas Chromatography and External Calibration
S-4-9	ASTM D 6060: 1996-00-00	Standard Practice for Sampling of Process Vents With a Portable Gas Chromatograph / Note: Reapproved 2001
S-4-10	ASTM E 260: 1996-00-00	Standard Practice for Packed Column Gas Chromatography / Note: Reapproved 2001
S-4-11	ASTM E 355: 1996-00-00	Standard Practice for Gas Chromatography Terms and Relationships / Note: Reapproved 2001
S-4-12	ASTM E 682 ANSI E 682: 1992-00-00	Standard Practice for Liquid Chromatography Terms and Relationships / Note: Reapproved 2000
S-4-13	ASTM E 685 ANSI E 685: 1993-00-00	Standard Practice for Testing Fixed-Wavelength Photometric Detectors Used in Liquid Chromatography / Note: Reapproved 2000
S-4-14	ASTM E 697: 1996-00-00	Standard Practice for Use of Electron-Capture Detectors in Gas Chromatography / Note: Reapproved 2001
S-4-15	ASTM E 840: 1995-00-00	Standard Practice for Using Flame Photometric Detectors in Gas Chromatography / Note: Reapproved 2000
S-4-16	ASTM E 1140: 1995-00-00	Standard Practice for Testing Nitrogen/Phosphorus Thermionic Ionization Detectors for Use In Gas Chromatography / Note: Reapproved 2000
S-4-17	ASTM E 1303: 1995-00-00	Practice for Refractive Index Detectors Used in Liquid Chromatography / Note: Reapproved 2000
S-4-18	ASTM E 1449: 1992-00-00	Standard Guide for Supercritical Fluid Chromatography Terms and Relationships / Note: Reapproved 2000
S-4-19	ASTM E 1510: 1995-00-00	Standard Practice for Installing Fused Silica Open Tubular Capillary Columns in Gas Chromatographs / Note: Reapproved 2000
S-4-20	ASTM E 1642: 2000-00-00	Standard Practice for General Techniques of Gas Chromatography Infrared (GC/IR) Analysis
S-4-21	ASTM E 1657: 1998-00-00	Standard Practice for Testing Variable-Wavelength Photometric Detectors Used in Liquid Chromatography / Note: Reapproved 2001
S-4-22	ASTM E 1698: 1995-00-00	Standard Practice for Testing Electrolytic Conductivity Detectors (ELCD) Used in Gas Chromatography / Note: Reapproved 2000
S-4-23	ISO 2718: 1974-04-00	Standard layout for a method of chemical analysis by gas chromatography
S-4-24	JIS K 0114: 2000-07-20	General rules for gas chromatographic analysis
S-4-25	JIS K 0115: 1992-02-01	General rules for molecular absorptiometric analysis
S-4-26	JIS K 0123: 1995-04-01	General rules for analytical methods in gas chromatography mass spectrometry

Chapter 6 Surface and Interface Characterization

Surface Chemical Analysis (6.1)

S-6-1	ASTM E 983: 1994-00-00	Standard Guide for Minimizing Unwanted Electron Beam Effects in Auger Electron Spectroscopy / Note: Reapproved 1999
S-6-2	ASTM E 984: 1995-00-00	Standard Guide for Identifying Chemical Effects and Matrix Effects in Auger Electron Spectroscopy / Note: Reapproved 2001
S-6-3	ASTM E 995: 1997-00-00	Standard Guide for Background Subtraction Techniques in Auger Electron and X-ray Photoelectron Spectroscopy
S-6-4	ASTM E 996: 1994-00-00	Standard Practice for Reporting Data in Auger Electron Spectroscopy and X-ray Photoelectron Spectroscopy / Note: Reapproved 1999
S-6-5	ASTM E 1078: 1997-00-00	Standard Guide for Procedures for Specimen Preparation and Mounting in Surface Analysis
S-6-6	ASTM E 1127: 1991-00-00	Standard Guide for Depth Profiling in Auger Electron Spectroscopy / Note: Reapproved 1997
S-6-7	ASTM E 1217: 2000-00-00	Standard Practice for Determination of the Specimen Area Contributing to the Detected Signal in Auger Electron Spectrometers and Some X-Ray Photoelectron Spectrometers
S-6-8	ISO/DIS 21270: 2002-09-00	Surface chemical analysis – X-ray photoelectron and Auger electron spectrometers – Linearity of intensity scale
S-6-9	DIN 28400-6: 1980-10-00	Vacuum technology; terms and definitions, surface analysis techniques
S-6-10	ASTM E 1162: 1987-00-00	Standard Practice for Reporting Sputter Depth Profile Data in Secondary Ion Mass Spectrometry (SIMS) / Note: Reapproved 2001
S-6-11	ASTM E 1438: 1991-00-00	Standard Guide for Measuring Widths of Interfaces in Sputter Depth Profiling Using SIMS / Note: Reapproved 2001
S-6-12	ASTM E 1504: 1992-00-00	Standard Practice for Reporting Mass Spectral Data in Secondary Ion Mass Spectrometry (SIMS) / Note: Reapproved 2001
S-6-13	ASTM E 1505: 1992-00-00	Standard Guide for Determining SIMS Relative Sensitivity Factors from Ion Implanted External Standards / Note: Reapproved 2001
S-6-14	ASTM E 1635: 1995-00-00	Standard Practice for Reporting Imaging Data in Secondary Ion Mass Spectrometry (SIMS) / Note: Reapproved 2000
S-6-15	ASTM E 1880: 1997-00-00	Standard Practice for Tissue Cryosection Analysis with SIMS / Note: Reapproved 2002
S-6-16	ASTM E 1881: 1997-00-00	Standard Guide for Cell Culture Analysis with SIMS / Note: Reapproved 2002
S-6-17	ASTM F 1366: 1992-00-00	Standard Test Method for Measuring Oxygen Concentration in Heavily Doped Silicon Substrates by Secondary Ion Mass Spectrometry / Note: Reapproved 2002
S-6-18	ASTM F 1528: 1994-00-00	Standard Test Method for Measuring Boron Contamination in Heavily Doped N-Type Silicon Substrates by Secondary Ion Mass Spectrometry / Note: Reapproved 1999
S-6-19	ASTM F 1617: 1998-00-00	Standard Test Method for Measuring Surface Sodium, Aluminum, Potassium, and Iron on Silicon and EPI Substrates by Secondary Ion Mass Spectrometry / Note: Reapproved 2002
S-6-20	ANSI/IEEE 759: 1984-00-00	Semiconductor X-Ray Energy Spectrometers, Test Procedures for / Note: reaffirmation of ANSI/IEEE 759-1984 (R1991)
S-6-21	ASTM C 1255: 1993-00-00	Standard Test Method for Analysis of Uranium and Thorium in Soils by Energy Dispersive X-Ray Fluorescence Spectroscopy / Note: Reapproved 1999
S-6-22	ASTM C 1271: 1999-00-00	Standard Test Method for X-ray Spectrometric Analysis of Lime and Limestone
S-6-23	ASTM E 539: 2002-00-00	Standard Test Method for X-Ray Emission Spectrometric Analysis of 6Al-4V Titanium Alloy
S-6-24	ASTM E 572: 1994-00-00	Standard Test Method for X-Ray Emission Spectrometric Analysis of Stainless Steel / Note: 1. editorial change. Reapproved 2000
S-6-25	ASTM E 902: 1994-00-00	Standard Practice for Checking the Operating Characteristics of X-Ray Photoelectron Spectrometers / Note: Reapproved 1999
S-6-26	ASTM E 1078: 1997-00-00	Standard Guide for Procedures for Specimen Preparation and Mounting in Surface Analysis
S-6-27	ASTM E 1085: 1995-00-00	Standard Test Method for X-Ray Emission Spectrometric Analysis of Low-Alloy Steels / Note: Reapproved 2000

S-6-28	ASTM E 1172: 1987-00-00	Standard Practice for Describing and Specifying a Wavelength-Dispersive X-Ray Spectrometer / Note: Reapproved 2001
S-6-29	ASTM E 1217: 2000-00-00	Standard Practice for Determination of the Specimen Area Contributing to the Detected Signal in Auger Electron Spectrometers and Some X-Ray Photoelectron Spectrometers
S-6-30	ASTM E 1523: 1997-00-00	Standard Guide to Charge Control and Charge Referencing Techniques in X-Ray Photoelectron Spectroscopy
S-6-31	ASTM E 2108: 2000-00-00	Standard Practice for Calibration of the Electron Binding-Energy Scale of an X-Ray Photoelectron Spectrometer
S-6-32	DIN 51009: 2001-12-00	Optical atomic spectral analysis – Principles and definitions
S-6-33	DIN EN 12544-3: 1999-12-00	Non-destructive testing – Measurement and evaluation of the X-ray tube voltage – Part 3: Spectrometric method; German version EN 12544-3:1999
S-6-34	ISO/DIS 15471: 2001-08-00	Surface chemical analysis – Auger electron spectroscopy – Description of selected instrumental performance parameters
S-6-35	ISO 17973: 2002-10-00	Surface chemical analysis – Medium-resolution Auger electron spectrometers – Calibration of energy scales for elemental analysis
S-6-36	ISO 17974: 2002-10-00	Surface chemical analysis – High-resolution Auger electron spectrometers – Calibration of energy scales for elemental and chemical-state analysis
S-6-37	ISO/DIS 18118: 2003-01-00	Surface chemical analysis – Auger electron spectroscopy and X-ray photoelectron spectroscopy – Guide to the use of experimentally determined relative sensitivity factors for the quantitative analysis of homogeneous materials

Adhesion Measurement Methods (6.3)

S-6-82 ANSI/SAE J 2375: 1997-08-00	The Selection of Adhesives for the Attachment of Exterior Aftermarket Accessories
S-6-83 ASTM D 903: 1998-00-00	Standard Test Method for Peel or Stripping Strength of Adhesive Bonds
S-6-84 ASTM D 905: 1998-00-00	Standard Test Method for Strength Properties of Adhesive Bonds in Shear by Compression Loading
S-6-85 ASTM D 906: 1998-00-00	Standard Test Method for Strength Properties of Adhesives in Plywood Type Construction in Shear by Tension Loading
S-6-86 ASTM D 1002: 2001-00-00	Standard Test Method for Apparent Shear Strength of Single-Lap-Joint Adhesively Bonded Metal Specimens by Tension Loading (Metal-to-Metal)
S-6-87 ASTM D 1144: 1999-00-00	Standard Practice for Determining Strength Development of Adhesive Bonds
S-6-88 ASTM D 2295: 1996-00-00	Standard Test Method for Strength Properties of Adhesives in Shear by Tension Loading at Elevated Temperatures (Metal-to-Metal) / Note: Reapproved 2002
S-6-89 ASTM D 2339: 1998-00-00	Standard Test Method for Strength Properties of Adhesives in Two-Ply Wood Construction in Shear by Tension Loading
S-6-90 ASTM D 2557: 1998-00-00	Standard Test Method for Tensile-Shear Strength of Adhesives in the Subzero Temperature Range from – 267.8 to – 55 °C (– 450 to – 67 fahrenheit)
S-6-91 ASTM D 3121: 1994-00-00	Standard Test Method for Tack of Pressure-Sensitive Adhesives by Rolling Ball / Note: Reapproved 1999
S-6-92 ASTM D 3359: 2002-00-00	Standard Test Methods for Measuring Adhesion by Tape Test
S-6-93 ASTM D 3528: 1996-00-00	Standard Test Method for Strength Properties of Double Lap Shear Adhesive Joints by Tension Loading / Note: Reapproved 2002
S-6-94 ASTM D 3808: 2001-00-00	Standard Test Method for Qualitative Determination of Adhesion of Adhesives to Substrates by Spot Adhesion
S-6-95 DIN EN 1902: 1999-10-00	Adhesives – Test method for adhesives for floor coverings and wall coverings – Shear creep test; German version EN 1902:1999
S-6-96 DIN EN 1939: 2002-07-00	Self adhesive tapes – Determination of peel adhesion properties; German version prEN 1939:2002
S-6-97 DIN EN 1939: 1996-11-00	Self adhesive tapes – Measurement of peel adhesion from stainless steel or from its own backing; German version EN 1939:1996
S-6-98 DIN EN 1944: 1996-04-00	Self adhesive tapes – Measurement of unwind adhesion at low speed; German version EN 1944:1996
S-6-99 DIN EN 1945: 1996-04-00	Self adhesive tapes – Measurement of quick stick; German version EN 1945:1996
S-6-100 DIN EN 1966: 2003-02-00	Structural adhesives – Characterization of a surface by measuring adhesion by means of the three point bending method; German version EN 1966:2002
S-6-101 DIN EN 12025: 1996-07-00	Self adhesive tapes – Measurement of tear resistance by the pendulum; German version EN 12025:1996
S-6-102 DIN EN 12026: 1996-07-00	Self adhesive tapes – Measurement of the unwinding force at high speed; German version EN 12026:1996

S-6-103	DIN EN 12028: 1996-07-00	Self adhesive tapes – Measurement of elongation under static load; German version EN 12028:1996
S-6-104	DIN EN 14410: 2003-06-00	Self adhesive tapes – Measurement of breaking strength and elongation at break; German version EN 14410:2003
S-6-105	DIN EN ISO 9664: 1995-08-00	Adhesives – Test methods for fatigue properties of structural adhesives in tensile shear (ISO 9664:1993); German version EN ISO 9664:1995
S-6-106	ISO 6922: 1987-12-00	Adhesives; Determination of tensile strength of butt joints
S-6-107	ISO 8510-1: 1990-12-00	Adhesives; peel test for a flexible-bonded-to-rigid test specimen assembly; part 1: 90° peel
S-6-108	ISO 8510-2: 1990-12-00	Adhesives; peel test for a flexible-bonded-to-rigid test specimen assembly; part 2: 180° peel
S-6-109	ISO 10123: 1990-12-00	Adhesives; determination of shear strength of anaerobic adhesives using pin-and-collar specimens
S-6-110	ISO 13445: 2003-04-00	Adhesives – Determination of shear strength of adhesive bonds between rigid substrates by the block-shear method
S-6-111	ISO 14679: 1997-09-00	Adhesives – Measurement of adhesion characteristics by a three-point bending method
S-6-112	EN 1372: 1999-06-00	Adhesives – Test method for adhesives for floor and wall coverings – Peel test
S-6-113	EN 1373: 1999-06-00	Adhesives – Test method for adhesives for floor and wall coverings – Shear test
S-6-114	NF T76-112, NF EN 1464: 1995-02-01	Adhesives. Determination of peel resistance of high-strength adhesive bonds. Floating roller method.
S-6-115	NF T76-125: 1986-09-01	Adhesives. Conventional determination of setting strength.
S-6-116	NF T76-152-2, NF EN 302-2: 1992-09-01	Adhesives for load-bearing timber structures. Test methods. Part 2: determination of resistance to delamination (laboratory method).
S-6-117	NF X41-022, NF EN 1939: 1996-12-01	Self adhesive tapes. Measurement of peel adhesion from stainless steel or from its own backing

Part C Measurement Methods for Materials Properties

Chapter 7 Mechanical Properties

Elasticity (7.1)

S-7-1	ASTM C 623: 1992-00-00	Standard Test Method for Young's Modulus, Shear Modulus, and Poisson's Ratio for Glass and Glass-Ceramics by Resonance / Note: Reapproved 2000
S-7-2	ASTM E 111: 1997-00-00	Standard Test Method for Young's Modulus, Tangent Modulus, and Chord Modulus
S-7-3	DIN 16913-2: 1981-04-00	Plastics; moulding materials; reinforced thermosetting moulding materials; prepreg; determination of properties of standardized test specimens
S-7-4	DIN 50992-1: 2002-05-00	Thickness measurement of coatings and characterising of surfaces with surface waves – Part 1: Evaluation of elastic constants, mass density and thickness of layers by laser-induced ultrasonic surface waves
S-7-5	DIN V ENV 843-2: 1996-02-00	Advanced technical ceramics – Monolithic ceramics – Mechanical properties at room temperature – Part 2: Determination of elastic moduli; German version ENV 843-2:1995
S-7-6	DIN V ENV 843-3: 1996-11-00	Advanced technical ceramics – Monolithic ceramics – Mechanical properties at room temperature – Part 3: Determination of subcritical crack growth parameters from constant stressing rate flexural strength tests; German version ENV 843-3:1996
S-7-7	DIN EN 12384: 1999-03-00	Copper and copper alloys – Determination of spring bending limit on strip; German version EN 12384:1999
S-7-8	DIN V ENV 14186: 2002-11-00	Advanced technical ceramics – Ceramic composites – Mechanical properties at room temperature; Determination of elastic properties by an ultrasonic technique; German version ENV 14186:2002
S-7-9	DIN EN ISO 1798: 2000-01-00	Flexible cellular polymeric materials – Determination of tensile strength and elongation at break (ISO 1798:1997); German version EN ISO 1798:1999

S-7-10	DIN EN ISO 6721-1: 2003-01-00	Plastics – Determination of dynamic mechanical properties – Part 1: General principles (ISO 6721-1:2001); German version EN ISO 6721-1:2002
S-7-11	DIN EN ISO 6721-2: 1996-12-00	Plastics – Determination of dynamic mechanical properties – Part 2: Torsion-pendulum method (ISO 6721-2:1994, including Technical Corrigendum 1:1995); German version EN ISO 6721-2:1996
S-7-12	DIN EN ISO 6721-3: 1996-12-00	Plastics – Determination of dynamic mechanical properties – Part 3: Flexural vibration; resonance-curve (ISO 6721-3:1994, including Technical Corrigendum 1:1995); German version EN ISO 6721-3:1996
S-7-13	DIN EN ISO 7231: 1998-01-00	Polymeric materials, cellular flexible – Method of assessment of air flow value at constant pressure-drop (ISO 7231:1984); German version EN ISO 7231:1997
S-7-14	DIN EN ISO 14129: 1998-02-00	Fibre-reinforced plastic composites – Determination of the in-plane shear stress/shear strain response, including the in-plane shear modulus and strength, by $\pm 45^\circ$ tension test method (ISO 14129:1997); German version EN ISO 14129:1997
S-7-15	DIN ISO 3312: 1990-10-00	Sintered metal materials and hardmetals; determination of young modulus; identical with ISO 3312:1987
S-7-16	DIN ISO 4506: 1991-07-00	Hardmetals; compression test; identical with ISO 4506:1979
S-7-17	ENV 14186: 2002-08-00	Advanced technical ceramics – Ceramic composites – Mechanical properties at room temperature, determination of elastic properties by an ultrasonic technique
S-7-18	EN 23312: 1993-04-00	Sintered metal and hardmetals; determination of Young moduls (ISO 3312:1987)
S-7-19	EN 24506: 1993-04-00	Hardmetals; compression test (ISO 4506:1979)
S-7-20	ISO 3312: 1987-07-00	Sintered metal materials and hardmetals; Determination of Young modulus
S-7-21	NF A03-001, NF EN 10002-1: 2001-10-01	Metallic materials – Tensile testing – Part 1: method of test at ambient temperature.
S-7-22	NF A37-502: 1984-10-01	Non-alloy carbon (C superior to 0.25 per cent) steel cold-rolled strip for heat treatment. Qualities
S-7-23	NF A49-191: 1975-10-01	Steel tubes. Spigot or mixed connections made of steel or cast iron for capillary brazing or braze welding. Dimensions. Technical delivery conditions
S-7-24	NF A50-703: 1984-07-01	Aluminium and aluminium alloys. Square section extruded bars. Dimensional tolerances and recommended dimensions

Plasticity (7.2)

S-7-25	ASTM C 1337: 1996-00-00	Standard Test Method for Creep and Creep Rupture of Continuous Fiber-Reinforced Ceramic Composites under Tensile Loading at Elevated Temperatures / Note: Reapproved 2000
S-7-26	ASTM E 139: 2000-00-00	Standard Test Methods for Conducting Creep, Creep-Rupture, and Stress-Rupture Tests of Metallic Materials / Note: 1. editorial change
S-7-27	ASTM E 633: 2000-00-00	Standard Guide for Use of Thermocouples in Creep and Stress-Rupture Testing to 1800 °F (1000 °C) in Air
S-7-28	DIN V ENV 820-4: 2001-12-00	Advanced technical ceramics – Monolithic ceramics; Thermo-mechanical properties – Part 4: Determination of flexural creep deformation at elevated temperatures; German version ENV 820-4:2001
S-7-29	DIN EN 10222-2: 2000-04-00	Steel forgings for pressure purposes – Part 2: Ferritic and martensitic steels with specified elevated temperature properties (including corrigendum AC:2000); German version EN 10222-2:1999 + AC:2000
S-7-30	DIN EN 10291: 2001-01-00	Metallic materials – Uniaxial creep testing in tension – Method of test; German version EN 10291:2000
S-7-31	DIN EN 10291 Supplement 1: 2001-01-00	Metallic materials – Uniaxial creep testing in tension – Method of test; indications for application
S-7-32	DIN EN 10319: 2001-01-00	Metallic materials – Tensile stress relaxation testing; German version prEN 10319:2000
S-7-33	DIN V ENV 13235: 1999-01-00	Advanced technical ceramics – Mechanical properties of ceramic composites at high temperature under inert atmosphere – Determination of creep behaviour; German version ENV 13235:1998

S-7-34	DIN EN ISO 899-1: 1997-03-00	Plastics – Determination of creep behaviour – Part 1: Tensile creep (ISO 899-1:1993); German version EN ISO 899-1:1996
S-7-35	DIN EN ISO 899-2: 1997-03-00	Plastics – Determination of creep behaviour – Part 2: Flexural creep by three-point loading (ISO 899-2:1993); German version EN ISO 899-2:1996
S-7-36	DIN EN ISO 6252: 1998-02-00	Plastics – Determination of environmental stress cracking (ESC) – Constant-tensile-stress method (ISO 6252:1992); German version EN ISO 6252:1997
S-7-37	DIN EN ISO 11403-1: 2002-09-00	Plastics – Acquisition and presentation of comparable multipoint data – Part 1: Mechanical properties (ISO 11403-1:2001); German version prEN ISO 11403-1:2002
S-7-38	DIN EN ISO 11403-1: 2000-05-00	Plastics – Acquisition and presentation of comparable multipoint data – Part 1: Mechanical properties (ISO 11403-1:1994); German version EN ISO 11403-1:1999
S-7-39	DIN ISO 2796: 1999-11-00	Cellular plastics, rigid – Test for dimensional stability (ISO 2796:1986); ASTM C 1291a: 2000-00-00; Standard Test Method for Elevated Temperature Tensile Creep Strain, Creep Strain Rate, and Creep Time-to-Failure for Advanced Monolithic Ceramics / Note: 2. revision 2000
S-7-40	EN 1778: 1999-10-00	Characteristic values for welded thermoplastic constructions – Determination of allowable stresses and moduli for design of thermoplastic equipment
S-7-41	EN 1902: 1999-09-00	Adhesives – Test method for adhesives for floor coverings and wall coverings – Shear creep test
S-7-42	EN 12107: 1997-08-00	Plastics piping systems – Injection-moulded thermoplastics fittings, valves and ancillary equipment – Determination of the long-term hydrostatic strength of thermoplastics materials for injection moulding of piping components
S-7-43	ENV 13235: 1998-11-00	Advanced technical ceramics – Mechanical properties of ceramic composites at high temperature under inert atmosphere – Determination of creep behaviour
S-7-44	EN ISO 899-1: 2003-06-00	Plastics – Determination of creep behaviour – Part 1: Tensile creep (ISO 899-1:2003)
S-7-45	EN ISO 899-2: 2003-06-00	Plastics – Determination of creep behaviour – Part 2: Flexural creep by three-point loading (ISO 899-2:2003)
S-7-46	EN ISO 6252: 1997-11-00	Plastics – Determination of environmental stress cracking (ESC) – Constant-tensile-stress method (ISO 6252:1992)
S-7-47	ISO 204: 1997-03-00	Metallic materials – Uninterrupted uniaxial creep testing in tension – Method of test
S-7-48	ISO/R 206: 1961-06-00	Creep stress rupture testing of steel at elevated temperatures
S-7-49	ISO 2007: 1991-11-00	Rubber, unvulcanized; determination of plasticity; rapid-plastimeter method
S-7-50	ISO 2039-2: 1987-07-00	Plastics; Determination of hardness; Part 2: Rockwell hardness
S-7-51	ISO/TR 7468: 1981-01-00	Summary of average stress rupture properties of wrought steels for boilers and pressure vessels
S-7-52	ISO 7500-2: 1996-10-00	Metallic materials – Verification of static uniaxial testing machines – Part 2: Tension creep testing machines – Verification of the applied load
S-7-53	JIS K 6859: 1994-02-01	Testing methods for creep rupture of adhesive bonds
S-7-54	JIS K 7105: 1981-03-01	Testing methods for optical properties of plastics
S-7-55	JIS K 7132: 1999-05-20	Cellular plastics, rigid – Determination of compressive creep under specified load and temperature conditions
S-7-56	JIS K 7135: 1999-05-20	Cellular plastics, rigid – Determination of compressive creep

Strength (7.3)

S-7-57	ASTM A 327M: 1991-00-00	Standard Test Methods for Impact Testing of Cast Irons (Metric) / Note: Reapproved 1997
S-7-58	ASTM B 490: 1992-00-00	Standard Practice for Micrometer Bend Test for Ductility of Electrodeposits / Note: Reapproved 1998
S-7-59	ASTM C 1292: 2000-00-00	Standard Test Method for Shear Strength of Continuous Fiber-Reinforced Advanced Ceramics at Ambient Temperatures
S-7-60	ASTM C 1341: 2000-00-00	Standard Test Method for Flexural Properties of Continuous Fiber-Reinforced Advanced Ceramic Composites
S-7-61	ASTM C 1366: 1997-00-00	Standard Test Method for Tensile Strength of Monolithic Advanced Ceramics at Elevated Temperatures

S-7-62	ASTM D 5023: 2001-00-00	Standard Test Method for Measuring the Dynamic Mechanical Properties: In Flexure (Three-Point Bending)
S-7-63	ASTM D 5026: 2001-00-00	Standard Test Method for Plastics: Dynamic Mechanical Properties: In Tension
S-7-64	ASTM E 8: 2001-00-00	Standard Test Methods for Tension Testing of Metallic Materials / Note: 1. editorial change
S-7-65	ASTM E 8M: 2001-00-00	Standard Test Methods for Tension Testing of Metallic Materials [Metric] / Note: 1. editorial change
S-7-66	ASTM E 9a: 1989-00-00	Standard Test Methods of Compression Testing of Metallic Materials at Room Temperature / Note: 2.revision 1989. Reapproved 2000
S-7-67	ASTM E 21: 1992-00-00	Standard Test Methods for Elevated Temperature Tension Tests of Metallic Materials / Note: 1. editorial change. Reapproved 1998
S-7-68	ASTM E 209: 2000-00-00	Standard Practice for Compression Tests of Metallic Materials at Elevated Temperatures with Conventional or Rapid Heating Rates and Strain Rates
S-7-69	ASTM E 290a: 1997-00-00	Standard Test Method for Bend Testing of Material for Ductility / Note: 2. revision 1997
S-7-70	ASTM E 292: 2001-00-00	Standard Test Methods for Conducting Time-for-Rupture Notch Tension Tests of Materials
S-7-71	ASTM E 338: 1991-00-00	Standard Test Method of Sharp-Notch Tension Testing of High-Strength Sheet Materials / Note: Reapproved 1997
S-7-72	ASTM E 345: 1993-00-00	Standard Test Methods of Tension Testing of Metallic Foil / Note: Reapproved 2002
S-7-73	ASTM E 602: 1991-00-00	Standard Test Method for Sharp-Notch Tension Testing with Cylindrical Specimens / Note: Reapproved 1997
S-7-74	ASTM E 1012: 1999-00-00	Standard Practice for Verification of Specimen Alignment Under Tensile Loading
S-7-75	DIN 50106: 1978-12-00	Testing of Metallic Materials; Compression Test
S-7-76	DIN 50116: 1982-07-00	Testing of zinc and zinc alloys; impact test
S-7-77	DIN 50125: 2003-05-00	Testing of metallic materials – Tensile test pieces
S-7-78	DIN 50148: 1975-06-00	Tensile test pieces for non-ferrous metals pressure die castings
S-7-79	DIN 51110-3: 1993-09-00	Testing of advanced technical ceramics; 4-point-bending test; statistical evaluation; determination of the Weibull-parameters
S-7-80	DIN 51211: 1978-09-00	Testing of Metallic Materials; Reverse Bend Test of Wires
S-7-81	DIN 51222: 1995-06-00	Materials testing machines – Impact test – Particular requirements on pendulum impact testing machines with a capacity of nominal energy ≤ 50 J and verification
S-7-82	DIN 51230: 1977-12-00	Material Testing Machines; Dynstat Apparatus for the Determination of Bending Strength and Impact Strength of Small Specimens

S-12-80 DIN EN ISO 7539-3: 1995-08-00	Corrosion of metals and alloys – Stress corrosion testing – Part 3: Preparation and use of U-bend specimens (ISO 7539-3:1989); German version EN ISO 7539-3:1995
S-12-81 DIN EN ISO 7539-4: 1995-08-00	Corrosion of metals and alloys – Stress corrosion testing – Part 4: Preparation and use of uniaxially loaded tension specimens (ISO 7539-4:1989); German version EN ISO 7539-4:1995
S-12-82 DIN EN ISO 7539-5: 1995-08-00	Corrosion of metals and alloys – Stress corrosion testing – Part 5: Preparation and use of C-ring specimens (ISO 7539-5:1989); German version EN ISO 7539-5:1995
S-12-83 DIN EN ISO 7539-6: 2003-07-00	Corrosion of metals and alloys – Stress corrosion testing – Part 6: Preparation and use of pre-cracked specimens (ISO 7539-6:2003); German version EN ISO 7539-6:2003
S-12-84 DIN EN ISO 7539-7: 2002-04-00	Corrosion of metals and alloys – Stress corrosion testing – Part 7: Slow strain rate testing (ISO/DIS7539-7:2002); German version prEN ISO 7539-7:2002
S-12-85 DIN EN ISO 9400: 1995-12-00	Nickel-based alloys – Determination of resistance to intergranular corrosion (ISO 9400:1990); German version EN ISO 9400:1995
S-12-86 DIN EN ISO 9591: 2001-06-00	Corrosion of aluminium alloys – Determination of resistance to stress corrosion cracking (ISO/DIS 9591:2001); German version prEN ISO 9591:2001
S-12-87 ISO 11846: 1995-10-00	Corrosion of metals and alloys – Determination of resistance to intergranular corrosion of solution heat-treatable aluminium alloys
S-12-88 SEP 1861: 1982-01-00	Testing of welded joints at plain and low-alloy steels for their resistance against stress corrosion cracking

Corrosion Fatigue (12.5.2)

S-12-89 ISO 11782-1: 1998-07-00	Corrosion of metals and alloys – Corrosion fatigue testing – Part 1: Cycles to failure testing
S-12-90 ISO 11782-2: 1998-07-00	Corrosion of metals and alloys – Corrosion fatigue testing – Part 2: Crack propagation testing using precracked specimens

High Temperature Oxidation (12.7)

S-12-91 ASTM A 409/A 409M: 2001-00-00	Standard Specification for Welded Large Diameter Austenitic Steel Pipe for Corrosive or High-Temperature Service
S-12-92 DIN EN 2183: 1999-05-00	Aerospace series – Heat resisting alloy NI-PH2301 (NiCr21Fe18Mo9), solution treated – Hand and die forgings, $D < 200$ mm
S-12-93 DIN EN 2184: 1999-05-00	Aerospace series – Heat resisting alloy NI-PH2301 (NiCr21Fe18Mo9), solution treated – Bar and section, $D < 200$ mm
S-12-94 DIN EN 2185: 1999-05-00	Aerospace series – Heat resisting alloy NI-PH2301 (NiCr21Fe18Mo9), solution treated – Sheet, strip and plate, $0.2 \text{ mm} < 10 \text{ mm}$
S-12-95 DIN EN 2187: 1999-05-00	Aerospace series – Heat resisting alloy NI-PH1301 (NiCr19Co18Mo4Ti3Al3), solution treated and precipitation treated – Hand and die forgings, $D < 200$ mm, $R > 1300$ MPa
S-12-96 DIN EN 3668: 1998-04-00	Aerospace series – Heat resisting alloy NI-PH2301 (NiCr21Fe18Mo9), non heat treated – Forging stock a or $D < 250$ mm

S-12-97 DIN EN 14483-2: 2002-08-00	Vitreous and porcelain enamels – Determination of resistance to chemical corrosion – Part 2: Determination of resistance to chemical corrosion by boiling acids, neutral liquids and/or their vapours; German version prEN 14483-2:2002
S-12-98 ISO 2744: 1998-03-00	Vitreous and porcelain enamels – Determination of resistance to boiling water and water vapour
S-12-99 VDI 2035 Blatt: 2000-09-00	Prevention of damage in water heating installations – Corrosion by fuel gases

Chapter 13 Wear

Tribological Test Methods (13.3)

S-13-1 ASTM C 808: 1975-00-00	Standard Guideline for Reporting Friction and Wear Test Results of Manufactured Carbon and Graphite Bearing and Seal Materials / Note: Reapproved 2000
S-13-2 ASTM G 65: 2000-00-00	Standard Test Method for Measuring Abrasion Using the Dry Sand/Rubber Wheel Apparatus/Note: 1. editorial change
S-13-3 ASTM G 75: 2001-00-00	Standard Test Method for Determination of Slurry Abrasivity (Miller Number) and Slurry Abrasion Response of Materials (SAR Number)
S-13-4 ASTM G 81a: 1997-00-00	Standard Test Method for Jaw Crusher Gouging Abrasion Test / Note: 2. revision 1997. 1. editorial change. Reapproved 2002
S-13-5 ASTM G 83: 1996-00-00	Standard Test Method for Wear Testing with a Crossed-Cylinder Apparatus
S-13-6 ASTM G 84: 1989-00-00	Standard Practice for Measurement of Time-of-Wetness on Surfaces Exposed to Wetting Conditions as in Atmospheric Corrosion Testing / Note: 1. editorial change. Reapproved 1999
S-13-7 ASTM G 99: 2003-00-00	Standard Test Method for Wear Testing with a Pin-on-Disk Apparatus
S-13-8 DIN EN 13523-16: 2003-03-00	Coil coated metals – Test methods – Part 16: Resistance to abrasion; German version prEN 13523-16:2003
S-13-9 ENV 1071-6: 2002-07-00	Advanced technical ceramics – Methods of test for ceramic coatings – Part 6: Determination of the abrasion resistance of coatings by a micro-abrasion wear test
S-13-10 prEN 13523-16: 2003-03-00	Coil coated metals – Test methods – Part 16: Resistance to abrasion
S-13-11 VDI 3822 Blatt 5: 1999-01-00	Failure-analysis – Failures caused by tribology working conditions

Chapter 14 Biodegradation

Biological Testing of Wood – Attack by Microorganisms (14.2.1)

S-14-1 AFNOR: HFA-AAS008:1998-12	Field Test method to evaluate the Efficacy of Anti-Sapstain Wood Preservatives
S-14-2 AFNOR: HFA-AAS014:1998-03	Determination of anti-sapstain preservatives against blue stain and mould fungi (laboratory method)
S-14-3 AFNOR:X 41-547:1992-12	Determination of fungicidal efficacy of products used for temporary protection of green sawn timber (laboratory method)
S-14-4 AFNOR:X 41-548:1992-12	Determination of the fungicidal efficacy of products used for temporary protection of fresh cut wood billets. (Laboratory method)
S-14-5 AFNOR:X 41-549:1993-11	Determination of the fungicidal efficacy of products used for temporary protection of green sawn timber (Field method)
S-14-6 AS 1157.5-1998:1998	Methods of testing materials for resistance to growth – resistance of timber to surface fungal growth
S-14-7 AS/NZS 4266.18:1995	Reconstituted wood-based panels – Methods of test – Determination of efficacy of fungicide treatment
S-14-8 ASTM D1006-93:1993	Standard Recommended Practice for Conducting Exterior Exposure Tests of Paints on Wood
S-14-9 AWP	AWPA Field Test Method for Anti-Sapstain Protection (second draft)
S-14-10 AWP E 5-93:1993	Test Method for Accelerated Evaluation of Wood Preservatives for Marine Services by Means of Small Size Specimens

S-14-11	AWPA E 7-93:1993	Standard Method of Evaluating Wood Preservatives by Field Tests with Stakes
S-14-12	AWPA E 8-56:1956	Standard Method for Field Tests with Posts
S-14-13	AWPA E 9-97:1997	Standard Field Test for the Evaluation of Wood Preservatives to be used in Non-Soil Contact
S-14-14	AWPA E 10-91:1991	Standard Method of Testing Wood Preservatives by Laboratory Soil-Block Cultures
S-14-15	AWPA E14-94:1994	Standard Method of Evaluating Wood Preservatives in a Soil Bed
S-14-16	EN 152-1:1988-02 BS 7066-1 NF EN 152-1:1988-06 DIN EN 152-1:1989-08	Laboratory method for determining the protective effectiveness of a preservative treatment against blue stain in service. – Part 1: Brushing procedure
S-14-17	EN 152-2:1989-04 BS 7066-2 NF EN 152-2:1988-06 DIN EN 152-2:1989-08	Laboratory method for determining the protective effectiveness of a preservative treatment against blue stain in service. – Part 2: Application by methods other than brushing
S-14-18	EN 252:1989-06 NF EN 252 (X 41-545):1989-09 DIN EN 252:1990-04	Field test method for determining the relative protective effectiveness of a wood preservative in ground contact
S-14-19	EN 275:1992-09 NF EN 275 (X 40-505):1992-12 DIN EN 275:1992-11	Wood preservatives; determination of the protective effectiveness against marine borers
S-14-20	EN 330:1993 NF EN 330 (X 41-546):1993-07 DIN EN 330:1993/06	Wood preservatives; Field test method for determining the relative protective effectiveness of a wood preservative for use under a coating and exposed out of ground contact: L-joint method

Chapter 16 Performance Control and Condition Monitoring

Non-destructive Evaluation: Ultrasonic (16.1.2)

S-16-1 ASTM E 114: 1995-00-00	Standard Practice for Ultrasonic Pulse-Echo Straight-Beam Examination by the Contact Method / Note: Reapproved 2001
S-16-2 ASTM E 214: 2001-00-00	Standard Practice for Immersed Ultrasonic Examination by the Reflection Method Using Pulsed Longitudinal Waves
S-16-3 ASTM E 317: 2001-00-00	Standard Practice for Evaluating Performance Characteristics of Ultrasonic Pulse-Echo Examination Instruments and Systems Without the Use of Electronic Measurement Instruments

S-16-4 ASTM E 428: 2000-00-00	Standard Practice for Fabrication and Control of Steel Reference Blocks Used in Ultrasonic Examination
S-16-5 ASTM E 494: 1995-00-00	Standard Practice for Measuring Ultrasonic Velocity in Materials / Note: Reapproved 2001
S-16-6 ASTM E 587: 2000-00-00	Standard Practice for Ultrasonic Angle-Beam Examination by the Contact Method
S-16-7 ASTM E 588: 1995-00-00	Standard Practice for Detection of Large Inclusions in Bearing Quality Steel by the Ultrasonic Method
S-16-8 ASTM E 1001a: 1999-00-00	Standard Practice for Detection and Evaluation of Discontinuities by the Immersed Pulse-Echo Ultrasonic Method Using Longitudinal Waves / Note: 2. revision 1999
S-16-9 ASTM E 1002: 1996-00-00	Standard Test Method for Leaks Using Ultrasonics
S-16-10 ASTM E 1544: 1999-00-00	Standard Practice for Construction of a Stepped Block and Its Use to Estimate Errors Produced by Speed-of-Sound Measurement Systems for Use on Solids
S-16-11 ASTM E 1736: 2000-00-00	Standard Practice for Acousto-Ultrasonic Assessment of Filament-Wound Pressure Vessels
S-16-12 ASTM E 1816: 1996-00-00	Standard Practice for Ultrasonic Examinations Using Electromagnetic Acoustic Transducer (EMAT) Techniques / Note: Reapproved 2002
S-16-13 DIN 25450: 1990-09-00	Ultrasonic equipment for manual testing
S-16-14 DIN 54123: 1980-10-00	Non-destructive Test; Ultrasonic Method of Testing Claddings, Produced by Welding, Rolling and Explosion
S-16-15 DIN EN 583-1: 1998-12-00	Non-destructive testing – Ultrasonic examination – Part 1: General principles; German version EN583-1:1998
S-16-16 DIN EN 583-2: 2001-04-00	Non-destructive testing – Ultrasonic examination – Part 2: Sensitivity and range setting; German version EN 583-2:2001
S-16-17 DIN EN 583-3: 1997-06-00	Non-destructive testing – Ultrasonic testing – Part 3: Transmission technique; German version EN583-3:1997
S-16-18 DIN EN 583-4: 2002-12-00	Non-destructive testing – Ultrasonic examination – Part 4: Examination for discontinuities perpendicular to the surface; German version EN 583-4:2002
S-16-19 DIN EN 583-5: 2001-02-00	Non-destructive testing – Ultrasonic examination – Part 5: Characterization and sizing of discontinuities; German version EN 583-5:2000
S-16-20 DIN V ENV 583-6: 2000-03-00	Non-destructive testing – Ultrasonic examination – Part 6: Time-of-flight diffraction technique as a method for detection and sizing of discontinuities; German version ENV 583-6:2000
S-16-21 DIN EN 1330-4: 2000-03-00	Non-destructive testing – Terminology – Part 4: Terms used in ultrasonic testing; Trilingual version EN1330-4:2000
S-16-22 DIN EN 10160: 1999-09-00	Ultrasonic testing of steel flat product of thickness equal to or greater than 6 mm (reflection method); German version EN 10160:1999
S-16-23 DIN EN 10228-3: 1998-07-00	Non-destructive testing of steel forgings – Part 3: Ultrasonic testing of ferritic or martensitic steel forgings; German version EN 10228-3:1998
S-16-24 DIN EN 10228-4: 1999-10-00	Non-destructive testing of steel forgings – Part 4: Ultrasonic testing of austenitic and austenitic-ferritic stainless steel forgings; German version EN 10228-4:1999
S-16-25 DIN EN 10246-6: 2000-03-00	Non-destructive testing of steel tubes – Part 6: Automatic full peripheral ultrasonic testing of seamless steel tubes for the detection of transverse imperfections; German version EN 10246-6:1999
S-16-26 DIN EN 10246-7: 2002-09-00	Non-destructive testing of steel tubes – Part 7: Automatic full peripheral ultrasonic testing of seamless and welded (except submerged arc welded) steel tubes for the detection of longitudinal imperfections; German version prEN 10246-7:2002
S-16-27 DIN EN 10246-7: 1996-04-00	Non-destructive testing of steel tubes – Part 7: Automatic full peripheral ultrasonic testing of seamless and welded (except submerged arc-welded) steel tubes for the detection of longitudinal imperfections; German version EN 10246-7:1996
S-16-28 DIN EN 10246-8: 2000-03-00	Non-destructive testing of steel tubes – Part 8: Automatic ultrasonic testing of the weld seam of electric welded steel tubes for the detection of longitudinal imperfections; German version EN 10246-8:1999
S-16-29 DIN EN 10246-9: 2000-06-00	Non-destructive testing of steel tubes – Part 9: Automatic ultrasonic testing of the weld seam of submerged arc-welded steel tubes for the detection of longitudinal and/or transverse imperfections; German version EN 10246-9:2000

S-16-30 DIN EN 10246-13: 2000-07-00	Non-destructive testing of steel tubes – Part 13: Automatic full peripheral ultrasonic thickness testing of seamless and welded (except submerged arc welded) steel tubes; German version EN 10246-13:2000
S-16-31 DIN EN 10246-14: 2000-03-00	Non-destructive testing of steel tubes – Part 14: Automatic ultrasonic testing of seamless and welded (except submerged arc-welded) steel tubes for the detection of laminar imperfections; German version EN 10246-14:1999
S-16-32 DIN EN 10246-15: 2000-07-00	Non-destructive testing of steel tubes – Part 15: Automatic ultrasonic testing of strip/plate used in the manufacture of welded steel tubes for the detection of laminar imperfections; German version EN 10246-15:2000
S-16-33 DIN EN 10246-16: 2000-07-00	Non-destructive testing of steel tubes – Part 16: Automatic ultrasonic testing of the area adjacent to the weld seam of welded steel tubes for the detection of laminar imperfections; German version EN 10246-16:2000
S-16-34 DIN EN 10246-17: 2000-07-00	Non-destructive testing of steel tubes – Part 17: Ultrasonic testing of tube ends of seamless and welded steel tubes for the detection of laminar imperfections; German version EN 10246-17:2000
S-16-35 DIN EN 10306: 2002-04-00	Iron and steel – Ultrasonic testing of H beams with parallel flanges and IPE beams; German version EN 10306:2001

Acknowledgements

B.5 Nanoscopic Architecture and Microstructure

by Koji Maeda, Hiroshi Mizubayashi

The authors would like to thank Drs. M. Hasegawa, A. Hida, K. Hono, M. Ichihara, H. Jinnai, R. Matsuo, A. Momose, S. Morita, T. Nish, K. Oshima, Y. Satow, T. Sekiguchi, I. Shimada and I. Yonenaga for useful discussions or kindly supplying us with unpublished materials and data.

B.6 Surface and Interface Characterisation

by Martin Seah, Leonardo De Chiffre

The authors would like to thank Ian Gilmore and Steve Spencer, National Physical Laboratory, for critical reading of the text and preparing some of the Figs, Pietro Lonardo, University of Genova, for valuable contributions during preparation of the section on surface topography, and Jørgen Garnæs, Danish Fundamental Metrology, for valuable contributions during preparation of the text on scanning probe microscopy. Part of this work is supported by the National Measurement System of the UK Department of Trade and Industry through the Valid Analytical Measurements Programme.

C.7 Mechanical Properties

by Sheldon M. Wiederhorn, Richard J. Fields, Samuel Low, Gun-Woong Bahng, Alois Wehrstedt, Junhee Hahn, Yo Tomota, Takashi Miyata, Haiqing Lin, Benny D. Freeman, Shuji Aihara, Yukito Hagihara, Tetsuya Tagawa

Sect. 7.1. The authors are grateful to ASTM International and to ASM International for giving us permission to

republish copyrighted figures from their publications. Figures 7.4 to 7.12 are reprinted with permission of ASTM International, 100 Barr Harbor Drive, West Conshohocken, PA 19428. The ASTM standard designation number and title for each figure are given in the figure caption and in the reference to the figure. Figures 7.13 to 7.15 were reprinted with the permission of ASM International, Materials Park, OH (2000).

Sect. 7.6. We gratefully acknowledge partial support of this work by the Chemical Sciences, Geosciences and Biosciences Division, Office of Basic Energy Sciences, Office of Science, U.S. Department of Energy (grant no. DE-FG03-02ER15362). This research work was also partially supported by the U.S. Department of Energy's National Energy Technology Laboratory under a subcontract from Research Triangle Institute through their prime contract no.: DE-AC26-99FT40675.

E.21 Phase Field

by Toshiyuki Koyama

The author would like to thank Professors T. Miyazaki, M. Doi, and H. Onodera for useful discussions on many occasions. He also thanks Dr. M. Ode for useful comment concerning the thin interface model of the phase-field method. This work was partly supported by the Special Coordination Funds for Promoting Science and Technology on Nanohetero Metallic Materials, the NAREGI Nanoscience Project, Ministry of Education, Culture, Sports, Science and Technology, Japan, and the CREST of the Japan Science and Technology Agency.

About the Authors

Shuji Aihara

Nippon Steel Corporation
Steel Research Laboratories
Chiba, Japan
s-aihara@re.nsc.co.jp

Chapter C.7, Sect. 7.5

Dr. Shuji Aihara is an expert in the field of welding metallurgy and fracture mechanics. He received awards from the Society of Naval Architects, Japan and the Institute of Steel and Iron, Japan for his achievements in the research of fracture mechanics and metallurgy of high-strength low-alloy welded structural steels.

Tsutomu Araki

Osaka University
Graduate School of Engineering Science
Osaka, Japan
araki@me.es.osaka-u.ac.jp

Chapter C.11, Sect. 11.7

Professor Tsutomu Araki received his Ph.D. degree in applied physics from Osaka University, Japan, in 1977. After being a post doctoral Fellow with the University of Wisconsin, Madison, he joined the faculty of the University of Tokushima, Japan and received the Ph.D. degree in medical sciences from the University of Tokushima in 1986. He is currently a Professor in the Department of Mechanical Sciences and Bioengineering of Osaka University. His research interests include development of a new biomedical and biophysical measurement systems using a fast pulse laser. He is a member of the Society for Applied Spectroscopy, the Optical Society of America, the Japan Society of Mechanical Engineering, and the Japan Society of Applied Physics.

Masaaki Ashida

Osaka University
Graduate School of Engineering Science
Osaka, Japan
ashida@mp.es.osaka-u.ac.jp

Chapter C.11, Sects. 11.1, 11.4

Masaaki Ashida received the Ph.D. degree in physics from Kyoto University, Japan, in 1994. He has worked on laser spectroscopy on solids. In 2003 he joined the department of Materials Engineering Science at Osaka University. His current interests are in ultrafast optical nonlinearity of strongly correlated electron systems and nanoscale materials. He recently developed an ultra broadband THz time-domain spectroscopy. He is a member of the Physical Society of Japan, the Japan Society of Applied Physics and the Optical Society of America.

Peter D. Askew

IMSL, Industrial Microbiological Services
Limited
Hartley Wintney, Hants, UK
peter.askew@imsl-uk.com

Chapter D.14, Sects. 14.1, 14.3, 14.5

Pete has been working since 1977 as an industrial microbiologist and is the Managing Director of IMSL, a specialised microbiological testing and consultancy service. As well as qualifications in microbiology, he is an Associate of the Oil and Colour Chemists Association and is a consultant to the OECD on treated articles and Secretary General of the International Biodeterioration Research Group.

Heinz-Gunter Bach

Heinrich-Hertz-Institut
Components/Integration Technology,
Fraunhofer-Institute for
Telecommunications
Berlin, Germany
bach@hhi.fhg.de

Chapter C.9, Sect. 9.4

Heinz-Gunter Bach received the M.S. degree in electrical engineering from TU Berlin, Germany. From 1978 to 1981 he was with the Hahn–Meitner-Institute Berlin working on the electrical characterization of BCCDs. He received the Ph.D. degree in 1982. In 1981 he joined the Heinrich-Hertz-Institut für Nachrichtentechnik Berlin GmbH heading the electrical characterization group within the photonics division. He was involved in III–V materials characterization, heterostructure analysis, and device optimization. Further he was engaged in project management of topics such as HEMT optimization, optoelectronic packaging and within the last 13 years on ultra-high-speed photodetector development and photoreceiver integration. He gives annual lectures at the Technical University on “optoelectronic semiconductor devices” and “measurement techniques for semiconductor devices”. He is member of VDE, Elektrotechnischer Verein (ETV) e.V. ITG and serves as a technical committee member of the international conference on Optical Fiber Communications.

Gun-Woong Bahng

Korea Research Institute of Standards and Science
Division of Chemical and Materials
Metrology
Daejeon, South Korea
gwbahng@kriss.re.kr

Chapter C.7, Sect. 7.3

Gun-Woong Bahng received his B.S. in 1976 from Seoul National University and his Ph.D. in 1982 from Northwestern University, Evanston. He is Chairman of the APEC network for Materials Properties Evaluation (2002-2006). His scientific work concentrates on mechanical behaviour of materials at low temperature, hardness standards, certified reference materials, the traceability and metrology of materials properties, and standard reference data. In 2004 he received the Science and Technology Medal from the Korean Government.

Claude Bathias

Conservatoire National des Arts et Métiers, Laboratoire ITMA
Institute of Technology and Advanced Materials
Paris, France
bathias@cnam.fr

Chapter D.16, Sect. 16.3

Claude Bathias is Professor “Classe Exceptionnelle” at the Conservatoire National des Arts et Métiers, School of Science and Technology for Engineering in Paris, France. He is Director of ITMA and Head of the MS Education (Materials Engineering). Professor Claude Bathias has dedicated his research carrier to the fracture of materials by fatigue in both of fundamental and technological aspects. Three periods can be distinguished in his activity: In the 1970ies he has worked about the modelling of fatigue crack growth and has displayed the mechanism of cyclic plastic deformation at the fatigue crack tip. In the 1980ies he applied fracture mechanics to the delamination of laminate composite materials and to the fatigue crack propagation in elastomers. Finally, in the 1990ie Professor Bathias and co-workers gave the experimental confirmation, for the first time, that all of the metals can fail in fatigue beyond the quadrillion of cycles range which is evidence of that the concept of infinite fatigue life does not exist.

Günther Bayreuther

University of Regensburg
Physics Department
Regensburg, Germany
guenther.bayreuther@physik.uni-regensburg.de

Chapter C.10, Sect. 10.4

Günther Bayreuther is Professor of Physics at the University of Regensburg. He has a long experience in magnetic films and surfaces. Current areas of research are ferromagnetic order and phase transitions in epitaxial nanostructures, spin-dependent transport phenomena in epitaxial metal-semiconductor layered structures, spin injection into semiconductors and ultrafast magnetization dynamics.

Nick Boley

LGC Ltd.
Proficiency Testing and Training
Teddington, UK
nick.boleyn@gc.co.uk

Chapter A.2

Nick Boley graduated in 1978 from Loughborough University of Technology in Industrial Chemistry. He is a Chartered Scientist and a member of the Royal Society of Chemistry. He has over eight years experience in all aspects of the management of proficiency testing schemes and has authored or co-authored many papers on proficiency testing. He is currently the Chair of the EA-Eurolab-EURACHEM Joint Working Group on Proficiency Testing in Accreditation Procedures which is concerned with the development and harmonization of good practice in proficiency testing on a European and, increasingly, international, scale.

Wolfgang Buck

Physikalisch-Technische Bundesanstalt,
Institut Berlin
Division 7
Berlin, Germany
wolfgang.buck@ptb.de

Chapter C.8

Wolfgang Buck has over 25 years of experience in metrological work gained at the Physikalisch Technische Bundesanstalt (PTB). Most of these years he worked in field of low-temperature physics and thermometry and in the development of the Provisional Low-Temperature Scale 2000. He made contributions to the planning and construction of highly magnetically shielded rooms and an electron storage ring for synchrotron radiation. Since 2002 he is the head of the division and head of the Berlin Institute of PTB.

Richard R. Cavanagh

National Institute of Standards and Technology (NIST)
Surface and Microanalysis Science
Division, Chemical Science and
Technology Laboratory (CSTL)
Gaithersburg, MD, USA
richard.cavanagh@nist.gov

Chapter B.4

Richard R. Cavanagh earned his Ph.D. from Harvard University. He came to NIST in 1979 to pursue postdoctoral studies in the area of Surface Science. Since that time, he has published over 100 papers in the area of molecular processes at surfaces, incorporating measurement methods ranging from inelastic neutron scattering, picosecond and femtosecond lasers spectroscopy, and near-field optics. Dr. Cavanagh is the Chief of the Surface and Microanalysis Science Division, overseeing programs in microanalysis research, surface and interface research, and analytical microscopy. His Division provides the measurement science that underpins micro- and nanoscale chemical characterization of natural and man-made structures. Expertise in the Division spans electron microscopy, X-ray diffraction and fluorescence, SIMS, Raman, IR, NLO, scanned probes, optical microscopy, and AES.

Department of Manufacturing
Engineering and Management
Kgs. Lyngby, Denmark
ldc@ipl.dtu.dk

Chapter B.6

Leonardo De Chiffre is an internationally recognized expert in manufacturing and metrology. He has created and directed since its formation the Centre for Geometrical Metrology at the Technical University of Denmark which is part of the Danish National Laboratory for Geometrical Metrology. Professor De Chiffre is active member of CIRP, panel member of the Foundation Committee of Euspen, and Associate Editor of Precision Engineering.

**Steven J. Choquette**

National Institute of Standards and Technology
Biochemical Science Division
Gaithersburg, MD, USA
steven.choquette@nist.gov

Chapter B.4, Sect. 4.1

Steven Choquette is a Research Chemist at the National Institute of Standards and Technology, Gaithersburg, Maryland. He has been employed in the Analytical Chemistry Division since 1987. His current research interests are in the development of performance validation standards for Near Infrared and Raman spectroscopy. He is a member of several ASTM committees and currently serves as the vice-chair of ASTM E 13.08 committee on Raman Spectroscopy. He obtained a Ph.D. in analytical chemistry in 1987 at the Virginia Polytechnical Institute and State University, Blacksburg, VA. His B.S. degree in Chemistry and Electrical Engineering was obtained from Santa Clara University, in Santa Clara, CA in 1980.

Horst Czichos

University of Applied Sciences Berlin
Department of Electrical Engineering and
Precision Engineering
Berlin, Germany
horst.czichos@t-online.de

Chapter A.3

Horst Czichos has been President of BAM, the German Federal Institute for Materials Research and Testing (1992-2002) and of EUROLAB, the European Federation of National Associations of Measurement, Testing and Analytical Laboratories (1999-2003). He holds degrees in precision engineering, physics and materials science, and obtained a Dr. h.c. from KU Leuven for his research work in tribology. He is currently Professor for Mechatronics at the University of Applied Sciences, TFH Berlin.

Werner Daum

Federal Institute for Materials Research and Testing (BAM)
Division VIII.1
Berlin, Germany
werner.daum@bam.de

Chapter D.16, Sect. 16.6

Dr. Werner Daum studied electrical engineering with a major in measuring techniques at the Technical University of Berlin. Upon graduation in 1984 he entered Federal Institute for Materials Research and Testing (BAM). Until 1989 his main activity was R&D in the field of non-destructive testing with special focus on digital image processing and radioscopy. In 1989 he became head of the laboratory for optical measuring methods and experimental stress analysis and commenced with the development of optical NDT methods. In 1994 he received his Ph.D. from the Technical University of Berlin. In 1996 he became a Director and Professor at BAM and head of the division Measurement and Testing Technology; Sensors. The emphasis of his work is the development of sensor technology to be embedded into materials and structures, of fiber-optic sensors, and of sensor technology for smart structures and materials. Since 1999 he is chairman of the German Society of Experimental Structure Analysis (GESA).

Paul DeRose

National Institute of Standards and Technology
Biochemical Science Division
Gaithersburg, MD, USA
paul.derose@nist.gov

Chapter B.4, Sect. 4.1

Paul DeRose is a physical/analytical chemist who came to NIST as a National Research Council Postdoctoral Fellow in 1996. Before coming to NIST, he earned his Ph.D. in chemistry from the University of Pennsylvania where he studied laser spectroscopy and excited-state dynamics. His current research interests concern the development of fluorescence standards and methods for validation of chemical and clinical assays.

Stephen L.R. Ellison

LGC Ltd.
Bioinformatics and Statistics
Middlesex, UK
s.ellison@lgc.co.uk

Chapter A.2

Dr. Ellison is head of the Bioinformatics and Statistics section at LGC. Originally qualified as a chemist, his research and application interests include statistics, chemometrics and computing applied to chemical and biological measurement. He is a recognised international expert in measurement uncertainty and traceability for analytical methods, and has contributed to a range of national and international committees and guidance documents in that field.

Anton Erhard

Federal Institute for Materials Research and Testing (BAM)
Department Non-destructive Testing;
Acoustical and Electrical Methods
Berlin, Germany
anton.erhard@bam.de

Chapter D.16, Sect. 16.1

Prof. Dr.-Ing. Anton Erhard studied metal physics at the Technical University Berlin. Since 1976 he is employed at the Bundesanstalt für Materialforschung und -prüfung (BAM) Berlin. His scientific work was honored with two awards; 1984 from the German Society of Non-Destructive Testing (DGZfP) and 1985 from the American Society for Nondestructive Testing (ASNT). His scientific results are presented in more than 200 publications.

Uwe Ewert

Federal Institute for Materials Research and Testing (BAM)
Division VIII.3 Radiology
Berlin, Germany
uwe.ewert@bam.de

Chapter D.16, Sect. 16.2

Dr. Uwe Ewert is Director and Professor of the division Radiology in the Department Non-destructive Testing of BAM, the Federal Institute for Materials Research and Testing. He received his Ph.D. from the Humboldt-University in Berlin on calculations of electron spin resonance (ESR) spectra of metal complex compounds. He developed tomography systems at the centre of scientific instruments in Berlin-Adlershof up to 1990 and developed pulsed ESR tomography methods at the Cornell University in New York State. Since 1992 he is engaged at BAM in material characterisation, new intelligent testing methods of industrial components and their standardization. He is chairman of the radiology committee of the German Society of NDT since 1997.

**Richard J. Fields**

Chapter C.7, Sect. 7.2

National Institute of Standards and Technology
Materials Science and Engineering Laboratory
Gaithersburg, MD, USA
richard.fields@nist.gov

Richard J. Fields is a Ph.D. metallurgist and has worked at the National Institute of Standards and Technology and the National Bureau of Standards for the past 27 years, supervising groups of scientists doing research in metal forming, nanolaminates, and powder metallurgy. His group also certifies the U.S. national standards for Rockwell B and C hardness scales.

**Benny D. Freeman**

Chapter C.7, Sect. 7.6

The University of Texas at Austin, Center for Energy and Environmental Resources
Department of Chemical Engineering
Austin, TX, USA
freeman@che.utexas.edu

Dr. Freeman's research is mass transport of small molecules through polymers. He directs 14 Ph.D. students performing fundamental research projects in gas and liquid separations using polymer membranes and barrier packaging. Current topics include vapor separation materials, new materials for hydrogen separation and natural gas purification, nanocomposite membranes, reactive barrier packaging, and new materials for improving fouling resistance for liquid separations.

Mark Gee

National Physical Laboratory
Division of Engineering and Processing Control
Teddington, TW11 0LW, UK
mark.gee@npl.co.uk

Chapter D.13

Mark Gee is the Knowledge Leader for the Performance Materials Team in the Division of Engineering and Process Control at the National Physical Laboratory. He manages projects which are concerned with the development of an improved infrastructure for friction and wear testing in the UK. Particular research interests are the mechanisms of abrasive wear for ceramics and other hard materials. He has published over 200 papers and reports. He has recently been Chairman of the Institute of Physics Tribology Group, and is now Secretary of the Surface Engineering Committee of the Institute of Materials, Mining and Minerals. He is also a member of the International Advisory Editorial Board of Tribology International. He convenes the meetings of the UK Forum on Friction and Wear Testing, and is a member of ASTM Committee G2 on Wear.

Jürgen Goebbels

Federal Institute for Materials Research and Testing (BAM)
Radiology (VIII.3)
Berlin, Germany
juergen.goebbels@bam.de

Chapter D.16, Sect. 16.4

Dr. Jürgen Goebbels received his Ph.D. from the Technical University Karlsruhe in 1976 on Surface resistance of amorphous superconducting films. He has worked for six years in the field of low-temperature solid-state physics and nuclear magnetic resonance (NMR) at the Karlsruhe Nuclear Research Centre and at the Free University Berlin. Since 1982 he is at the Federal Institute for Materials Research and Testing (BAM) and is at present head of the working group 'Computed tomography'. Since the foundation 1987 he is chairman of the subcommittee 'Computed Tomography' of the German Society of Non-destructive Testing (DGZIP).

**Anna A. Gorbushina**

Chapter D.14, Sect. 14.4

Carl von Ossietzky Universität Oldenburg
Geomicrobiology, ICBM
Oldenburg, Germany
a.gorbushina@uni-oldenburg.de

Anna Gorbushina studied Biology, Material Sciences and Physics at St. Petersburg University. She received her Ph.D. from Komarov Institute, Russian Academy of Sciences. Professor Gorbushina is teaching materials science and microbiology at the Applied University Cologne and mycology and landscape ecology (architectural ecology) at Oldenburg University. She is working on biodeterioration by and molecular ecology of micromycetes (lower fungi). She is a member of International Board of Environmental Biogeochemistry.

**Robert R. Greenberg**

Chapter B.4, Sect. 4.1

National Institute of Standards and Technology
Analytical Chemistry Division
Gaithersburg, MD, USA
robert.greenberg@nist.gov

Dr. Greenberg has been a Research Chemist at NBS/NIST since 1976, and the Group/Team Leader of the Nuclear Methods Group/Team since 1989. His research has focused on the development and application of high-accuracy nuclear and radioanalytical chemistry methods for elemental analysis, the development of complete uncertainty budgets for the nuclear analytical chemistry methods, and the establishment of quality assurance procedures.

Manfred Grinda

Chapter D.14, Sect. 14.2

Berlin, Germany
manfred.grinda@t-online.de

Diplom Holzwirt Manfred Grinda studied wood science and technology at the University of Hamburg. He was the head of the project group "Reliability and Resistance of Materials to Biodeterioration at the Federal Institute for Materials Research and Testing (BAM)". Until his retirement he was a member of several working groups of CEN/TC 38 "Durability of Wood and Derived Materials". His main interests are the methodology of meaningful materials testing against wood destroying fungi.

Roland Grössinger

Chapter C.10, Sect. 10.3

Technical University Vienna
Institut für Festkörperphysik
Vienna, Austria
rgroess@ifp.tuwien.ac.at

Roland Grössinger studied Technical Physics at the Technical University in Vienna where he received the title Diplom Ingenieur. During his employment at the Institute of Experimental Physics at the Technical University Vienna he received the Doctor for Technical Sciences in 1975. In 1983 he graduated as "Dozent" for Experimental Metal Physics, and was awarded the Planseepreis for the industrial development of a magnet key in 1985. In 1993 he was awarded the title Universitäts Professor. He has more than 400 publications in international journals and gave more than 500 talks and presentations at international conferences. His research interests are physical properties of magnetic materials and physics and technology of high magnetic fields and their measurement methods.

Yukito Hagihara

Chapter C.7, Sect. 7.5

Sophia University
Faculty of Science and Technology,
Department of Mechanical Engineering
Tokyo, Japan
hagihara@me.sophia.ac.jp

Professor Yukito Hagihara's main area of research is the fracture of steel and the integrity of welded structures based on fracture mechanics. He received his Dr. Eng. from the University of Tokyo in 1973. He worked at the Nippon Steel Corporation for 28 years (1973-2001) and at the National Institute for Materials Science for 3 years (2001-2004), where he was engaged in the ultra-steel project.

Junhee Hahn

Chapter C.7, Sect. 7.3

Korea Research Institute of Standards and Science (KRISS)
Chemical Metrology and Materials
Evaluation Div.
Daejeon, South Korea
juny@kriss.re.kr

Junhee Hahn's research fields are the synthesis of nanostructured thin films, the assessment of mechanical reliability of thin film and standardizing test methods. His current research activities comprise the development of equipment and methods to make super-hard nanostructured (superlattices, nanocomposite) thin films. He participates in standardizing the instrumental indentation test method and prepared the first draft of nanoindentation standard.

Holger Hanselka

Fraunhofer-Institute for Structural
Durability and System Reliability (LBF)
Darmstadt, Germany
holger.hanselka@lbf.fraunhofer.de

Chapter D.16, Sect. 16.7

Holger Hanselka studied general machine engineering at the Technical University of Clausthal and worked as scientific assistant at the German Centre 01' Aviation and Spare Travel in Braunschweig. In 1992 he graduated with a Ph.D. from TU Clausthal. In 1997, he was called to lecture at the Otto-von-Guericke University of Magdeburg; Hanselka held the chair of Adaptronics and was head of the work group Experimental Mechanics. Since 2001 he is head of the Fraunhofer-Institute of Structural Durability and System Reliability LBF in Darmstadt. He is also head of the special subject "System Reliability in Machine Engineering" as university lecturer at the Technical University of Darmstadt. Moreover, Professor Hanselka is chairman of the integrated European research project (IP) "Intelligent Materials for Active Noise Reduction – INMAR", chairman of the executive board of MATFORM and member of the executive board of Materials Valley e.V.

Manfred P. Hentschel

Federal Institute for Materials Research
and Testing (BAM)
VIII.3, Nondestructive Testing
Berlin, Germany
manfred.hentschel@bam.de

Chapter D.16, Sect. 16.5

Dr. Manfred P. Hentschel is manager of working group "X-Ray Scattering Topography" at Federal Institute for Materials Research and Testing (BAM) and Professor at the Technical University Berlin. He received his Ph.D. in physics from the Free University of Berlin. For developing new imaging and computed tomography techniques of X-ray scattering he was awarded the Roentgen Plaque in 2000. He is co-editor of RNDE and "Materialprüfung/Materials Testing".

Horst Hertel

Federal Institute for Materials Research
and Testing (BAM)
Division IV.1
Berlin, Germany
horst.hertel@bam.de

Chapter D.14, Sect. 14.2

Horst Hertel is biologist with a Ph.D. in Natural Sciences. He is lecturer at the Institute of Neurobiology, Free University of Berlin and, Head of Division Biology in Materials Protection and Environmental Issues" at the Federal Institute for Materials Research and Testing (BAM). His main interests are in materials protection against wood destroying insects on a biological basis.

Ian Hutchings

University of Cambridge, Institute for
Manufacturing
Department of Engineering
Cambridge, UK
imh2@cam.ac.uk

Chapter D.13

Currently GKN Professor of Manufacturing Engineering at the University of Cambridge, Ian Hutchings is also Editor-in-Chief of the journal *Wear*, and has research interests in the tribological behaviour of materials, surface engineering, and manufacturing processes for all classes of materials. He is a Fellow of the Royal Academy of Engineering and holds the Tribology Trust Silver Medal (1994) and the NPL Award for Materials Metrology (2000).

Xiao Hu

National Institute for Materials Science
Strong Coupling Modeling Group,
Computational Materials Science Center
Tsukuba, Japan
hu.xiao@nims.go.jp

Chapter E.22

Xiao Hu has a Ph. D. degree from Tokyo University (1990). He was Research Associate and Associate Professor at the Institute for Material Research, Tohoku University (1991–1995); Senior Scientist, Group Leader at the National Institute for Materials Science (NIMS) (1995–resent). His research area is the measurement in condensed matter physics and simulation in physics. His current research interests are the vortex state in type-II superconductors and novel spin phenomena.

Werner Hässelbarth

Federal Institute for Materials Research and Testing (BAM)
Analytical Chemistry; Reference Materials
Berlin, Germany
werner.haesselbarth@bam.de

Chapter A.2

Werner Hässelbarth is a chemist with strong influence from theoretical chemistry and mathematics. His university research career (15 years) was focussed on theoretical and physical chemistry. Since 1987 he has been working at Federal Institute for Materials Research and Testing (BAM) in different fields including chemical safety, gas analysis and quality management. Current research is focussed on technical issues in metrology and quality assurance in analytical chemistry, e.g. measurement uncertainty and traceability.

**Shoji Imatani**

Kyoto University
Department of Energy Conversion Science
Kyoto, Japan
imatani@energy.kyoto-u.ac.jp

Chapter E.18

Shoji Imatani started his research on inelastic constitutive modeling and finite element simulation in the middle of 1980's. His current interest is in the field of nonlinear continuum mechanics, particularly in material inhomogeneity and macro-/micro-combined analysis of inelastic materials.

**Hanspeter Ischi**

The Swiss Accreditation Service (SAS)
Berne, Switzerland
hanspeter.ischi@metas.ch

Chapter A.2

After his graduation as an analytical chemist Hanspeter Ischi worked in the chemical industry in the field of quality control. In this function he gained first experience in establishing industrial quality management systems and quality assurance in analytical chemistry already in 1980. Afterwards he continuously improved his knowledge in modern management systems including development of staff in the area of communication, leadership, organization and conflict management, as well as in quality assurance in testing. He is the head of the Swiss Accreditation Service since 1991, a member of the Executive Committees of the European Cooperation for Accreditation (EA) and the International Laboratory Accreditation Cooperation (ILAC). In EA he is the chairman of the laboratory committee.

Bernd Isecke

Federal Institute for Materials Research and Testing (BAM)
Corrosion and Corrosion Protection
Berlin, Germany
bernd.isecke@bam.de

Chapter D.12

Bernd Isecke has a Diploma in Materials Science (1974) and a Ph.D. (1977) from the Technical University in Berlin. Since 1978 he is with the Federal Institute for Materials Research and Testing (BAM), where he became head of the Division "Corrosion and Corrosion Protection" in 1989. His main areas of research include corrosion in steel reinforced concrete, corrosion monitoring and testing, stainless steels and hydrogen embrittlement of high strength materials. Dr. Isecke is Chairman of the Gesellschaft für Korrosionsschutz GfKorr, Past President of the European Federation of Corrosion EFC, German Delegate to the International Corrosion Council ICC and Chairman and member of various Standardisation committees in ISO, CEN and DIN.

Tadashi Itoh

Graduate School of Engineering Science,
Osaka University
Department of Materials Engineering Science
Osaka, Japan
itoh@mp.es.osaka-u.ac.jp

Chapter C.11, Sects. 11.2, 11.3

Tadashi Itoh is a Professor of Materials Physics, Osaka University since 1998, where he also graduated in Engineering Science with a Ph.D. in 1974. His fields of research include photophysics of bulk and nanostructured materials, nonlinear and time-resolved laser spectroscopy, optical microspectroscopy, and the fabrication of nanostructured opto-materials. He is a members of the Physical Society of Japan, the Japan Society of Applied Physics, and the Society of Nanoscience and Nanotechnology.

**Tetsuo Iwata**

Chapter C.11, Sect. 11.1

The University of Tokushima
Department of Mechanical Engineering
Tokushima, Japan
iwata@me.tokushima-u.ac.jp

Tetsuo Iwata received his Ph.D. degree in applied physics from Osaka University, Osaka, Japan, in 1984. He is currently a Professor with the Department of Mechanical Engineering, the University of Tokushima and with the Division of Energy System, Institute of Technology and Science, Graduate school of Tokushima University. His research interests are the development of optical and spectroscopic instruments based on new ideas.

**Gerd-Rüdiger Jaenisch**

Chapter D.16, Sect. 16.2

Federal Institute for Materials Research
and Testing (BAM)
Non-destructive Testing
Berlin, Germany
gerd-ruediger.jaenisch@bam.de

Dr. habil. Jaenisch, a physicist by education, received his Ph.D. in 1992 in theoretical nuclear physics and his habilitation in 2001 in materials science from Dresden University of Technology, Germany. Since 1992 he has been working in the field of non-destructive testing at the Federal Institute for Materials Research and Testing (BAM) in Berlin, Germany. His area of expertise extends to modelling and reconstruction in quantitative non-destructive evaluation with special focus on radiation techniques. Many activities were performed in cooperation with industrial partners. Since 2002 he has been appointed as university lecturer at Dresden University of Technology.

Oliver Jann

Chapter D.15, Sect. 15.2

Federal Institute for Materials Research
and Testing (BAM)
Emissions from Materials
Berlin, Germany
oliver.jann@bam.de

Dr. Oliver Jann studied Environmental Engineering at the Technical University Berlin (1981-1987). Since 1987 he is scientist at the Federal Institute for Materials Research and Testing (BAM). During this time he received his Dr.Eng. in 1993 and was project leader since 1996, and became head of the BAM-laboratory "Emissions from Materials" in 1997. His Scientific activities include research on emissions coming from materials, development of test methods. He is Lecturer at the University for Applied Sciences in Eberswalde, Germany.

Masanori Kohno

Chapter E.22

National Institute for Materials Science
Computational Materials Science Center
Tsukuba, Japan
kohno.masanori@nims.go.jp

Dr. Masanori Kohno received his Ph.D. degree in Physics from the university of Tokyo in 1998. Prior to joining National Institute for Materials Science, he worked at Mitsubishi Research Institute as a staff researcher. He mainly studied effects of strong correlations in condensed matter by using numerical techniques such as quantum Monte Carlo methods and the density-matrix renormalization method.

**Toshiyuki Koyama**

Chapter E.21

National Institute for Materials Science
Computational Materials Science Center
Ibaraki, Japan
koyama.toshiyuki@nims.go.jp

T. Koyama received the D.E. degree in materials science and engineering from Nagoya Institute of Technology in 1996. Since 2002 he is a senior researcher in the Computational Materials Science Center of the National Institute for Materials Science (NIMS). His current research focuses on the total free energy based analysis for the complex microstructure formation and the computer simulation of phase transformations based on the phase-field method.

**Gary W. Kramer**

Chapter B.4, Sect. 4.1

National Institute of Standards and
Technology
Biospectroscopy Group, Biochemical
Science Division
Gaithersburg, MD, USA
gary.kramer@nist.gov

Gary W. Kramer is the leader of the Biospectroscopy Group (BSG) at NIST. The BSG Group is responsible for developing, producing, and certifying instrument performance standards for molecular spectroscopy. Dr. Kramer, probably best known for his laboratory automation activities, received a Pioneer in Laboratory Robotics Award in 1985, the Association for Laboratory Automation (ALA) Achievement Award in 1998, and the ALA Charter Member Award in 2004.

Wolfgang E. Krumbein

BIOGEMA
Material Ecology
Edewecht, Germany
wek@biogema.de

Chapter D.14, Sect. 14.4

Wolfgang E. Krumbein, Professor of Geomicrobiology at Oldenburg, Germany, acted 10 years as Obmann in VDI Commissions, founded EUREKA-EUROCARE, served twice as President of the Committee of Leading Marine Scientists and was founding director of Institute for Chemistry and Biology of the Marine Environment, ICBM. Krumbein received the Credner-Price, the Lise Meitner - Alexander von Humboldt Price, and the Pasteur Medal. He presently works as Chairman of BIOGEMA, a consulting company on materials science and biodegradation in the fields of art restoration and intelligent building materials.

George Lamaze

National Institute of Standards and Technology
Analytical Chemistry Division
Gaithersburg, MD, USA
george.lamaze@nist.gov

Chapter B.4, Sect. 4.1

Dr. George Lamaze received his Ph.D. in nuclear physics in 1972 from Duke University. At NIST (formerly NBS) he measured standard neutron cross sections in the Center for Radiation Research using both LINAC and reactor sources. In the Analytical Chemistry Division his main activity was the measurement of depth profiles with cold neutrons. Dr. Lamaze retired in 2004.

Richard Lindstrom

National Institute of Standards and Technology, Mail stop 8395
Analytical Chemistry Division
Gaithersburg, MD, USA
richard.lindstrom@nist.gov

Chapter B.4, Sect. 4.1

Richard Lindstrom obtained his B.S. from the University of Wisconsin in 1963 and his Ph.D. from the University of California, San Diego in 1970. He did postdoctoral work with D. Lal at the Tata Institute of Fundamental Research in Mumbai, India and Raymond Davis, Jr. at Brookhaven National Laboratory. He is at NIST since 1972. His research areas are high-sensitivity and high-accuracy radionuclide measurement, conventional and prompt gamma neutron activation analysis, gamma-ray spectrometry, analytical chemistry, radiochemistry, and computer applications and nuclear data.

Haiqing Lin

Membrane Technology and Research, Inc.
Menlo Park, CA, USA
hlin@mtrinc.com

Chapter C.7, Sect. 7.6

Dr. Lin graduated from the University of Texas at Austin in 2005 and is currently a senior research engineer at Membrane Technology and Research, Inc, Menlo Park, CA. He is working on new membrane materials and processes for gas separations in refinery and natural gas applications.

Samuel Low

National Institute of Standards and Technology
Metallurgy Division, Materials Science and Engineering Laboratory
Gaithersburg, MD, USA
samuel.low@nist.gov

Chapter C.7, Sect. 7.3

Samuel Low is Materials Research Engineer at NIST for 27 years in the fields of properties and testing of materials. He began managing the NIST hardness standardization program in 1995. Currently, he is Chairman of the ASTM-International Committee on Indentation Hardness Testing, Head of the USA delegation to ISO TC164/SC3 on hardness testing, and Secretary of the CIPM Working Group on hardness.

Koji Maeda

The University of Tokyo
Department of Applied Physics
Tokyo, Japan
maeda@exp.t.u-tokyo.ac.jp

Chapter B.5

Professor Koji Maeda research focuses on defects in solids, especially extended ones and point defects in semiconductors. His recent activities are directed to atomic and molecular manipulation by electronic excitations and the development of various schemes of nanospectroscopical measurements using STM. His hobby is mountaineering.

**Willie E. May**

Chapter B.4

National Institute of Standards and Technology (NIST)
Chemical Science and Technology Laboratory (CSTL)
Gaithersburg, MD, USA
willie.may@nist.gov

Willie E. May obtained his B.S. from Knoxville College in 1968 and his Ph.D. from the University of Maryland in 1977. Dr. May is currently Director of the Chemical Science and Technology Laboratory (CSTL). CSTL is one of the seven technical Operational Units within the National Institute of Standards and Technology and has ≈ 325 technical staff members. CSTL is entrusted with the responsibility of developing, maintaining, advancing, and enabling the chemical measurement system for the United States of America. CSTL is organized into five Divisions along disciplinary lines: Biotechnology, Process Measurements, Surface and Microanalysis Science, Physical and Chemical Properties and Analytical Chemistry. He has a long list of awards among which are the Arthur Flemming Award for Outstanding Federal Service, 1986; NOBCCHE Percy Julian Award for Outstanding Research in Organic Analytical Chemistry and Presidential Rank Award of Meritorious Federal Executive, 1992, the Department of Commerce Gold Medal, 1992; the American Chemical Society Distinguished Service in the Advancement of Analytical Chemistry Award, 2001, the NOBCCHE Henry Hill Award for exemplary work and leadership in the field of chemistry, and the Science Spectrum Magazine Emerald Award, 2005.

**Takashi Miyata**

Chapter C.7, Sect. 7.5

Nagoya University
Department of Materials Science and Engineering
Nagoya, Japan
miyata@numse.nagoya-u.ac.jp

In 1972 Takashi Miyata earned his Dr.Eng. from Tokyo University. From 1972–1974 he was Lecturer in the Department of Materials Sciences and Engineering and from 1974–1990 Associate Professor at Nagoya University. He spent 1974–1976 as Guest Researcher at the Materialprüfungsanstalt (MPA), University of Stuttgart, Germany. From 1990 to present he is Professor in Department of Materials Science and Engineering, Nagoya University, Japan.

Hiroshi Mizubayashi

Chapter B.5

University of Tsukuba
Institute of Materials Science
Tsukuba, Ibaraki, Japan
mizuh@ims.tsukuba.ac.jp

Hiroshi Mizubayashi is a scientist in metal physics and Professor at the College of Engineering Sciences, University of Tsukuba, Japan. He has found new phenomena in amorphous alloys associated with a collective motion of many atoms and characteristic mechanical properties of nanostructured metals.

Kiyofumi Muro

Chapter C.11, Sect. 11.5

Chiba University
Faculty of Science, Department of Physics
Chiba, Japan
muro@physics.s.chiba-u.ac.jp

Professor Kiyofumi Muro's current research activities are spectroscopies based on fibre photonics, high sensitivity and high resolution spectroscopy based on microcavity, and terahertz spectroscopy of condensed matter with a femtosecond fibre laser. He has 15 years of industrial experience and more than 10 US patents in the development of diode-pumped solid-state lasers and high-power pump lasers.

**Rolf-Joachim Müller**

Chapter D.14, Sect. 14.3

Gesellschaft für Biotechnologische Forschung mbH
TU-BCE
Braunschweig, Germany
rmu@gbf.de

Dr. Rolf-Joachim Müller studied chemistry at the Technical University Braunschweig, Germany and made his dissertation on molecular characterization of high molecular synthetic polymers at the Institute of Technical Chemistry in Braunschweig. Since 1986, he is at the GBF, working on the characterization of biopolymers and the development and testing of biodegradable synthetic polymers.

**Yoshihiko Nonomura**

Chapter E.22

National Institute for Materials Science
Computational Materials Science Center
Ibaraki, Japan
nonomura.yoshihiko@nims.go.jp

Yoshihiko Nonomura received his Ph.D. at the Graduate School of Physics, University of Tokyo in 1994. Then he worked on classical and quantum random spin systems numerically at the Tokyo Institute of Technology and RIKEN. Currently he is studying superconducting vortex systems (especially effects of impurities and layered structures) using Monte Carlo and other numerical methods at the National Institute for Materials Science (NIMS) since 1998.

Jürgen Nuffer

Chapter D.16, Sect. 16.7

Fraunhofer Institute for Structural
Durability and System Reliability (LBF)
Darmstadt, Germany
juergen.nuffer@lbf.fraunhofer.de

Jürgen Nuffer studied Physics in Frankfurt/Main, Germany and obtained his Diploma degree in Physics in 1997. In 2000 he received his Ph.D. in Materials Science from the University of Technology Darmstadt. Since 2003 Dr. Nuffer is with the Fraunhofer Institute for Structural Durability and System Reliability (LBF) performing and coordinating research on the reliability assessment of complex adaptive and mechatronic systems.

Jan Obrzut

Chapter C.9, Sect. 9.5

National Institute of Standards and
Technology
Polymers Division
Gaithersburg, MD, USA
jan.obrzut@nist.gov

Jan Obrzut received a Ph.D. degree from Cracow Polytechnic, Poland in 1981. After a postdoctoral appointment at the Polymer Science Department and Radio Astronomy Observatory, University of Massachusetts, he joined IBM in 1988, where he conducted exploratory work on applications of dielectric and electrooptic materials for high speed electronics. He has been with the NIST Polymers Division since 1997, where he pursues research in metrology of dielectric and nanostructured hybrid materials.

**Hiroshi Ohtani**

Chapter E.20

Kyushu Institute of Technology
Department of Materials Science and
Engineering
Kitakyushu, Japan
ohtani@matsec.kyutech.ac.jp

Professor, Hiroshi Ohtani received doctor degree from Tohoku University (Japan) in 1985. His research activities have been concentrating on the thermodynamic analysis of alloys, ceramics and other materials using the CALPHAD method and first-principles calculations.

**Kurt Osterloh**

Chapter D.16, Sect. 16.2

Federal Institute for Materials Research
and Testing (BAM)
Division VIII.3
Berlin, Germany
kurt.osterloh@bam.de

After studies in chemistry and biology from 1969–1975 Dr. Osterloh received his Ph.D. in 1979. He did post-doctoral research in Munich (Germany) from 1980–1984, in Harrow/London (UK) from 1984–1986, in Mobile AL (USA) from 1986–1987, in New York NY (USA) 1987–1989, again in Munich (Germany) from 1989–1990, he spent the years from 1990–1994 in pharmaceutical industry in Berlin (Germany). After 5 years research at the Free University of Berlin (1995–2000) and development of ESR spectrometry at Magnetech in Berlin (1995–2000) he joined the Federal Institute for Materials Research and Testing (BAM) in 2000 working on radiology in safety and security applications.

Michael Pantke

Chapter D.14, Sect. 14.1

Federal Institute for Materials Research
and Testing (BAM)
Division IV.1, Materials and Environment
Berlin, Germany
michael.pantke@bam.de

Michael Pantke has a Diploma in Microbiology from the Free University of Berlin. He has experience in recognizing causes of damage by microbial attack on organic materials. He does pre-normative research for developing test methods for determining the behaviour of plastics to microbial attack. He works in co-operation with national (DIN) and international (CEN, IEC, ISO) standardization bodies. He is coordinator of international standardization activities in the field of biologically degradable plastics.

Karen W. Phinney

National Institute of Standards and Technology
Analytical Chemistry Division
Gaithersburg, MD, USA
karen.phinney@nist.gov

Chapter B.4, Sect. 4.1

Karen Phinney received her Ph.D. in analytical chemistry from the University of Hawaii-Manoa. She is currently a Research Chemist in the Analytical Chemistry Division at NIST. Her research interests include chiral separations, dietary supplements, forensic analysis, and various separation techniques, including capillary electrophoresis and supercritical fluid chromatography.

Rüdiger (Rudy) Plarre

Federal Institute for Materials Research and Testing (BAM)
Environmental Compatibility of Materials
Berlin, Germany
ruediger.plarre@bam.de

Chapter D.14, Sect. 14.2

Rudy Plarre is head of the working group Materials Protection against Fungi and Insects. This group conducts research in the field of applied pest control in urban environments including efficacy testing of integrated pest control strategies. Rudy is an entomologist by training and received his degree at the Free University of Berlin.

Kenneth W. Pratt

National Institute of Standards and Technology
Analytical Chemistry Division
Gaithersburg, MD, USA
kenneth.pratt@nist.gov

Chapter B.4, Sect. 4.1

Kenneth Pratt holds a Ph.D. from Iowa State University, Ames, USA. At NIST he is responsible for research and SRM certification in electrochemical analysis (coulometry, *pH*, conductimetry). He is active in international metrological organizations including CCQM and IUPAC working groups. Particular research interests are constant-current coulometry, classical analysis, absolute measurement of electrolytic conductivity and primary *pH* metrology.

Michael H. Ramsey

University of Sussex
Department of Biology and
Environmental Science, Centre for
Environmental Research
Brighton, UK
m.h.ramsey@sussex.ac.uk

Chapter A.2

Professor Michael H. Ramsey has published over 100 scientific papers, mainly on aspects of uncertainty in sampling and in measurement, as well as the effects of this uncertainty on decision making. Current research projects include investigation of uncertainty from sampling of contaminated land (DTI/CLAIRE funded) and contaminated food (FSA funded). He is currently Chair of both the Eurachem/Eurolab/Citac/Nordtest Working Group on Uncertainty from Sampling.

Gunnar Ross

Magnet-Physik Dr. Steingroever GmbH
Köln, Germany
ross@magnet-physik.de

Chapter C.10, Sect. 10.2

Dr. Ing. Gunnar Ross is Development and Production Manager for measuring equipment for magnetic quantities and magnetic material properties. He is Head of a Calibration Laboratory for magnetic quantities that is accredited in the Deutscher Kalibrierdienst (DKD).

Steffen Rudtsch

Physikalisch-Technische Bundesanstalt (PTB)
Dept. 7.4
Berlin, Germany
steffen.rudtsch@ptb.de

Chapter C.8

Dr. Steffen Rudtsch has 12 years of experience in thermophysical properties measurements at the Brandenburg Technical University at Cottbus. Between 1999 and 2002 he was working at the Physikalisch-Technische Bundesanstalt (PTB), Germany and at the National Institute of Standards and Technology (NIST), USA on adiabatic and differential scanning calorimetry. His current field of work is the development of a new generation of metallic, fixed points of the International Temperature Scale of 1990 (ITS-90) at the temperature department of PTB.

**Lane Sander**

Chapter B.4, Sect. 4.1

National Institute of Standards and Technology
Chemical Science and Technology
Laboratory, Analytical Chemistry Division
Gaithersburg, MD, USA
lane.sander@nist.gov

Lane Sander attended the University of Washington and received a Ph.D. in analytical chemistry in 1982. He is currently Leader of the Organic Chemical Metrology Group, in the Analytical Chemistry Division. Research interests include synthesis and characterization of novel stationary phases for liquid chromatography; elucidation of solute retention mechanisms; molecular modeling; and chromatographic metrology in environmental, clinical and food science disciplines.

Erich Santner

Chapter D.13

Federal Institute for Materials Research and Testing (BAM)
Berlin, Germany
erich.santner@bam.de

Erich Santner studied physics in Berlin (Freie Universität) where he received his D.Sc. for investigations in solid state physics. In the following years he concentrated on radiation protection and nuclear fuel analysis at the Federal Institute for Materials Research and Testing (BAM), intermittently working for one year as a technical officer in the Ministry of Economy in Bonn, Germany. He is now head of the Division of Tribology and Wear Protection at BAM. His current research and development activities are focused on the tribology of thin hard coatings, failure analysis, and on micro- and nanotribology.

Michele Schantz

Chapter B.4, Sect. 4.1

National Institute of Standards and Technology
Analytical Chemistry Division
Gaithersburg, MD, USA
michele.schantz@nist.gov

Dr. Michele Schantz is a research chemist in the Analytical Chemistry Division at the National Institute of Standards and Technology (NIST). She is currently the team leader for the gas chromatography team and has been involved in the certification of numerous environmental Standard Reference Materials and coordinating and participating in interlaboratory studies for organics in marine tissue and sediment, marine mammal blubber, and PM.2.5 air particulate.

**Guenter Schmitt**

Chapter D.14

Iserlohn University of Applied Sciences
Laboratory for Corrosion Protection
Iserlohn, Germany
schmitt.g@fh-swif.de

Professor Guenter Schmitt received his Ph.D. in Chemistry in 1971 from RWTH Aachen, Germany. He had professorships at Universities of Aachen, Bochum and Iserlohn, Germany. He is a member of major national and international scientific societies, the past president of GfKORR, the German Society for Corrosion Protection and Chairman of the EFC working Group Corrosion and Scale Inhibition. He is a NACE Fellow and was awarded the Rahmel-Schwenk-Medal of GfKORR.

**Bernd Schumacher**

Chapter C.9, Sect. 9.2

Physikalisch-Technische Bundesanstalt
Department 2.1 DC and Low Frequency
Braunschweig, Germany
bernd.schumacher@ptb.de

Dr. Bernd Schumacher received the Ph.D. degree in Electrical Engineering in 1991 from the University of Technology, Aachen, Germany. He joined the Physikalisch-Technische Bundesanstalt (PTB) Braunschweig, Germany, in 1991. He is working on measurement techniques for resistance standards. His research topics are the quantum Hall resistance standard and resistance measurement bridges based on the cryogenic current comparator.

Karin Schwibbert

Chapter D.14, Sect. 14.6

Federal Institute for Materials Research and Testing (BAM)
Division IV.1 Materials and Environment
Berlin, Germany
karin.schwibbert@bam.de

Dr. Karin Schwibbert is currently a research associate for microbiology at the Federal Institute for Materials Research and Testing (BAM). She obtained her Ph.D. from the University of Bonn in 1999 and continued her research at the University of Münster in the Department of Biochemistry. Her scientific interests are in the areas of: soil microbiology, biodeterioration and biodegradation, and the development of methodologies for identification and classification of microorganisms.

Michael Schütze

Karl-Winnacker-Institut
DECHEMA e.V.
Frankfurt am Main, Germany
schuetze@dechema.de

Chapter D.12

Professor Michael Schütze earned his Dipl.Ing. in Materials Science from the University of Erlangen-Nürnberg, Germany in 1978 and his Dr.Ing. from RWTH Aachen in 1983, followed by his State Doctorate in 1991. Since 1996 he is Director of DECHEMA's Karl-Winnacker-Institut in Frankfurt/Main, Germany and has a full professorship at RWTH Aachen since 1998. He was awarded the Friedrich-Wilhelm-Award (RWTH Aachen, 1991), the Rahmel-Schwenk-Medal (1999). Dr. Schütze was the past chairman of the Gordon Research Conference on Corrosion, is Chairman of EFC Working party and Convenor of ISO work group on high temperature corrosion. He has more than 200 publications, owns 18 patents and has written 6 books.

**John Henry Scott**

National Institute of Standards and
Technology
Surface and Microanalysis Science
Division
Gaithersburg, MD, USA
johnhenry.scott@nist.gov

Chapter B.4, Sect. 4.2

John Henry currently works as a physicist in the Microanalysis Research Group at NIST in Gaithersburg, MD. His research involves chemical characterization techniques in electron beam instruments, primarily analytical transmission electron microscopy (ATEM), as well as Monte Carlo simulation, correction procedures for quantitative microanalysis, and multivariate statistical methods.

**Martin Seah**

National Physical Laboratory
Quality of Life Division
Teddington, UK
martin.seah@npl.co.uk

Chapter B.6

Dr. Martin Seah is head of a research group at NPL leading work in standards for measurements and quantification in the surface analysis techniques of Auger electron spectroscopy, X-ray photoelectron spectroscopy, static secondary ion mass spectrometry and atomic force microscopy. He is Chair of a subcommittee for ISO TC 201 on Surface Chemical Analysis and set up relevant activities in the Consultative Committee for Amount of Substance and in VAMAS. He is a Fellow of the Institute of Physics, the Institute of Materials, Minerals and Mining and the American Vacuum Society. He has won awards from the American Society for Metals, American Vacuum Society, Institute of Physics and International Union for Vacuum Science, Technique and Applications.

Masato Shimono

National Institute for Materials Science
Computational Materials Science Center
Tsukuba, Japan
shimono.masato@nims.go.jp

Chapter E.17

Dr. Masato Shimono is research scientist at the National Institute for Materials Science (NIMS), Particle Simulation and Thermodynamics Group. He is currently working on projects in materials science and computational physics.

John R. Sieber

National Institute of Standards and
Technology
Chemical Science and Technology
Laboratory
Gaithersburg, MD, USA
john.sieber@nist.gov

Chapter B.4, Sect. 4.1

Dr. John R. Sieber is a research chemist in the Inorganic Chemical Metrology Group of the Analytical Chemistry Division, National Institute of Standards and Technology. He specializes in X-ray fluorescence spectrometry. Dr. Sieber spent nine years in the petroleum industry and is a member of ASTM International.

**Franz-Georg Simon**

Chapter D.15, Sect. 15.1

Federal Institute for Materials Research and Testing (BAM)
Waste Treatment and Remedial Engineering
Berlin, Germany
franz-georg.simon@bam.de

Dr. Simon studied chemistry in Frankfurt/Main (Diploma 1985) and Mainz (Ph.D. 1989), Germany and gained a master's degree in business engineering (AKAD Zurich, Switzerland 1997). He joined the Federal Institute for Materials Research and Testing (BAM) as Head of Division in 1998 after working for eight year in an industrial research centre in Switzerland. His Scientific activities encompass research on thermal waste treatment, groundwater remediation and ecomaterials.

**John Small**

Chapter B.4, Sect. 4.2

National Institute of Standards and Technology
Surface and Microanalysis Science Division
Gaithersburg, MD, USA
john.small@nist.gov

John A. Small is the Group Leader of the Microanalysis Research Group and a Senior Research Chemist in the Surface and Microanalysis Science Division at the National Institute for Standards and Technology (NIST). His research has focused on the quantitative chemical analysis of individual particles using X-ray microanalytical techniques. Recent research interests include X-ray microanalysis of nanoscale particles. He currently is a member of (NEHI) under the NNI, and works with the ESH working group under the NNI-Chi CBAN.

Melody V. Smith

Chapter B.4, Sect. 4.1

National Institute of Standards and Technology
Physical Science Technician (WEG),
Biospectroscopy Group, Biochemical Science Division
Gaithersburg, MD, USA
melody.smith@nist.gov

Melody Smith is a physical science technician who has been with the Analytical Chemistry Division of the National Institute of Standards and Technology since 1981. Before that, she was with the NBS Office of Standard Reference Materials. Her duties in the Biospectroscopy Group include the production and certification of spectrophotometric Standard Reference Materials.

Petra Spitzer

Chapter C.9, Sect. 9.3

Physikalisch-Technische Bundesanstalt (PTB)
Dept. 3.13 Metrology in Chemistry
Braunschweig, Germany
petra.spitzer@ptb.de

The emphasis of Ms. Spitzer's work is the development and application of primary electrochemical methods. She is head of the working group "Metrology in Electrochemistry" at the Physikalisch-Technische Bundesanstalt (PTB), Braunschweig, Germany. By education Ms. Spitzer is a physical chemist and received her diploma as chemist from the Humboldt University in Berlin, Germany. Before 1991 she worked on electrochemistry and adsorption at the Central Institute of Physical Chemistry, former Academy of Science.

**Ina Stephan**

Chapter D.14, Sect. 14.2

Federal Institute for Materials Research and Testing (BAM)
Division IV.1 Biology in Materials Protection and Environmental Issues
Berlin, Germany
ina.stephan@bam.de

Dr. Ina Stephan has a Ph.D. in Wood Science and Technology from the University of Hamburg, Germany and is head of the working group on the resistance of materials to microorganisms at the Federal Institute for Materials Research and Testing (BAM). Her main interests are in the testing of materials against fungi, algae and bacteria in a meaningful manner and the international harmonization of test standards for biodeterioration.

**Stephan J. Stranick**

Chapter B.4, Sect. 4.2

National Institute of Standards and Technology
Department of Commerce, Surface and Microanalysis Science Division
Gaithersburg, MD, USA
stranick@nist.gov

Stephan Stranick received a Ph.D. in Chemistry from The Pennsylvania State University in 1995. Stephan is currently a Research Chemist in the Chemical Science and Technology Laboratory of the National Institute of Standards and Technology where his present research focuses on the development of novel super-resolution probes of surface physicochemical properties. He has published over fifty papers on the subject and has been awarded fourteen patents associated with scanning probe microscopies for chemical and electrical characterization. Stephan's awards include the American Chemical Society's Nobel Laureate Signature Award and Arthur F. Findeis Award.

Hans-Henning Strehblow

Chapter D.12

Heinrich-Heine-Universität
Institute of Physical Chemistry
Düsseldorf, Germany
henning@uni-duesseldorf.de

Dr. Hans-Henning Strehblow is Professor of Physical Chemistry at the Heinrich-Heine-Universität, Düsseldorf, Germany since July 1982. He studied Chemistry at Freie Universität, Berlin (1959–1964) where he also earned his Ph.D. in Physical Chemistry (1971) as well as his State Doctorate in Physical Chemistry (1977). He is Fellow of the Electrochemical Society since 2005. His professional interests are electrochemistry, corrosion, surface analysis and physical chemistry of surfaces.

Tetsuya Tagawa

Chapter C.7, Sect. 7.5

Nagoya University
Department of Materials Science and Engineering
Nagoya, Japan
tagawa@numse.nagoya-u.ac.jp

Tetsuya Tagawa is Associate Professor at Nagoya University since 2000, where he also received his Ph.D. in 1994.

Akira Tezuka

Chapter E.19

National Institute of Advanced Industrial Science and Technology
Advanced Manufacturing Research Institute
Tsukuba, Japan
tezuka.akira@aist.go.jp

Dr. Akira Tezuka received his Ph.D. from the University of Tokyo in 1994 and started his career as a researcher at Hitachi Ltd. in 1994. His current interests are on combined multi-scale/multi-physics computational mechanics with advanced modeling schemes including adaptivity and extended-FEM with the help of parallel computing. He is member of the Executive Council of the Japan Society for Computational Engineering and Science and member of the General Council of the International Association of Computational Mechanics.

Yo Tomota

Chapter C.7, Sect. 7.4

Ibaraki University
Department of Materials Science, Faculty of Engineering
Hitachi, Japan
tomota@mx.ibaraki.ac.jp

Professor Yo Tomota's current research topics include neutron diffraction studies of phase transformation, microstructural evolution and mechanical behavior of ecomaterials. The development of environmentally compatible materials, so called "ecomaterials" are his concern for realizing a sustainable human society. Therefore Professor Tomota is studying material flow and recycling, ecomaterials design etc. Nanostructure analysis using neutron diffraction is a powerful tool to develop nanocrystalline ecomaterials and to study the deformation and fracture of materials.

John Travis

Chapter B.4, Sect. 4.1

National Institute of Standards and Technology
Analytical Chemistry Division (Retired)
Gaithersburg, MD, USA
john.travis@nist.gov

John Travis joined NBS/NIST after earning his Ph.D. in physics from the University of Texas in 1967. His research generated over 85 papers in Mössbauer spectroscopy, applications of tunable lasers to chemical analysis, Fourier transform spectroscopy, atomic emission and molecular absorption spectrometry. He retired in October of 2004, becoming an Emeritus Scientist pursuing intrinsic standards for molecular absorption spectrometry.

Gregory C. Turk

National Institute of Standards and Technology
Analytical Chemistry Division
Gaithersburg, MD, USA
turk@nist.gov

Chapter B.4, Sect. 4.1

Dr. Gregory C. Turk is leader of the Inorganic Chemical Metrology Group at the National Institute of Standards and Technology, where he has worked in the area of spectrochemistry since 1976. His research background includes the use of laser spectroscopy for trace metal analysis, including the development of Laser Enhanced Ionization Spectrometry. Present research includes the development of improved strategies for instrument calibration in spectrochemical analysis. He received his Ph.D. degree from the University of Maryland.

**Thomas Vetter**

National Institute of Standards and Technology (NIST)
Analytical Chemistry Division
Gaithersburg, MD, USA
thomas.vetter@nist.gov

Chapter B.4, Sect. 4.1

Thomas Vetter is an inorganic analytical chemist at NIST. Over the past 20 years at NIST he has assayed major constituents in numerous Standard Reference Materials by gravimetry coupled with instrumental techniques and by gravimetric titrimetry. In addition, over the past 10 years, he has promoted a step-wise quantification of measurement uncertainty to improve measurement quality.

**Andrew Wallard**

Pavillon de Breteuil
Bureau International des Poids Et Mesures
Sèvres, France
awallard@bipm.org

Chapter A.1

Professor Wallard has been Director of the BIOPM since January 2004. The BIPM's task is to ensure uniformity of measurements world-wide and has interests in physics, engineering, chemistry, laboratory medicine and other areas in which traceable measurement is important.

Joachim Wecker

Siemens AG
Corporate Technology
Erlangen, Germany
joachim.wecker@siemens.com

Chapter C.10

Dr. Joachim Wecker is Senior Principal Research Scientist and Project Manager at Siemens, Erlangen, Germany. He earned his Ph.D. in Physics from the University of Göttingen. Previous and current field of work are hard and soft magnetic materials, superconductors, thin film magnetic and organic electronic devices. Dr. Wecker is member of the advisory board of the German Materials Society, DGM and the Magnetism section of the German Physical Society.

Wolfhard Wegscheider

Montanuniversität Leoben
General and Analytical Chemistry
Leoben, Austria
wegschei@unileoben.ac.at

Chapter A.2

Wolfhard Wegscheider is Professor of General and Analytical Chemistry at the University of Leoben, Austria. He received his education from the Graz University of Technology majoring in Technical Chemistry with a specialisation in Biochemistry and Food Chemistry. As Fulbright Scholar he worked in Denver, CO, mainly on energy-dispersive X-ray fluorescence spectrometry. Much of his research centers on the development of chemometric procedures for analytical chemical problems. Professor Wegscheider is member of several learned societies, past chairman of CITAC and EURACHEM, has cooperation on International Traceability in Analytical Chemistry, Austrian Delegate to EURACHEM where he is member of the Executive Committee, of the Working Group on Education and Training, of the Working Group on Measurement Uncertainty and Traceability, and of the Working Group Analytical Quality Assurance at Universities. Currently he serves as Vice-President of the Austrian Society of Analytical Chemistry – ASAC. He is a consultant to the Austrian Federal Ministry for Agriculture, Forestry, Environment and Water Management and a lead auditor in the Austrian Accreditation of Laboratories.

**Alois Wehrstedt**

Chapter C.7, Sect. 7.3, Appendix

DIN Deutsches Institut für Normung
Normenausschuss Materialprüfung (NMP)
Berlin, Germany
alois.wehrstedt@din.de

Alois Wehrstedt studied materials science at the Technical University Dresden, Germany. He is manager of the department for materials testing at the Central Institute for Solid State Physics and Material Science in Dresden. Since 1989 he worked in the Standardization Committee for Materials Testing (NMP) of the German Institute for Standardization in Berlin for which he is the manager since 2005. Since 1994 he is the secretary of the international standardization committee ISO/TC 164/SC 3 Hardness Testing of Metallic Materials.

**Michael Welch**

Chapter B.4, Sect. 4.1

National Institute of Standards and Technology
Gaithersburg, MD, USA
michael.welch@nist.gov

Dr. Welch received a Ph.D. in analytical chemistry from Arizona State University in 1976 and has been at the National Institute of Standards and Technology since 1978. His research interests focus on development of mass spectrometry based reference methods and standard reference materials for organic analytes in blood, drugs of abuse in urine, hair, and other matrices, and nutrients in foods.

Ulf Wickström

Chapter D.15, Sect. 15.3

SP Swedish National Testing and Research Institute
Department of Fire Technology
Borås, Sweden
ulf.wickstrom@sp.se

Professor Ulf Wickström is heading the department of fire technology at the Swedish National Testing and Research Institute (SP). The department has a staff of about 50 involved in fire testing and research and is one of the leading laboratories of its kind in the world. Professor Wickström has a Ph.D. from the Lund University of Technology (1979) in fire technology, a Master of Science from University of California (1977), Berkeley. Professor Wickström's special scientific interest is heat transfer analysis of structures exposed to fire where he has published several scientific papers. Among other things he has developed the computer code TASEF for calculating temperature in fire exposed concrete and steel structures.

Sheldon M. Wiederhorn

Chapter C.7, Sect. 7.1

National Institute of Standards and Technology
Materials Science and Engineering Laboratory
Gaithersburg, MD, USA
sheldon.wiederhorn@nist.gov

Sheldon M. Wiederhorn received his B.S. degree in 1956 from Columbia University and his Ph.D. degree in 1960 from the University of Illinois. He joined the National Institute of Standards and Technology in 1963, where he developed methods for quantifying subcritical crack growth in glasses and ceramics. He was elected a member of the National Academy of Engineering in 1991.

**Scott Wight**

Chapter B.4, Sect. 4.2

National Institute of Standards and Technology
Surface and Microanalysis Science Division
Gaithersburg, MD, USA
scott.wight@nist.gov

Scott Wight is a Research Chemist in the Surface and Microanalysis Science Division at NIST. Scott received his B.S. in Chemistry from State University of New York, Plattsburgh in 1986 and a MS in analytical-nuclear-environmental chemistry from the University of Maryland in 1989. His current research is in Auger electron spectroscopy and he is active in ASTM E42 and ISO TC 201 committees for surface analysis.

**Michael Winchester**

Chapter B.4, Sect. 4.1

National Institute of Standards and Technology
Analytical Chemistry Division
Gaithersburg, MD, USA
mrw@nist.gov

Dr. Michael Winchester has been a Research Chemist at NIST for over fifteen years (first two years as a National Research Council Postdoctoral Fellow). His research focuses mainly on plasma source atomic spectroscopy. He is also involved in the production and certification of Standard Reference Materials. Dr. Winchester earned the Ph.D. in analytical chemistry from Clemson University in 1990.

Noboru Yamada

Matsushita Electric Industrial Company, Ltd.
Optical Media Group, Storage Media
Systems Development Center
Moriguchi, Japan
yamada.noboru@jp.panasonic.com

Chapter C.11, Sect. 11.6

Dr. Noboru Yamada graduated from Kyoto University and entered the Central Research Laboratory of Matsushita Electric in 1974. He first found an epoch-making phase-change in $\text{GeTe} - \text{Sb}_2\text{Te}_3$ in 1987 and developed DVD-RAM media in 1998. He obtained his Ph.D. in engineering from Kyoto University in 2001 and received the Matsushita science prize in 2001 and 24th JJAP Paper Award from the Japan Applied Physics Society in 2002.

Rolf Zeisler

National Institute of Standards and
Technology
Analytical Chemistry Division
Gaithersburg, MD, USA
rolf.zeisler@nist.gov

Chapter B.4, Sect. 4.1

Dr. Rolf Zeisler joined NIST in 1978 with his degree from the Technical University, Munich, Germany (1974) on instrumental neutron activation analyses of tissues and their application to investigations of metallosis. Activation analysis formed the core of his research, expanding the technique's applications in the life sciences and in chemical metrology. Post doctoral studies at Texas A&M University, assignment to the IAEA Laboratories, Austria, and many collaborations allowed him to explore the various forms of nuclear based analysis.

Uwe Zscherpel

Federal Institute for Materials Research
and Testing (BAM)
Division "NDT – Radiological Methods"
Berlin, Germany
uwez@bam.de

Chapter D.16, Sect. 16.2

Dr. Uwe Zscherpel received his Ph.D. from the University of Leipzig, Germany, on Fourier transform infrared spectroscopy of zeolites. In 1992 he changed to non-destructive testing and since 1996 he is head of the working group "Digital Radiology and Image Analysis" at the Federal Institute for Materials Research and Testing (BAM), Berlin, Germany. His area of expertise is digital image processing in industrial radiology, including NDT film digitization, digital image analysis, pattern recognition and digital reference catalogues for weldings and castings. Additional working fields are new radiographic image detectors such as imaging plates and digital detector arrays for industrial applications, standardization and reliability.

Adolf Zschunke

Leipzig, Germany
zschunke35@aol.com

Chapter A.2

Adolf Zschunke was head of the department Analytical Chemistry; Reference Materials at the Federal Institute for Materials Research and Testing (BAM) and Professor of Analytical Chemistry at the Humboldt-University in Berlin, Germany. He was chairman of the international working group on Reference Materials of EURACHEM, EUROLAB, EUROMET and EA. He retired in 2002. He is still member of Executive Committee of EURACHEM.
