
Springer Handbook of Materials Measurement Methods

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical sciences and engineering. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of physical and technical information.

The volumes will be designed to be useful as readable desk reference books to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Springer Handbook of Materials Measurement Methods

Horst Czichos, Tetsuya Saito, Leslie Smith (Eds.)

With CD-ROM, 970 Figures and 158 Tables

Springer

Preface

The ability to compare measurements between laboratories is one of the cornerstones of the scientific method. All scientists and engineers are trained to make accurate measurements and a comprehensive volume that provides detailed advice and leading references on measurements to scientific and engineering professionals and students is always a worthwhile addition to the literature. The principal motivation for this Springer Handbook of Materials Measurement Methods, however, stems from the increasing demands of technology for measurement results that can be used reliably anywhere in the world. These demands are especially intense in materials science and technology, where many characterization methods are needed, from scientific *composition–structure–property* relations to technological *performance–quality–reliability* assessment data, during the various stages of materials and product cycles.

In order for new materials to be used and incorporated into practical technology, their most important characteristics must be known well enough to justify large research and development costs. Furthermore, the research may be performed in one country while the engineering design is done in another and the prototype manufacture in yet another region of the world. This great emphasis on international comparison means that increasing attention must be paid to internationally recognized standards and calibration methods that go beyond careful, internally consistent, methods. This handbook was developed to assist scientists and engineers in both industry and academe in this task.

The useful properties of materials are generally responses to external fields under specific conditions. The stimulus field and environmental conditions must be completely specified in order to develop a reproducible response. Standard test methods describe these conditions and the Chapters and an Appendix in this book contain references to the relevant international standards.

We sought out experts from all over the world that have been involved with concerns such as these. We were extremely fortunate to find a distinguished set of authors who met the challenge: to write brief chapters that nonetheless contain specific useful recommendations and resources for further information. This is the hallmark of a successful handbook. While the diverse nature of the topics covered has led to different styles of presentation, there is a commonality of purpose evident in the chapters that come from the authors' understanding of the issues facing researchers today.

This handbook would not have been possible without the visionary support of Dr. Hubertus von Riedesel, who embraced the concept and encouraged us to pursue it. We must also acknowledge the constant support of Dr. Werner Skolaut, whose technical editing has met every expectation of professional excellence. Finally, throughout the entire development of the handbook we were greatly aided by the able administrative support of Ms. Daniela Bleienberger.

1. Measurement Principles and Structures

Part A of this handbook introduces the materials measurement system, proceeding from general to specific aspects:

- The present chapter describes the basic elements of metrology, the system that allows measurements made in different laboratories to be confidently compared. As the aim of this chapter is to give an overview of the whole field, the development of metrology from its roots to the birth of the meter convention and metrology in the 21st century is given.
- Chapter 2 deals with measurement strategy and quality and presents the elements required to make reliable measurements. This includes sampling, traceability, comparability, accuracy, measurement uncertainty, reference procedures, and human aspects in a laboratory.
- Chapter 3 reviews the basic features of materials as a basis for the classification of the various methods used to characterize materials by analysis, measurement, testing, modeling, and simulation.

1.1 What Is Metrology?

Metrology is generally defined as the “science of measurement.” This, of course, includes its application to a huge range of measurements in science, industry, the environment, as well as in healthcare or food quality; metrology is all around each and every one of us. Measurement provides us with a reference for our daily life in the measurement of time, weight, length and all the hundreds of measurements that influence us.

In this general introduction to the subject, we shall first look at some of the early measurements and the

need to put them on a sound basis, and then review the development of the worldwide system of standards. We will then take a look at the institutions and infrastructure which now exists to coordinate accurate measurement throughout the world and the acceptance of such measurements by those who need to use them. Finally, some of the new and emerging trends and issues which characterize the subject and which bring their own scientific, economic or social challenges are addressed.

1.2 The Roots and Evolution of Metrology

From the earliest times it has been important to compare things through measurements. This had much to do with

fair exchange, barter, or trade between communities and simple weights such as the stone or measures such as

the cubit were common. At this level, parts of the body such as hands and arms were adequate for most needs. Initially, wooden length bars were easy to compare and weights could be weighed against each other. Various forms of balance were commonplace in early history and in religion. Egyptian tomb paintings show the Egyptian god Anubis weighing the soul of the dead against an ostrich feather – the sign of purity (Fig. 1.1). Noah’s Ark was, so the book of Genesis reports, 300 cubits long, by 50 cubits wide and 30 cubits high. No one really knows why it was important to record such details but the Bible, as just one example, is littered with metrological references and the symbolism of metrology was part of early culture and art.

A steady progression from basic artifacts to naturally occurring reference standards has been part of the entire history of metrology. Metrologists are familiar with the use of the carob seed in the early Mediterranean civi-

lizations as a natural reference for length and for weight and hence volume. The Greeks were early traders who paid attention to metrology and they were known to keep copies of the weights and measures of the countries with which they traded.

The Magna Carta of England set out a framework for a citizen’s rights and established “one measure throughout the land.” Kings and queens took interest in national weights and measures, Fig. 1.2 shows the Winchester yard, the bronze rod that was the British standard from 1497 to the end of the 16th century. The queen’s mark we see here is that of Elizabeth the First (1558–1603). In those days, the acre was widely used as a measurement and derived from the area that a team of oxen could plough in a day. Ploughing an acre meant that you had to walk 66 furlongs, a linear dimension measured in rods.

The problem with many length measurements was that the standard was made of the commonly available metals brass or bronze, which have a fairly large coefficient of expansion. Iron or steel measures were not developed for a couple of centuries. Brass and bronze therefore dominated the length reference business until the early 19th century by which time metallurgy had developed well enough – though it was still something of a black art – for new, lower-expansion metals to be used and reference temperatures quoted. The UK imperial references were introduced in 1854 and reproduced in Trafalgar Square in the center of London (Fig. 1.3) and the British Empire’s domination of international commerce saw the British measurement system adopted in many of its colonies.

In the mid 18th century, Britain and France compared their national measurement standards and realized that they differed by a few percent for the same unit. Although the British system was reasonably consistent throughout the country, the French found that differences of up to 50% were common in length measurement within France. The ensuing technical debate was the start of what we now accept as the metric system. France led the way, and even in the middle of the French revolution the Academy of Science was asked to “deduce an invariable standard for all the measures and all the weights.” The important word was “invariable.” There were two options available for the standard of length: the seconds’ pendulum and the length of the earth’s meridian. The obvious weakness of the pendulum approach was that its period depended on the local acceleration due to gravity. The Academy therefore chose to measure a portion of the earth’s circumference and relate it to the official French meter. Delambre and Méchain, who were entrusted with a survey of the meridian between Dunkirk

Fig. 1.1 Anubis

Fig. 1.2 Winchester Yard

and Barcelona, created the famous Mètre des Archives, a platinum end standard.

The international nature of measurement was driven, just like that of the Greek traders of nearly 2000 years before, by the need for interoperability in trade and advances in engineering measurement. The displays of brilliant engineering at the Great Exhibitions in London and Paris in the 19th century largely rested on the ability to measure well. The British Victorian engineer Joseph Whitworth coined the famous phrase “you can only make as well as you can measure” and pioneered accurate screw threads. He immediately saw the potential of end standard gauges rather than line standards where the reference length was defined by a scratch on the surface of a bar. The difficulty, he realized, with line standards was that optical microscopes were not then good enough to compare measurements of line standards well enough for the best precision engineering. Whitworth was determined to make the world’s best measuring machine. He constructed the quite remarkable “millionth machine” based on the principle that touch was better than sight for precision measurement. It appears that the machine had a “feel” of about 1/10 of a thousandth of an inch. Another interesting metrological trend at the 1851 Great Exhibition was military: the word “calibrate” comes from the need to control the calibre of guns.

At the turn of the 19th century, many of the industrialized countries had set up National Metrology Institutes, generally based on the model established in Germany with the Physikalisch Technische Reichsanstalt, which was founded in 1887. The economic benefits of such a national institute were immediately recognized and, as a result, scientific and industrial organizations in a number of industrialized countries began pressing their Governments to make similar investments. In the UK, the British Association for the Advancement of Science reported that, without a national laboratory to act as a focus for metrology, the country’s industrial competitiveness would be weakened. The cause was taken up more widely and the UK set up the National Physical Laboratory (NPL) in 1900. The US created the National Bureau of Standards in 1901 as a result of similar industrial pressure. The major national metrology institutes (NMIs), however, had a dual role. In general, they were the main focus for national research programs on applied physics and engineering. Their scientific role in the development of units – what became the International System of Units, the SI – began to challenge the role of the universities in the measurement of the fundamental constants. This was especially true after

Fig. 1.3 Imperial length standards. Trafalgar Square, London

the development of quantum physics in the 1920s and 1930s. Most early NMIs therefore began with two major elements to their mission:

- a requirement to satisfy industrial needs for accurate measurements, through standardization and verification of instruments; and
- determining the physical constants so as to improve and develop the SI system.

The new industries which emerged after the First World War made huge demands on metrology and, together with mass production and the beginnings of multinational production sites, raised new challenges which brought NMIs into direct contact with companies, so causing a close link to develop between them. At that time, and even up to the mid 1960s, nearly all calibrations and measurements that were necessary for industrial use were made in the NMIs, and in the gauge rooms of the major companies, as most measurements were in engineering metrology. The industries of the 1920s, however, developed a need for electrical and optical measurements so NMIs expanded their coverage and their technical abilities.

The story since then is one of steady technical expansion until after the Second World War. In the 1950s, though, there was a renewed interest in a broader applied focus for many NMIs so as to develop civilian applications for much of the declassified military technology. The squeeze on public budgets in the 1970s and 1980s saw a return to core metrology and many other institutions, public and private, took on the responsibility for developing many of the technologies, which had been initially fostered at NMIs. The NMIs adjusted to their new roles. Many restructured and found new, often improved, ways of serving industrial needs. This recreation of the NMI role was also shared by most Governments, which increasingly saw

them as tools of industrial policy with a mission to stimulate industrial competitiveness and, at the end of

the 20th century, to reduce technical barriers to world trade.

1.3 BIPM: The Birth of the Meter Convention

During the 1851 Great Exhibition and the 1860 meeting of the British Association for the Advancement of Science (BAAS) a number of scientists and engineers met to develop the case for a single system of units based on the metric system. This built on the early initiative of Gauss to use the 1799 meter and kilogram in the Archives de la République, Paris and the second, as defined in astronomy, to create a coherent set of units for the physical sciences. In 1874, the three-dimensional CGS system, based on the centimeter, gram and second, was launched by the BAAS. However, the size of the electrical units in the CGS system were not particularly convenient and, in the 1880s, the BAAS and the International Electrotechnical Commission (IEC) approved a set of practical electrical units based on the ohm, the ampere, and the volt. Parallel to this attention to the units, a number of governments set up what was then called the Committee for Weights and Money, which in turn led to the 1870 meeting of the Commission Internationale du Mètre. Twenty-six countries accepted the invitation of the French Government to attend; however, only 16 were able to come as the Franco-Prussian war intervened, so the full committee did not meet until 1872. The result was the Convention du Mètre and the creation of the Bureau International des Poids et Mesures, the BIPM (in English the International Bureau of Weights and Measures), in the old Pavillon de Breteuil at Sèvres (Fig. 1.4), as a permanent scientific agency supported by the signatories to the convention. As this required the support of

governments at the highest level the Meter Convention was not finally signed until 20th May 1875.

The BIPM's role was to “establish new metric standards, conserve the international prototypes” (then the meter and the kilogram) and “to carry out the comparisons necessary to assure the uniformity of measures throughout the world.” As an intergovernmental, diplomatic treaty organization, the BIPM was placed under the authority of the General Conference on Weights and Measures (CGPM). A committee of 18 scientific experts, the International Committee for Weights and Measures (CIPM), now supervises the running of the BIPM. The aim of the CGPM and the CIPM was, and still is, to assure the “international unification and development of the metric system.” The CGPM now meets every four years to review progress, receive reports from the CIPM on the running of the BIPM and to establish the operating budget of the BIPM, whereas the CIPM meets annually to supervise the BIPM's work.

When it was set up, the staff of the BIPM consisted of a director, two assistants and the necessary number of employees. In essence, then, a handful of people began to prepare and disseminate copies of the international prototypes of the meter and the kilogram to member states. About 30 copies of the meter and 40 copies of the prototype kilogram were distributed to member states by ballot. Once this was done, some thought that the job of the BIPM would simply be that of periodically checking (in the jargon, verifying) the national copies of these standards. This was a short-lived vision as the early investigations immediately showed the importance of reliably measuring a range of quantities that influenced the performance of the international prototypes and their copies. As a result, a number of studies and projects were launched which dealt with the measurement of temperature, density, pressure and a number of related quantities. The BIPM immediately became a research body, although this was not recognized formally until 1921.

Returning to the development of the SI; one of the early decisions of the CIPM was to modify the CGS system to base measurements on the meter, kilogram and second – the MKS system. In 1901, Giorgi showed that it was possible to combine the MKS system with the prac-

Fig. 1.4 Bureau International des Poids et Mesures, Sèvres

tical electrical units to form a coherent four-dimensional system by adding an electrical unit and rewriting some of the equations of electromagnetism in the so-called rationalized form. In 1946, the **CIPM** approved a system based on the meter, kilogram, second and ampere – the MKSA system. Recognizing the ampere as a base unit of the metric system in 1948, and adding, in 1954, units for thermodynamic temperature (the kelvin) and luminous intensity (the candela), the 11th CGPM in 1960 coined the name *Système internationale d'Unités*, the

SI. At the 14th CGPM in 1971, the present day SI system was completed by adding the mole as the base unit for the amount of substance, bringing the total number of base units to seven. Using these base units, a hierarchy of derived units and quantities of the SI have been developed for most, if not all, measurements needed in today's society. A substantial treatment of the SI is to be found in the SI brochure published by the BIPM in its seventh edition in 1998, with the publication of an eighth edition expected in 2005 [1.1].

1.4 BIPM: The First 75 Years

After its intervention in the initial development of the SI, the BIPM continued to develop fundamental metrological techniques in mass and length measurement but soon had to react to the metrological implications of major developments in atomic physics and interferometry. In the early 1920s, Albert Michelson came to work at the BIPM and built an eponymous interferometer to measure the meter in terms of light from the cadmium red line – an instrument which, although modified, did sterling service until the 1980s. In temperature measurement, the old hydrogen thermometer scale was replaced with a thermodynamic-based scale and a number of fixed points. After great debate, electrical standards were added to the work of the BIPM in the 1920s with the first international comparisons of resistance and voltage. In 1929, an electrical laboratory was added and photometry arrived in 1939.

In these early days, it was clear that the BIPM needed to find a way of consulting and collaborating with the experts in the world's **NMIs**. The solution adopted is one which still exists and flourishes today. The best way of working was in face-to-face meetings, so the concept of a consultative committee to the **CIPM** was born. Members of the committee were drawn from experts active in the world's **NMIs** and met to deal with matters concerning the definitions of units and the techniques of comparison and calibration. The consultative committees are usually chaired by a member of the **CIPM**. Much information was shared although, for obvious logistical reasons, the meetings were not too frequent. Over the years, the need for new consultative committees grew in reaction to the expansion of metrology and now ten consultative committees exist, with over 25 working groups.

The **CIPM** is rightly cautious about establishing a new committee but proposals for new ones are considered from time to time, usually after an initial survey through a working group. In the last ten years, joint committees have been created to tackle issues such as the international approach to the estimation of measurement uncertainties or to the establishment of a common vocabulary for metrology. Most of these joint committees bring the BIPM together with international or intergovernmental bodies such as the International Organization for Standardization (**ISO**), the International Laboratory Accreditation Cooperation (**ILAC**), and the IEC. As the work of the Meter Convention moves into areas other than its traditional activities in physics and engineering, joint committees are an excellent way of bringing the BIPM together with other bodies that bring specialist expertise – an example being the joint committee for laboratory medicine, established recently with the International Federation of Clinical Chemists and the **ILAC**.

The introduction of ionizing radiation standards to the work of the BIPM came when Marie Curie deposited her first radium standard at the BIPM in 1913. As a result of pressure, largely from the USSR delegation to the CGPM, the **CIPM** took the decision to deal with metrology in ionizing radiation.

In the mid 1960s, and at the time of the expansion into ionizing radiation, programs on laser length measurement were also started. These contributed greatly to the redefinition of the meter in 1983. The BIPM also acted as the world reference center for laser wavelength or frequency comparisons in much the same way as it did for physical artifact-based standards. In the meantime, however, the meter bar had already been replaced, in 1960, by an interferometric-based definition using optical radiation from a krypton lamp.

Table 1.1 List of consultative committees with dates of formation

Names of consultative committees and the date of their formation
(Names of consultative committees have changed as they have gained new responsibilities: the current name is cited)
Consultative Committee for Electricity and Magnetism, CCEM. (1997, but created in 1927)
Consultative Committee for Photometry and Radiometry, CCPR. (1971 but created in 1933)
Consultative Committee for Thermometry, CCT (1937)
Consultative Committee for Length, CCL (1997 but created in 1952)
Consultative Committee for Time and Frequency, CCTF. (1997, but created 1956)
Consultative Committee for Ionizing Radiation, CCRI. (1997, but created in 1958)
Consultative Committee for Units, CCU. (1964, but replacing a similar commission created in 1954)
Consultative Committee for Mass and Related Quantities, CCM. (1980)
Consultative Committee for Amount of Substance and Metrology in Chemistry, CCQM. (1993)
Consultative Committee for Acoustics, Ultrasound and Vibration, CCAUV. (1999)

1.5 Quantum Standards: A Metrological Revolution

Technology did not stand still and, in reaction to the developments and metrological applications of superconductivity, important projects on the Josephson, quantum Hall and capacitance standards were launched in the late 1980s and 1990s. The BIPM played a key role in establishing worldwide confidence in the performance of these new devices through an intense program of comparisons which revealed many of the systematic sources of error and found solutions to them. The emergence of these and other quantum-based standards, however, was an important and highly significant development. In retrospect, these were one of the drivers for change in the way in which world metrology organizes itself and had implications nationally as well as internationally.

The major technical change was, in essence, a belief that standards based on quantum phenomena were the same the world over. Their introduction sometimes made it unnecessary for a single, or a small number of, reference standards to be held at the BIPM or in a few of the well-established and experienced NMIs. Quantum-based standards were, in reality, available to all and, with care, could be operated outside the NMIs at very high levels of accuracy.

There were two consequences. Firstly, that the newer NMIs that wanted to invest in quantum-based standards needed to work with experienced metrologists in existing NMIs in order to develop their skills as rapidly as

possible. Many of the older NMIs, therefore, became adept at training and providing the necessary experience for newer metrologists. The second consequence was an increased pressure for comparisons of standards, as the ever-conservative metrology community sought to develop confidence in new NMIs as well as in the quantum-based standards. These included frequency-stabilized lasers, superconducting voltage and resistance standards, cryogenic radiometers (for measurements related to the candela), atomic clocks (for the second) and a range of secondary standards.

Apart from its responsibility to maintain the international prototype kilogram (Fig. 1.5), which remains the last artifact-based unit of the SI, the BIPM was therefore no longer always the sole repository of an international primary reference standard. However there were, and still are, a number of unique reference facilities at the BIPM for secondary standards and quantities of the SI. Staff numbers had also leveled off at about 70.

If it was going to maintain its original mission of a scientifically based organization with the responsibility for coordinating world metrology, the BIPM recognized it needed to discharge particular aspects of its treaty obligation in a different way. It also saw the increased value of developing the links needed to establish collaboration at the international and intergovernmental level. In addition, the staff had the responsibility to pro-

Fig. 1.5 International prototype kilogram

vide the secretariat to the ten consultative committees of the CIPM as well as an increasing number of working groups. The last ten years of the 20th century, therefore, saw the start of a significant change in the BIPM's way of working. During this period, it was also faced with the need to develop a world metrology infrastructure in new areas such as the environment, chemistry, medicine and food. The shift away from physics and engineering was

possible, fortunately, as a result of the changing way in which the SI units can be realized, particularly through the quantum-based standards. Other pressures for an increase in the BIPM's coordination role, resulted from the increasingly intensive program of comparisons brought about by the launch of the CIPM's mutual recognition arrangement in the 1990s.

The most recent consequence of these trends was that the CIPM decided that the photometry and radiometry section would close due to the need to operate within internationally agreed budgets, ending nearly 70 years of scientific activity at the BIPM. Additional savings would also be made by restricting the work of the laser and length group to a less ambitious program.

A small, 130-year-old institution was therefore in the process of reinventing itself to take on and develop a changed but nevertheless unique niche role. This was still based on technical capabilities and laboratory work but was one which had to meet the changing, and expanding, requirements of its member states in a different way. Much more also needed to be done as the benefits of precise, traceable measurement became seen as important in a number of the new disciplines for metrology. This change of emphasis was endorsed at the 2003 General Conference on Weights and Measures as a new four-year work program (2005–8) was agreed, as well as the first real-terms budget increase since the increase agreed in the mid 1960s which then financed the expansion into ionizing radiation.

1.6 Regional Metrology Organizations

The growth of the number of NMIs and the emergence of world economic groupings such as the Asia–Pacific Economic Cooperation and the European Union mean that regional metrological groupings have become a useful way of addressing specific regional needs and can act as a mutual help or support network. The first such group was probably in Europe, where an organization now named EUROMET emerged from a loose collaboration of NMIs based on the Western European Metrology Club. There are now five regional metrology organizations (RMOs): the Asian–Pacific Metrology Program (APMP) with perhaps the largest geographical coverage from India in the west to New Zealand in the east and extending into Asia, the Euro–Asian Cooperation in Metrology amongst the Central European Countries (COOMET), the European Cooperation in Measurement Standards (EUROMET), the Southern African

Development Community Cooperation in Measurement Traceability (SADCMET), and Sistema Interamericano de Metrología or Inter-American Metrology System (SIM) which covers Southern, Central and North America). The RMOs play a vital role in encouraging coherence within their region and between regions; without their help the Meter Convention would be far more difficult to administer and its outreach to nonmembers – who may, however, be members of an RMO – would be more difficult.

Traditionally, NMIs have served their own national customers. It is only within the last ten years that regional metrology organizations have started to become more than informal associations of national laboratories and have begun to develop strategies for mutual dependence and resource sharing, driven by concerns about budgets and the high cost of capital facilities. The sharing of

resources is still, however, a relatively small proportion of all collaborations between NMIs, most of which are still at the research level. It is, of course, no coincidence

that RMOs are based on economic or trading blocs and that these groupings are increasingly concerned with free trade within and between them.

1.7 Traceability of Measurements

Traceability of measurement has been a core concern of the Meter Convention from its inception. Initially, a measurement is always made in relation to a more accurate reference and these references are themselves calibrated or measured against an even more accurate reference standard. The chain follows the same pattern until one reaches the national standards. (For technical details see Chap. 2.)

The NMIs' job was to make sure that the national standards were traceable to the SI and were accurate enough to meet national needs. As NMIs themselves stopped doing all but the highest accuracy measurements and as accredited laboratories, usually in the commercial sector, took on the more routine tasks, the concept of a national hierarchy of traceable measurements became commonplace, and was frequently called a National Measurement System. In general, the technical capabilities of the intermediate laboratories are assured by their accreditation to the international documentary standards ISO/IEC 17025 by a national accreditation body, usually a member of the International Laboratory Accreditation Cooperation (ILAC), see Chap. 2. At the top of the traceability system, measurements were relatively few in number and had the lowest uncertainty. Progressing down the traceability chain introduced a greater level of uncertainty of measurement and, generally speaking, a larger number of measurements are involved. Traceability itself also needed to be defined. The *international vocabulary of metrology* (VIM) defines traceability as “*The property of a measurement result relating the result to a stated metrological reference through an unbroken chain of calibrations or comparisons each contributing to the stated uncertainty*” [1.2].

The important emphasis is on uncertainty of measurement [for a detailed treatment of measurement uncertainty, the reader is referred to [1.3] the guide to the expression of uncertainty in measurement (GUM)] and the need for the continuous unbroken chain of mea-

surement. Comparisons of standards or references are a common way of demonstrating confidence in the measurement processes and in the reference standards held either in the NMIs or in accredited laboratories. The national accreditation body usually takes care of these comparisons at working levels, sometimes called inter-laboratory comparisons (ILCs) or proficiency testing, see Chap. 2.

At the NMI level, the framework of the BIPM and the CIPM's consultative committees (CCs) took care of the highest level comparisons. However, the increased relevance of traceable measurement to trade, and the need for demonstrable equivalence of the national standards held at NMIs, and to which national measurements were traceable, took a major turn in the mid 1990s. This event was stimulated by the need, from the accreditation community as much as from regulators and trade bodies, to know just how well the NMI standards agreed with each other. Unlike much of the work of the consultative committees, this involved NMIs of all states of maturity to work at all levels of accuracy. The task of comparing each and every standard was too great and too complex for the CC network so a novel approach needed to be adopted. In addition, it became increasingly clear that the important concept was one of measurements traceable to the SI through the standards realized and maintained at NMIs, rather than to the NMI-based standards themselves. Not to develop and work with this concept would run the risk of creating technical barriers to trade (TBTs) if measurements in a certain country were legally required to be traceable to the NMI standards or if measurements made elsewhere were not recognized. The World Trade Organization was turning its attention towards the need for technical measurements to be accepted worldwide and were setting challenging targets for the reduction of TBTs. The metrology community needed to react.

1.8 Mutual Recognition of NMI Standards: The CIPM MRA

The result was the creation, by the CIPM, of a mutual recognition arrangement (MRA) for the recognition and

acceptance of NMI calibration and test certificates. The CIPM MRA is one of the key events of the last few

years, and one which may be as significant as the Meter Convention itself. The CIPM MRA has a direct impact on the reduction of technical barriers to trade and to the globalization of world business. The CIPM MRA was launched at a meeting of NMIs from member states of the Meter Convention held in Paris on 14th October 1999, at which the directors of the national metrology institutes of 38 member states of the convention, and representatives of two international organizations became the first signatories.

1.8.1 The Essential Points of the MRA

The objectives of the CIPM MRA are:

- to establish the degree of equivalence of national measurement standards maintained by NMIs;
- to provide for the mutual recognition of calibration and measurement certificates issued by NMIs; and
- thereby to provide governments and other parties with a secure technical foundation for wider agreements related to international trade, commerce and regulatory affairs.

The procedure through which an NMI, or any other recognized signatory, joins the MRA is based on the need to demonstrate their technical competence, and to convince other signatories of their performance claims. In essence, these performance claims are the uncertainties associated with the routine calibration services which are offered to customers and which are traceable to the SI. Initial claims, called calibration and measurement capabilities (CMCs), are first made by the laboratory concerned. They are then first reviewed by technical experts from the local regional metrology organization and, subsequently, by other RMOs. The technical evidence for the CMC claims is generally based on the institute's performance in a number of comparisons carried out and managed by the relevant CIPM consultative committees (CCs) or by the RMO. This apparently complex arrangement is needed because it would be technically, financially or organizationally impossible for each participant to compare its own SI standards with all others. The CIPM places particular importance on two types of comparisons:

- international comparisons of measurements, known as CIPM key comparisons and organized by the CCs and which generally involve only those laboratories which perform at the highest level. The subject of a key comparison is chosen carefully by the CC to

be representative of the ability of the laboratory to make a range of related measurements;

- key or supplementary international comparisons of measurements usually organized by the RMOs and which include some of the laboratories which took part in the CIPM comparisons as well as other laboratories from the RMO. RMO key comparisons are in the same technical area as the CIPM comparison whereas supplementary comparisons are usually carried out to meet a special regional need.

Using this arrangement, we can establish links between all participants to provide the technical basis for the comparability of the SI standards at each NMI. Reports of all the comparisons are published in the key comparison database maintained by the BIPM on its web site (www.bipm.org).

These comparisons differ from those traditionally carried out by the CCs, which were largely for scientific reasons and which established the dependence of the SI realizations on the effects which contributed to the uncertainty of the realization. In CIPM and RMO key or supplementary comparisons, however, each participant carries out the measurements without knowing the results of others until the comparison has been completed. They provide, therefore, an independent assessment of performance. The CIPM, however, took the view that comparisons are made at a specific moment in time and so required participating NMIs to install a quality system which could help demonstrate confidence in the continued competence of participants in between comparisons. All participants have chosen to use the ISO/IEC 17025 standard and have the option of a third-party accreditation by an ILAC member or a self-declaration together with appropriate peer reviews.

The outcome of this process is that it gives NMIs the confidence to recognize the results of key and supplementary comparisons as stated in the database and therefore to accept the calibration and measurement capabilities of other participating NMIs.

When drawing up its MRA, the CIPM was acutely aware that its very existence, and the mutual acceptance of test and calibration certificates between its members, might be seen as a technical barrier to trade in itself. The concept of associate members of the CGPM was therefore developed. An associate has, in general, the right to take part in the CIPM MRA but not to benefit from the full range of BIPM services and activities, which are restricted to convention members. The associate status is increasingly popular with developing countries as it helps them gain recognition worldwide and does not

commit them to the additional expense of convention membership, which may be less appropriate for them at their stage of development.

1.8.2 The Key Comparison Database (KCDB)

The key comparison database, referred to in the [MRA](#) is available on the BIPM web pages (www.bipm.org). The content of the database is evolving rapidly. Appendix A lists signatories, and Appendix B contains details of the set of key comparisons together with the results from those that have been completed. The database will also contain a list of those old comparisons selected by the consultative committees that are to be used on a provisional basis. Appendix C contains the calibration and measurement capabilities of the [NMIs](#) that have already been declared and reviewed within their own regional metrology organization (RMO) as well as those other RMOs that support the [MRA](#).

1.8.3 Take Up of the CIPM MRA

The KCDB data is, at the moment, largely of interest to metrologists. However, a number of [NMIs](#) are keen to see it taken up more widely and there are several examples of references to the [CIPM MRA](#) in regulation. This campaign is at an early stage and an EU–US trade agreement cites the [CIPM MRA](#) as providing an appropriate technical basis for acceptance of measurements and tests and the USA's National Institute of Standards and Technology ([NIST](#)) has opened up a discussion with the Federal Aviation Authority (FAA) and other regulators as to the way in which they can use the KCDB

data to help the FAA accept the results of tests and of certificates which have been issued outside the USA.

There is a range of additional benefits and consequences of the [CIPM MRA](#). Firstly, anyone can use the KCDB to look for themselves at the validated technical capability of any [NMI](#). As a result, they can, with full confidence, choose to use its calibration services rather than those of their national laboratory and have the results of these services accepted worldwide. They can also use the [MRA](#) database to search for [NMIs](#) that can satisfy their needs if they are not available nationally. This easy access and the widespread and cheap availability of information may well drive a globalization of the calibration service market and will enable users to choose the supplier that best meets their needs. As the [MRA](#) is implemented, it will be a real test of market economics. Secondly, there is the issue of rapid turnarounds. Companies that have to send their standards away for calibration do not have them available for in-house use. This can lead to costly duplication if continuity of an internal service is essential, or to a tendency to increase the calibration interval if calibrations are expensive. [NMIs](#) therefore have to concentrate more and more on reducing turnaround times, or providing better customer information through calibration management systems. Some calibrations will always require reasonable periods of time away from the workplace because of the need for stability or because [NMIs](#) can only (through their own resource limitations) provide the service at certain times. This market sensitivity is now fast becoming built into service delivery and is, in some cases, more important to a customer than the actual price of a calibration.

1.9 Metrology in the 21st Century

In concluding this review of the work of the Meter Convention, it seems appropriate to take a glance at what the future may have in store for world metrology and, in particular, at the new industries and technologies which require new measurements.

1.9.1 Industrial Challenges

The success of the Meter Convention and, in particular, the recognized technical and economic benefits of the [CIPM MRA](#) – one estimate by the consulting company KPMP puts its potential impact on the reduction of TBTs

at some € 4 billion (see the BIPM website) – has attracted the interest and attention of new communities of users.

New Technologies

A challenge which tackles the needs of new industries and exploits new technologies is to enhance our ability to measure the large, the small, the fast and the slow. Microelectronics, telecommunications, the study and characterization of surfaces and thin films will benefit. Many of these trends are regularly analyzed by [NMIs](#) as they formulate their technical programs and a summary can be found in the recent report to the 22nd CGPM, by

its secretary, Dr Robert Kaarls entitled “Evolving Needs for Metrology in Trade, Industry, and Society and the Role of the BIPM”. The report can be found on the BIPM web site (www.bipm.org).

Materials Characterization

Of particular relevance to the general topic of this book, there has been an interest in a worldwide framework for the traceable measurement of material characteristics. The potential need is for validated, accepted reference data to characterize materials with respect to their properties (see Part C) and their performance (see Part D). To a rather limited extent, some properties are already covered in a metrological sense: hardness, some thermo-physical or optical properties, for example, but the vast bulk of materials characteristics, which are not intrinsic properties but system-dependent attributes, (see Chap. 3), remain outside the work of the convention. Therefore, relatively few NMIs have been active in materials metrology but a group is meeting to decide whether to make proposals for a new sphere of Meter Convention activity. A report recommending action was presented to the CIPM in 2004 and will be followed up in a number of actions launched by the committee.

Product Appearance

Another challenge is the focus by manufacturers on the design or appearance of a product, which differentiates it in the eyes of the consumer from those of their competitors. These rather subjective attributes of a product are starting to demand an objective basis for comparison. Appearance measurement of quantities such as gloss, or the need to measure the best conditions in which to display products under different lighting or presentation media (such as a TV tube, flat-panel display, or a printed photograph), or the response for different types of sounds combine hard physical or chemical measurements with the subjective and varying responses of, say, the human eye or ear. Yet these are precisely the quantities that a consumer uses to judge textiles, combinations of colored products, or the relative sound reproduction of music systems. They are therefore also the selling points of the marketer and innovator. How can the consumer choose and differentiate? How can they compare different claims? Semi-subjective measurements like these are moving away from the carefully controlled conditions of the laboratory into the high street and are presenting exciting new challenges.

NMIs are already become familiar with the needs of users of their color or acoustical measurement services which require a degree of modeling of the user

response and the differing reactions depending on environmental conditions such as ambient lighting or noise backgrounds. The fascination of this area is that it combines objective metrology with physiological measurements and the inherent variability of the human eye or ear, or the ways in which our brains process optical or auditory stimuli.

Real-Time In-Process Measurements

The industries of today and tomorrow are starting to erode one of the century-old metrology practices within which the user must bring their own instruments and standards to the NMI for calibration. Some of this relates to the optimization of industrial processes where far more accurate, real-time, in-process measurements are made. The economics of huge production processes demand just-in-time manufacture, active data management and clever process modeling. By reliably identifying where subelements of a process are behaving poorly, plant engineers can take rapid remedial action and so identify trouble spots quickly. But real real-time systems measurements are difficult, and it is only recently that some NMIs have begun to address the concept of an industrial measurement system. New business areas such as this will require NMIs to work differently if, for no other reason, because their customers work differently and they need to meet the customers' requirements. Remote telemetry, data fusion and new sensor techniques are becoming linked with process modeling, numerical algorithms and approximations so that accurate measurement can be put, precisely, at the point of measurement. These users are already adopting the systems approach and some NMIs are starting to respond to this challenge.

Quantum-Based Standards

There is a trend towards quantum-based standards in industry, as already highlighted in this chapter. This is a result of the work of innovative instrument companies which now produce, for example, stabilized lasers, Josephson-junction voltage standards and atomic clocks for the mass market. The availability of such highly accurate standards in industry is itself testimony to companies' relentless quest for improved product performance and quality. But, without care and experience, it is all too easy to get the wrong answer. Users are advised to undertake comparisons and to cooperate closely with their NMIs to make sure that these instruments are operated with all the proper checks and with attention to best practice so that they may, reliably, bring increased accuracy closer to the end user [1.4]. Industry presses

NMIs – rightly so – for better performance and in some areas of real practical need, NMI measurement capabilities are still rather close to what industry requires. It is, perhaps, in these highly competitive and market-driven areas that the key comparisons and statements of equivalence that are part of the CIPM MRA will prove their worth. Companies specify the performance of their products carefully in these highly competitive markets and any significant differences in the way in which NMIs realize the SI units and quantities will have a direct bearing on competitiveness, market share and profitability.

1.9.2 Chemistry, Pharmacy and Medicine

Chemistry, biosciences and pharmaceuticals are, for many of us, the new metrology. We are used to the practices of physical and engineering metrology and so the new technologies are challenging our understanding of familiar concepts such as traceability, uncertainty and primary standards. Much depends here on the interaction between a particular chemical or species and the solution or matrix in which it is to be found, as well as the processes or methods used to make the measurement. The concept of reference materials (RMs) (see Chap. 2) is well developed in the chemical field and the Consultative Committee for Quantity of Matter Metrology in Chemistry (CCQM) has embarked on a series of RM and other comparisons to assess the state of the art in chemical and biological measurements.

Through the CIPM MRA, the international metrology community has started to address the needs and concerns of regulators and legislators. This has already brought the Meter Convention into the areas of laboratory medicine, food (genetically modified organisms (GMOs), pesticides, and trace elements). We are only beginning to tackle and respond to the world of medicine and pharmacy and have created a partnership with the International Federation of Clinical Chemistry (IFCC) and ILAC to address these needs in a Joint Committee for Traceability in Laboratory Medicine (JCTLM). This is directed initially at a database of reference materials which meet certain common criteria of performance. Recognition of the data in the JCTLM data base will, in particular, help demonstrate compliance of the products

of the in vitro diagnostic industry with the requirements of a recent directive of the European Union. The BIPM has signed a memorandum of understanding with the World Health Organization to help pursue these matters at an international level.

1.9.3 Environment, Public Services and Infrastructures

In the area of the environment, our current knowledge of the complex interactions of weather, sea currents and the various layers of our atmosphere is still not capable of a full explanation of environmental issues. The metrologist is, however, beginning to make a recognized contribution by insisting that slow or small changes, particularly in large quantities, should be measured traceably and against the unchanging reference standards offered through the units and quantities of the SI system. Similar inroads are being made into the space community where, for example, international and national space agencies are starting to appreciate that solar radiance measurements can be unreliable unless related to absolute measurements. We await the satellite launch of a cryogenic radiometer which would do much to validate and monitor long-term trends in solar physics. The relevance of these activities is far from esoteric. Governments spend huge sums of money in their efforts to tackle environmental issues and it is only by putting measurements on a sound basis that we can begin to make sure that these investments are justified and are making a real difference in the long term.

Traceable measurements are beginning to be needed as governments introduce competition into the supply of public services and infrastructures. Where utilities, such as electricity or gas, are offered by several different companies, the precise moment at which a consumer changes supplier can have large financial consequences. Traceable timing services are now used regularly in these industries as well as in stock exchanges and the growing world of e-commerce. Global trading is underpinned by globally accepted metrology, often without the users appreciating the sophistication, reliability and acceptability of the systems in which they place such implicit trust.

1.10 The SI System and New Science

Science never stands still and there are a number of trends already evident which may have a direct bearing on the definitions of the SI itself. Much of

this is linked with progress in measuring the fundamental constants, their coherence with each other and the SI and the continued belief that they are

time and space invariant. Figure 1.6 shows the current relationships.

The figure represents some of the links between the base units of the SI (shown in circles) and the fundamental physical and atomic constants (shown in boxes). It is intended to show that the base units of the SI are linked to measurable quantities through the unchanging and universal constants of physics.

The base units of the International System of Units are:

A = ampere
K = kelvin
s = second
m = meter
kg = kilogram
cd = candela
mol = mole

The surrounding boxes, lines and uncertainties represent measurable quantities.

The numbers marked next to the base units are estimates of the standard uncertainties of their best practical realizations.

The fundamental and atomic constants shown are:

R_K = von Klitzing constant
K_J = Josephson constant
R_{K-90} and K_{J-90} : the conventional values of these constants, introduced on 1st January 1990.
N_A = Avogadro constant
F = Faraday constant
G = Newtonian constant of gravitation
m_{12C} = mass of ^{12}C
m_e = electron mass
R_∞ = Rydberg constant
h = Planck constant
c = speed of light
μ_0 = magnetic constant
α = fine-structure constant
R = molar gas constant
k = Boltzmann constant
e = elementary charge

The numbers next to the fundamental and atomic constants represent the relative standard uncertainties

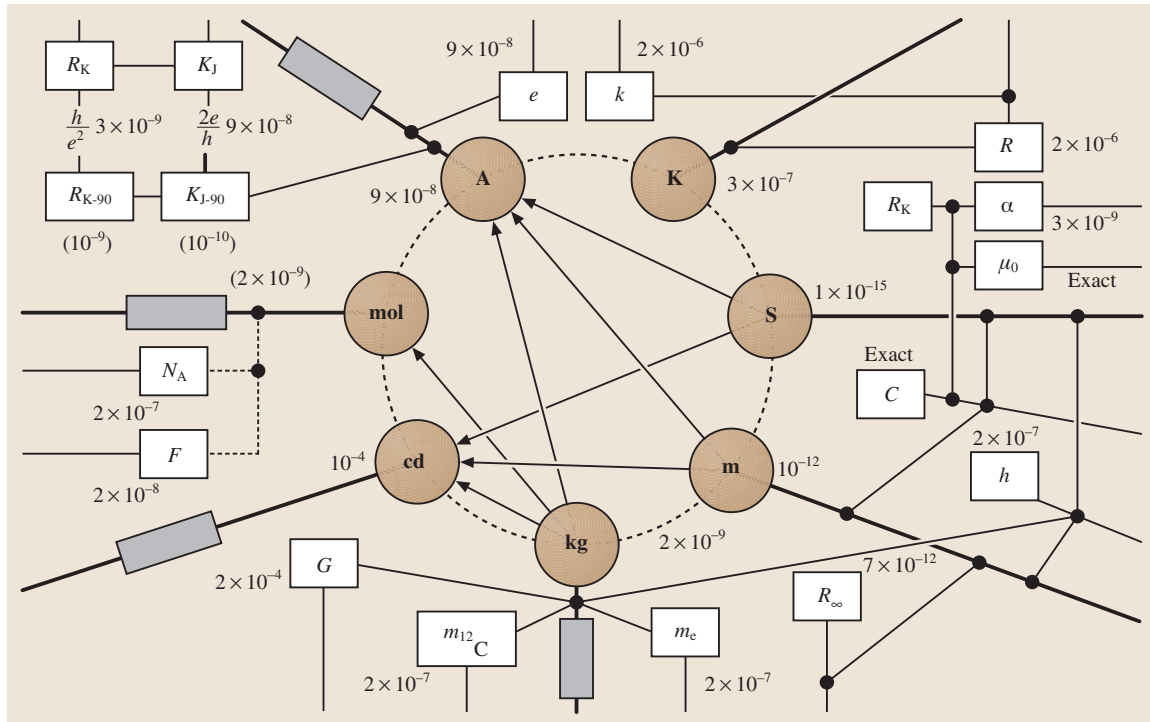

Fig. 1.6 Uncertainties of the fundamental constants: CODATA 2002; of the realization of the SI base units: present best estimates

of our knowledge of these constants (from the 2002 CODATA adjustment).

The grey boxes reflect the unknown long-term stability of the kilogram artifact and its consequent effects on the practical realization of the definitions of the ampere, mole and candela.

Based on the fundamental SI units, derived physical quantities have been defined which can be expressed in terms of the fundamental SI units. For example: the unit of force = mass \times acceleration is newton = mkg/s^2 , or the unit of work = force \times distance is joule = m^2kg/s^2 . A compilation of the units which are used today in science and technology is given in the Springer Handbook of Condensed Matter and Materials Data [1.5].

In the next few years, we can expect, perhaps, a redefinition of the kilogram. Several experiments in a number of NMIs are aimed at relating the mechanical kilogram to the electrical quantities with uncertainties which make it possible to monitor any changes in the international prototype itself at better than 1 part in 10^8 . Length and time units have been related by a fixed value for the speed of light for a number of years, and length

is defined in relation to the time unit. New femtosecond laser techniques and the high performance of ion or atom trap standards may soon enable us to turn this definition on its head and define time in terms of the optical transitions. Temperature and light intensity measurement all relate to the Boltzmann constant and, if several efforts to improve our knowledge of it and the Planck constant are successful, we then might open up the possibility of a different approach to thermodynamic temperature and light intensity measurement. These are exciting times for metrologists. Trends in measurement are taking us into new regimes, chemistry is introducing us to the world of reference materials and processes and to application areas which would have amazed our predecessors. What is, however, at face value surprising is the ability of a 130-year-old organization to respond flexibly and confidently to these changes. It is a tribute to our forefathers that the basis they set up for meter bars and platinum kilograms still applies to GMOs and measurement of cholesterol in blood. Metrology is, truly, one of the oldest sciences and is one which continues to meet changing needs in a changing world.

Measurement

Technology and today's global economy depend on reliable measurements and tests that are accepted internationally. In this context, metrology, the science of measurement, is a fundamental element in the materials measurement system, as has been explained in Chap. 1. Metrology can be considered in categories with different levels of complexity and accuracy:

- Scientific metrology deals with the organisation and development of measurement standards and with their maintenance.
- Industrial metrology has to ensure the adequate functioning of measurement instruments used in industry as well as in production and testing processes.
- Legal metrology is concerned with measurements that influence the transparency of economic transactions, health, and safety.

However all scientific, industrial, and legal metrological tasks need appropriate methodologies for *measurement strategy and quality*, which are compiled in this chapter. These are the essential tools to achieve the quality and competence required by today's market.

2.1 Sampling

Sampling is arguably the most important part of the measurement process. It is usually the case that it is impossible to measure the required quantity, such as concentration, in an entire batch of material. The taking of a sample is therefore the essential first step of nearly all measurements. However, it is commonly agreed that the quality of a measurement can be no better than the quality of the sampling upon which it is based. It follows that the highest level of care and attention paid to the instrumental measurements is ineffectual, if the original sample is of poor quality.

2.1.1 Quality of Sampling

The *traditional approach* to ensuring the quality of sampling is procedural rather than empirical. It relies initially on the selection of a correct sampling protocol for the particular material to be sampled under a particular circumstance. For example the material may be copper metal, and the circumstances could be manufacturers' quality control prior to sale. In general, such a protocol may be specified by a regulatory body, or recommended in an international standard or trade organisation. The second step is to train the personnel who are to take the samples (i. e., the samplers) in the correct application of the protocol. No sampling protocol can be completely unambiguous in its wording, so uniformity of interpretation relies on the samplers being educated, not just in how to interpret the words, but also in an appreciation of the rationale behind the protocol and how it can be adapted to the changing circumstances that will arise in the real world, without invalidating the protocol. This step is clearly related to the management of sampling by organisations, which is often separated from the man-

agement of the instrumental measurements, even though they are both inextricably linked to the overall quality of the measurement. The fundamental basis of the traditional approach to assuring sampling quality is to assume that the correct application of a correct sampling protocol will give a representative sample, by definition.

An *alternative approach* to assuring sampling quality is to estimate the quality of sampling empirically. This is analogous to the approach that is routinely taken to instrumental measurement, where as well as specifying a protocol, there is an initial validation and ongoing quality control to monitor the quality of the measurements actually achieved. The key parameter of quality for instrumental measurements is now widely recognised to be the uncertainty of each measurement. This concept will be discussed in detail later (Sect. 2.4), but informally this uncertainty of measurement can be defined as the range within which the true value lies, for the quantity subject to measurement, with a stated level of probability. If the quantity subject to measurement (the measurand) is defined in terms of the batch of material (the sampling target), rather than merely in the sample delivered to the lab, then measurement uncertainty includes that arising from primary sampling. Given that sampling is the first step in the measurement process, then the uncertainty of the measurement will also arise in this first step, as well as in all of the other steps, such as the sampling preparation and the instrumental determination.

The key measure of sampling quality is therefore this sampling uncertainty, which includes contributions not just from the random errors often associated with sampling variance [2.1] but also from any systematic errors

Fig. 2.1a–d Experimental designs for the estimation of measurement uncertainty by the duplicate method. The simplest and cheapest option **(a)** has single analyses on duplicate samples taken on around 10% ($n \geq 8$) of the sampling targets, and only provides an estimate of the random component of the overall measurement uncertainty. If the contribution from the analytical determination is required separately from that from the sampling, the duplication of analysis is required on either one **(b)** or both **(c)** of the sample duplicates. If the contribution from the physical sample preparation is required to be separated from the sampling, as well as that from the analysis, then duplicate preparations also have to be made **(d)**. (*Analysis and Analyse can more generally be described as the determination of the measurand)

that have been introduced by sampling bias. Rather than assuming the bias is zero when the protocol is correct, it is more prudent to aim to include any bias in the estimate of sampling uncertainty. Such bias may often be unsuspected, and arise from a marginally incorrect application of a nominally correct protocol. This is equivalent to abandoning the assumption that samples are representative, but replacing it with a measurement result that has an associated estimate of uncertainty which includes errors arising from the sampling process.

Selection of the most appropriate sampling protocol is still a crucial issue in this alternative approach. It is possible however, to select and monitor the appropriateness of a sampling protocol, by knowing the uncertainty of measurement that it generates. A judgement can then be made on the fitness for purpose (FFP) of the measurements, and hence the various components of the measurement process including the sampling, by comparing the uncertainty against the target value indicated by the FFP criterion. Two such FFP criteria are discussed below.

Two approaches have been proposed for the estimation of uncertainty from sampling. The first or *bottom-up* approach, requires the identification of all of the individual components of the uncertainty, the separate estimation of the contribution that each component makes, and then summation across all of the components [2.2]. Initial feasibility studies suggest that the use of sampling theory to predict all of the components will be impractical for all but a few sampling systems, where the material is particulate in nature and

the system conforms to a model in which the particle size/shape, and analyte concentration is simple, constant and homogeneously distributed. One recent application successfully mixes theoretical and empirical estimation techniques [2.3]. The second, more practical and pragmatic approach is entirely empirical, and has been called the *top-down* estimation of uncertainty [2.4].

Four methods have been described for the empirical estimation of uncertainty of measurement, including that from primary sampling [2.5]. These methods can be applied to any sampling protocol for the sampling of any medium for any quantity, if the general principles are followed. The simplest of these methods (#1) is called the *duplicate method*. At its simplest, a small proportion of the measurements are made in duplicate. This is not just a duplicate analysis (i. e. determination of the quantity), made on one sample, but made on a fresh primary sample, from the same sampling target as the original sample, using a fresh interpretation of the same sampling protocol (Fig. 2.1a). The ambiguities in the protocol, and the heterogeneity of the material, are therefore reflected in the difference between the duplicate measurements (and samples). Only 10% ($n \geq 8$) of the samples need to be duplicated to give a sufficiently reliable estimate of the overall uncertainty. If the separate sources of the uncertainty need to be quantified, then extra duplication can be inserted into the experimental design, either in the determination of quantity (Fig. 2.1b) or in other steps, such as the physical preparation of the sample (Fig. 2.1d). This duplication can either be on just one sample duplicate (in an *unbalanced* design, Fig. 2.1b),

or on both of the samples duplicated (in a *balanced* design, Fig. 2.1c).

The uncertainty of the measurement, and its components if required, can be estimated using the statistical technique called analysis of variance (ANOVA). The frequency distribution of measurements, such as analyte concentration, often deviate from the normal distribution that is assumed by classical ANOVA. Because of this, special procedures are required to accommodate outlying values, such as robust ANOVA [2.6]. This method has successfully been applied to the estimation of uncertainty for measurements on soils, river sediments and food materials. Its weakness is that it ignores the contribution of systematic errors (from sampling or analytical determination) to the measurement uncertainty. Estimates of analytical bias, made with certified reference materials, can be added to estimates from this method. Systematic errors caused by a particular sampling protocol can be detected by use of different method (#2) in which different sampling protocols are applied by a single sampler. Systematic errors caused by the sampler can also be incorporated into the estimate of measurement uncertainty by the use of a more elaborate method (#3) in which several samplers apply the same protocol. This is equivalent to holding a *collaborative trial in sampling* (CTS). The most reliable estimate of measurement uncertainty caused by sampling uses the most expensive method (#4), in which several samplers each apply whichever protocol they consider most appropriate for the stated objective. This incorporates possible systematic errors from the samplers, and the measurement protocols, together with all of the random errors. It is in effect a sampling proficiency test (SPT), if the number of samplers is at least eight [2.5].

Evidence from applications of these four empirical methods suggests that small-scale heterogeneity is often the main factor limiting the uncertainty. In this case, methods that concentrate on repeatability, even with just one sampler and one protocol as in the duplicate method (#1), are good enough to give an acceptable approximation of the sampling uncertainty. Proficiency test measurements have also been used in the *top-down* estimation of uncertainty of analytical measurements [2.7]. They do have the added advantage that the participants are scored for the proximity of their measurement value to the true value of the quantity subject to measurement. This true value can be estimated either by consensus of the measured values, or by artificial spiking with a known quantity of analyte [2.8]. The score from such SPTs could also be used for both the ongoing assessment and the accreditation of samplers [2.9]. These are

all new approaches that can be applied to improving the quality of sampling that is actually achieved.

2.1.2 Judging Whether Strategies of Measurement and Sampling are Appropriate

Once methods are in place for the estimation of uncertainty, the selection and implementation of a correct protocol become less crucial. Nevertheless an appropriate protocol is essential to achieve fitness for purpose. The FFP criterion may however vary, depending on the circumstances. There are cases for example where an uncertainty of 80% of the measured value, can be shown to be fit for certain purposes. One example is using *in situ* measurements of lead concentration to identify any area requiring remediation in a contaminated land investigation. The contrast between the concentration in the contaminated and in the uncontaminated areas can be several orders of magnitude, and so uncertainty within one order (i.e. 80%) does not result in errors in classification of the land. A similar situation applies when using laser ablation–inductively coupled plasma for the determination of silver to differentiate between particles of anode copper from widely different sources. The Ag concentration can differ by several orders of magnitude, so again a large measurement uncertainty (e.g. 70%) can be acceptable. One mathematical way of expressing this FFP criterion, is that the measurement uncertainty should not contribute more than 20% to the total variance over samples from a set of similar targets [2.6]. A second FFP criterion also includes financial considerations, and aims to set an optimal level of uncertainty that minimise the financial loss. This loss arises not just from the cost of the sampling and the determination, but also from the financial losses that may arise from incorrect decisions caused by the uncertainty [2.10]. The approach has been successfully applied to the sampling of both contaminated soil [2.11] and to food materials [2.12].

2.1.3 Options for the Design of Sampling

There are three basic approaches to the design/selection of a sampling protocol for any quantity (measurand) in any material. The first option is to select a previously specified protocol. These exist for most of the material/quantity combinations considered in Chap. 3 of this handbook. This approach is favoured by regulators, who expect that the specification an application of a standard protocol will automatically deliver comparability of results between samplers. It is also used as

a defence in legal cases to support the contention that measurements will be reliable if a standard protocol has been applied. The rationale of a standard protocol is to specify the procedure to the point where the sampler needs to make no subjective judgements. In this case the sampler would appear not to require any grasp of the rationale behind the design of the protocol, but merely the ability to implement the instructions given. However, experimental video monitoring of samplers implementing specified protocols suggests that individual samplers often do extemporise, especially when events occur that were unforeseen or unconsidered by the writers of the protocols. This would suggest that samplers therefore need to appreciate the rationale behind the design, in order to make appropriate decisions on implementing the protocol. This relates to the general requirement for improved training and motivation of samplers discussed below.

The second option is to use a theoretical model to design the required sampling protocol. Sampling theory has produced a series of increasingly complex theoretical models, recently reviewed [2.13], that are usually aimed at predicting the sampling mass required to produce a given level of variance in the required measurement result. Such models all depend on several assumptions about the system that is being modelled. The model of Gy [2.1], for example, assumes that the material is particulate, the particles in the batch can be classified according to volume and type of material and that the analyte concentration in a contaminated particle and its density do not vary between particles. It was also assumed that the volume of each particle in the batch is given by a constant factor multiplied by the cube of the particle diameter. The models also all require large amounts of information about the system, such as particle diameters, shape factors, size range, liberation and composition. The cost of obtaining all of this information can be very high, but the model also assumes that these parameters will not vary in space or time. These assumptions may not be justified for many systems in which the material to be sampled is highly complex, heterogeneous and variable. This limits the real applicability of this approach for many materials. These models do have a more generally useful role, however, in facilitating the prediction of how uncertainty from sampling can be changed, if required, as discussed below.

The third option for designing a sampling protocol is to adapt an existing method in the light of site-specific information, and monitor its effectiveness empirically. There are several factors that require consideration in this adaptation.

Clearly identifying the *objective of the sampling* is the key factor that helps in the design of the most appropriate sampling protocol. For example, it may be that the acceptance of a material is based upon the best estimate of the *mean* concentration of some analyte in a batch. Alternatively, it may be the *maximum* concentration, within some specified mass, that is the basis for acceptance or rejection. Protocols that aim at low uncertainty in estimation of the mean value are often inappropriate for the reliable detection of the maximum value.

A *desk-based review* of all of the relevant information about the sampling target, and findings from similar targets, can make the protocol design much more cost effective. For example, the history of a contaminated land site, can suggest the most likely contaminants and their probable spatial distribution within the site. This information can justify using *judgemental sampling* in which the highest sampling density is concentrated in the area of highest predicted probability. This approach does however, have the weakness that it may be self-fulfilling, by missing contamination in areas that were unsuspected.

The actual *mode of sampling* varies greatly therefore, depending not just on the physical nature of the materials, but also on the expected heterogeneity in both the spatial and temporal dimension. Some protocols are designed to be random (or nonjudgemental) in their selection of samples, which in theory creates the least bias in the characterisation of the measurand. There are various different options for the design of random sampling, such as stratified random sampling, where the target is subdivided into regular units before the exact location of the sampling is determined using randomly selected coordinates. In a situation where judgemental sampling is employed, as described above, the objective is not to get a representative picture of the sampling target. Another example would be in an investigation of the cause of defects in a metallurgical process, where it may be better to select items within a batch by their aberrant visual appearance, or contaminant concentration, rather than at random.

There may also be a question of the most appropriate *medium to sample*. The answer may seem obvious, but consider the objective of detecting which of several freight containers holds nuts that are contaminated with mycotoxins. Rather than sampling the nuts themselves, it may be much more cost effective to sample the atmosphere in each container for the spores released by the fungi that makes the mycotoxin. Similarly in contaminated land investigation, if the objective is to assess potential exposure of humans to cadmium at an

allotment site, it may be most effective to sample the vegetables rather than the soil.

The *specification of the sampling target* needs to be clear. Is it a whole batch, or a whole site of soil, or just the top 1 m of the soil? This relates to the objective of the sampling, but also to the site-specific information (e.g. there is bedrock at 0.5 m) and logistical constraints.

The next key question to address is the *number of samples* required (n). This may be specified in an accepted sampling protocol, but should really depend on objective of the investigation. Cost–benefit analysis can be applied to this question, especially if the objective is the mean concentration at a specified confidence interval. In that case, and assuming a normal distribution of the variable, the Student's t -distribution can be used to calculate the required value of n . A closely related question is whether *composite samples* should be taken, and if so, what is the required number of increments (i). This approach can be used to reduce the uncertainty of measurement caused by the sampling. According to the theory of Gy, taking an i -fold composite sample should reduce the main source of the uncertainty by \sqrt{i} , compared with the uncertainty for a single sample with the same mass as one of the increments. Not only do the increments increase the sample mass, but also improve the sample's ability to be representative of the sampling target. If however, the objective is to identify maximum rather than mean values, then a different approach is needed for calculating the number of samples required. This has been addressed for contaminated land by calculating the probability of hitting an idealised hot-spot [2.14].

The *quantity of sample* to be taken (e.g. mass or volume) is another closely related consideration in the design of a specified protocol. The mass may be specified by existing practice and regulation, or calculated from sampling theory such as that of Gy. Although the calculation of the mass from first principles is problematic for many types of sample, as already discussed, the theory is useful in calculating the factor by which to change to sample mass to achieve a specified target for uncertainty. If the mass of the sample is increased by some factor, then the sampling variance should reduce by the same factor, as discussed above for increments. The mass required for measurement, is often smaller than that required to give an acceptable degree of representativeness (and uncertainty). In this case, a larger sample must be taken initially and then reduced in mass, without introducing bias. This *comminution of samples*, or reduction in grain size by grinding, is a common method for reducing the uncertainty introduced by this subsampling procedure. This can however have unwanted side-effects

in changing the measurand. One example is the loss of certain analytes during the grinding, either by volatilisation (e.g. mercury) or by decomposition (e.g. most organic compounds).

The *size of the particles* in the original sampling target that should constitute the sample needs consideration. Traditional wisdom may suggest that a representative sample of the whole sampling target is required. However, sampling all particle sizes in the same proportions that they occur in the sampling target may not be possible. This could be due to limitations in the sampling equipment, which may exclude largest particles (e.g. pebbles in soil samples). A representative sample may not even be desirable, as in the case where only the small particles in soil ($< 100 \mu\text{m}$) form the main route of human exposure to lead by hand-to-mouth activity. The objectives of the investigation may require therefore, that a specific size fraction be selected.

Contamination of samples is probable during many of these techniques of sampling processing. It is often easily done, irreversible in its effect, and hard to detect. It may arise from the other materials at the sampling site (e.g. top soil contaminating subsoil) or from processing equipment (e.g. cadmium plating) or from the remains of previous samples left in the equipment. The traditional approach is to minimise the risk of contamination occurring by careful drafting of the protocol, but a more rigorous approach is to include additional procedures that can detect any contamination that has occurred (e.g. using an SPT).

Once a sample has been taken, the protocol needs to describe how to *preserve the sample*, without changing to the quantity subject to measurement. For some measurands the quantity begins to change almost immediately after sampling (e.g. the redox potential of groundwaters) and *in situ* measurement is the most reliable way of avoiding the change. For other measurands specific actions are required to prevent change. For example, acidification of water, after filtration, can prevent adsorption of many analyte ions onto the surfaces of a sample container.

The final, and perhaps most important factor to consider in designing a sampling protocol, is the logistical *organisation of the samples* within the investigation. Attention to detail in the unique numbering and clear description of samples can avoid ambiguity and irreversible errors. This improves the quality of the investigation by reducing the risk of gross errors. Moreover, it is often essential for legal traceability to establish an unbroken chain of custody for every sample. This forms part of the broader quality assurance of the sampling procedure.

There is no such thing as either a perfect sample or a perfect measurement. It is better therefore, to estimate the uncertainty of measurements from all sources, including primary sampling. The uncertainty should not just be estimated in an initial method validation, but also monitored routinely for every batch using a sampling and analytical quality control scheme (SAQCS). This allows the investigator to judge whether each batch of measurements are FFP, rather than to

assume that they are because some standard procedure was nominally adhered to. It also enables the investigator to propagate the uncertainty value through all subsequent calculations to allow the uncertainty on the interpretation of the measurements to be expressed. This approach allows for the imperfections in the measurement methods and the humans who implement them, and also for the heterogeneity of the real world.

2.2 The Traceability of Measurements

2.2.1 Introduction

Clients of laboratories will expect that results are correct and comparable. It is further anticipated that complete results and values produced include an estimated uncertainty. A comparison between different results or between results achieved and given specifications can only be done correctly if the measurement uncertainty of the results is taken into account.

To achieve comparable results, the traceability of the measurement results to SI units through an unbroken chain of comparisons, all having stated uncertainties, is fundamental (see Sect. 1.7 *Traceability of measurements*). Among others due to the strong request from the International Laboratory Accreditation Cooperation (ILAC) several years ago, the International Committee for Weights and Measures (CIPM), which is the governing board of the International Bureau of Weights and Measures (BIPM), has realised a CIPM mutual recognition arrangement (MRA) on the mutual recognition of national measurement standards and of calibration and measurement certificates issued by the National Metrology Institutes, under the scope of the meter convention. Details of this MRA can be found in Chap. 1 *Measurement Principles and Structures* Sect. 1.8 or at <http://www1.bipm.org/en/convention/mra/>.

The range of national measurement standards and best measurement capabilities needed to support the calibration and testing infrastructure in an economy or region can normally be derived from the web sites of the respective national metrology institute or from the web site of CIPM. Traceability to these national measurement standards through an unbroken chain of comparisons is an important means to achieve accuracy and comparability of the measurement results.

Access to suitable national measurement standards may be more complicated in those economies where

the national measurement institute does not yet provide national measurement standards recognised under the BIPM MRA. It is further to be noted that an unbroken chain of comparisons to national standards in various fields such as the chemical and biological sciences is much more complex and subject to a lot of scientific and technical activities to define the (certified) reference materials needed. As of today in these fields there are few reference materials that can be traced back to SI units available on the market. This means that other tools should also be applied to assure at least comparability of measurement results, such as, e.g., participation in suitable proficiency testing programs or the use of reference materials provided by reliable and competent providers.

2.2.2 Terminology

According to the *International Vocabulary of Basic and General Terms in Metrology* VIM-1993 [VIM, International Standards Organisation (ISO) – ISBN 92-67-01075-1], the following definitions apply.

Primary Standard

Standard that is designated or widely acknowledged as having the highest metrological qualities and whose value is accepted without reference to other standards of the same quality.

International Standard

Standard recognised by an international agreement to serve internationally as the basis for assigning values to other standards of the quality concerned.

National Standard

Standard recognised by a national decision to serve, in a country, as the basis for assigning values to other standards of the quantity concerned. Under the CIPM MRA

these standard can be assigned with best calibration and measurement capabilities.

Reference Standard

Standard, generally having the highest metrological quality available at a given location or in a given organisation, from which the measurements made there are derived.

Working Standard

Standard that is used routinely to calibrate or check material measures, measuring instruments and reference materials.

Note that a working standard is usually calibrated against a reference standard. Working standards may also at the same time be reference standards. This is particularly the case for working standards directly calibrated against the standards of a national standards laboratory.

2.2.3 Traceability of Measurement Results to SI Units

The formal definition of traceability is given in Chap. 1, Sect. 1.7 as: the property of a measurement result relating the result to a stated metrological reference through an unbroken chain of calibrations or comparisons, each contributing to the stated uncertainty. This chain is also called the traceability chain. It must, as defined, end at the respective primary standard.

The uncertainty of measurement for each step in the traceability chain must be calculated or estimated according to agreed methods and must be stated so that an overall uncertainty for the whole chain may be calculated or estimated. Such methods are officially given in the Guide to the Expression of Uncertainty in Measurement [GUM, International Standards Organisation (ISO) – ISBN 92-67-10188-9]. ILAC and regional organisations of accreditation bodies (see under peer and third-party assessment) provided application documents derived from the GUM, providing good examples. These documents are available on their web sites.

Competent testing laboratories, e.g. those accredited by accreditation bodies that are member of the ILAC MRA, can demonstrate that calibration of equipment that has a significant contribution to the uncertainty and hence the measurement results generated by that equipment are traceable to the international system of units (SI units) wherever this is technically possible.

In cases where traceability to the SI units is not (yet) possible, laboratories use other means to assure at least

comparability of their results. Such means are, e.g. the use of certified reference materials, provided by a reliable and competent producer or they assure at least comparability by participating in inter-laboratory comparisons provided by a competent and reliable provider. See also Sects. 2.5 and 2.6 on *Inter-laboratory Comparisons and Proficiency Testing* and *Reference Materials*, respectively.

The Traceability Chain

National Metrology Institutes. In most cases the national metrology institutes maintain the *national standards* that are the sources of traceability for the quantity of interest. The national metrology institutes ensure the comparability of these standards through an international system of key comparisons, as explained in detail in Chap. 1, Sect. 1.8.

If a national metrology institute has an infrastructure to realise a given primary standard themselves, that national standard is identical to or directly traceable to that *primary standard*. If the institute does not have such an infrastructure, it will ensure that its national standard is traceable to a primary standard maintained in another country's institute. Under <http://kcdb.bipm.org/AppendixC/default.asp>, the calibration and measurement capabilities (CMCs) declared by national metrology institutes are shown.

Calibration Laboratories. For *calibration laboratories* accredited according to the ISO/International Electrotechnical Commission (IEC) standard ISO/IEC 17025, accreditation is granted for specified calibrations with a defined best measurement capability that can (but not necessarily must) be achieved with a specified measuring instrument, reference or working standard.

The *best measurement capability* is defined as the smallest uncertainty of measurement that a laboratory can achieve within its scope of accreditation, when performing more or less routine calibrations of nearly ideal measurement standards intended to realise, conserve or reproduce a unit of that quantity or one or more of its values, or when performing more or less routine calibrations of nearly ideal measuring instruments designed for the measurement of that quantity.

Most of the accredited laboratories provide calibrations for customers, (e.g. for organisations that do not have own calibration facilities with a suitable measurement capability or for testing laboratories) on request. If the service of such an accredited calibration laboratory is taken into account, it must be assured that its scope of accreditation fits into the needs of the customer.

Accreditation bodies are obliged to provide a list of accredited laboratories with a detailed technical description of their scope of accreditation. <http://www.ilac.org/> provides a list of the accreditation bodies which are member of the **ILAC MRA**.

If a customer is using a nonaccredited calibration laboratory or if the scope of accreditation of a particular calibration laboratory does not fully cover a specific calibration required, the customer of that laboratory must ensure that:

- the traceability chain as described above is maintained correctly;
- there is a concept to estimate the overall measurement uncertainty in place and applied correctly;
- the staff is thoroughly trained to perform the activities within their responsibilities;
- clear and valid procedures are available to perform the required calibrations;
- a system to deal with errors is applied and the calibration operations include statistical process control such as, e.g., the use of control charts.

In-House Calibration Laboratories (Factory Calibration Laboratories). Frequently the calibration services are provided by in-house calibration laboratories which regularly calibrate the measuring and test equipment used in a company, e.g. in a production facility against its reference standards that are traceable to an accredited calibration laboratory or a national metrology institute.

An in-house calibration system normally assures that all measuring and test equipment used within a company is calibrated regularly against working standards, calibrated by an accredited calibration laboratory. In-house calibrations must fit into the internal applications in a way that the results obtained with the measuring and test equipment are accurate and reliable. This means that for in-house calibration the following elements should be considered as well:

- the uncertainty contribution of the in-house calibration should be known and taken into account if statements of compliance, e.g. internal criteria for measuring instruments, are made;
- the staff should be trained to perform the calibrations required correctly;
- clear and valid procedures should be available also for in-house calibrations;
- a system to deal with errors should be applied (e.g. in the frame of an overall quality management system) and the calibration operations should include

a statistical process control (e.g. the use of control charts).

To assure correct operation of the measuring and test equipment, a concept for the maintenance of that equipment should be in place. Aspects to be considered when establishing calibration intervals are given in Sect. 2.4.

The Hierarchy of Standards. The hierarchy of standards and a resulting metrological organisational structure for tracing measurement and test results within a company to national standards are shown in Fig. 2.2.

Equipment used by testing and calibration laboratories that has a significant effect on the reliability and uncertainty of measurement should be calibrated using standards connected to the national standards with a known uncertainty.

Alternative Solutions

Accreditation bodies which are members of the **ILAC MRA** require accredited laboratories to ensure traceability of their calibration and test results. Accredited laboratories also know the contribution of the uncertainty derived through the traceability chain to their calibration and test results.

Where such traceability is not (yet) possible, laboratories should at least assure comparability of their results by alternative methods. This can be done either through the use of appropriate reference materials (**RM**) or by participating regularly in appropriate proficiency tests (**PT**) or inter-laboratory comparisons. Appropriate means that the **RM** producers or the **PT** providers are competent or at least recognised in the respective sector.

2.2.4 Calibration of Measuring and Testing Devices

The draft revision of the VIM dated April 2004 gives two definitions for calibration:

Definition (a)

Operation that establishes the relation between quantity values provided by measurement standards and the corresponding indications of a measuring system, carried out under specified conditions and including evaluation of measurement uncertainty;

Definition (b)

Operation that establishes the relation, obtained by reference to one or more measurement standards, that exists under specified conditions, between the indication of

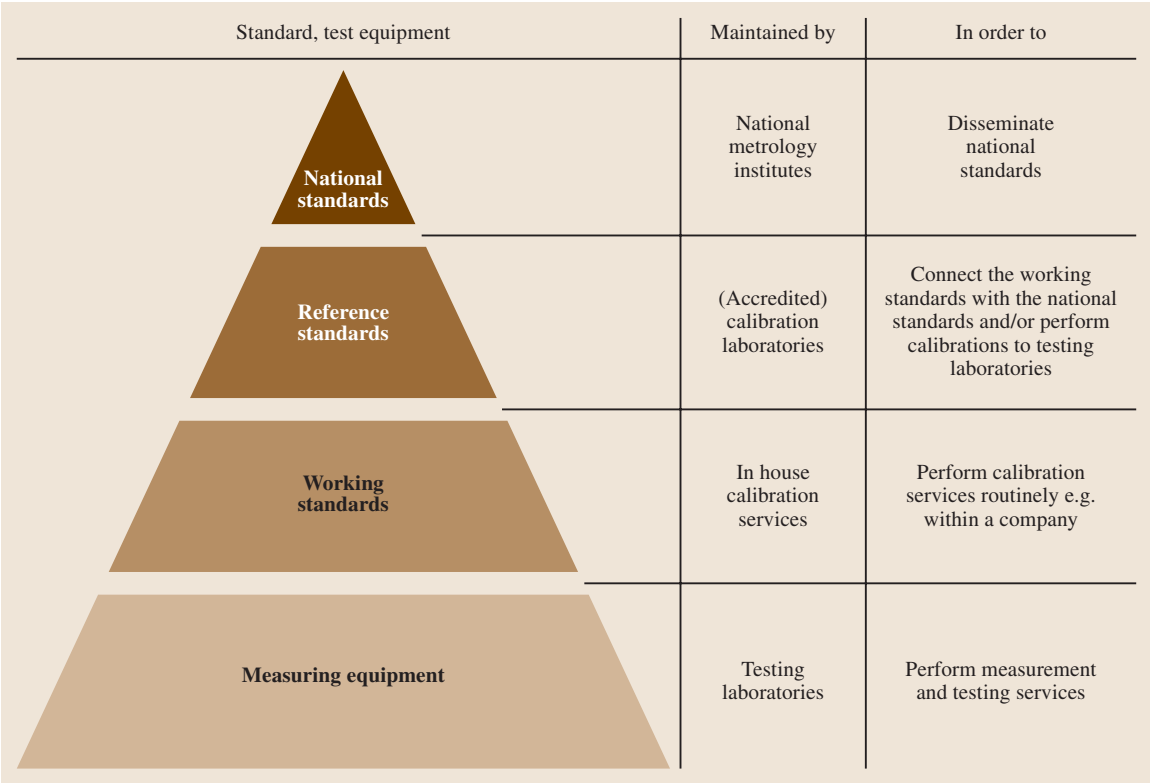

Fig. 2.2 The calibration hierarchy

a measuring system and the measurement result that would be obtained using the measuring system.

It is common and important that testing laboratories regularly maintain and control their testing instruments, measuring systems, reference and working standards. Laboratories working according to the standard ISO/IEC 17025 as well as manufacturers working according e.g. to the ISO 9001 series of standards maintain and calibrate their measuring instruments, reference and working standards regularly according to well defined procedures.

Clause 5.5.2 of the standard ISO/IEC 17025 requires that:

“Calibration programmes shall be established for key quantities or values of the instruments where these properties have a significant effect on the results.”

“Whenever practicable, all equipment under the control of the laboratory and requiring calibration shall be labeled, coded, or otherwise identified to indicate the status of calibration, including the data when last calibrated and the date or expiration criteria when recalibration is due.” (Clause 5.5.8)

Clause 7.6 of ISO 9001:2000 requires that:

“Where necessary to ensure valid results, measuring equipment shall be calibrated or verified at specified intervals, or prior to use, against measurement standards traceable to international or national measurement standards.”

In the frame of the calibration programs of their measuring instruments, reference and working standards, laboratories will have to define the time that should be permitted between successive calibrations (recalibrations) of the used measurement instruments, reference or working standards in order to:

- confirm that there has not been any deviation of the measuring instrument that could introduce doubt about the results delivered in the elapsed period,
- assure that the difference between a reference value and the value obtained using a measuring instrument is within acceptable limits, also taking into account the uncertainties of both values,
- assure that the uncertainty that can be achieved with the measuring instrument is within expected limits.

A large number of factors can influence the time interval to be defined between calibrations and should be taken into account by the laboratory. The most important factors are usually:

- the information provided by the manufacturer;
- the frequency of use and the conditions under which the instrument is used;
- the risk of the measuring instrument drifting out of the accepted tolerance;
- consequences which may arise from inaccurate measurements (e.g. failure costs in the production line or aspects of legal liability);
- the cost of necessary corrective actions in case of drifting away from the accepted tolerances;
- environmental conditions such as, e.g., climatic conditions, vibration, ionising radiation, etc;
- trend data obtained, e.g., from previous calibration records or the use of control charts;
- recorded history of maintenance and servicing;
- uncertainty of measurement required or declared by the laboratory.

These examples show the importance of establishing a concept for the maintenance of the testing instruments and measuring systems. In the frame of such a concept the definition of the calibration intervals is one important aspect to consider. To optimise the calibration

intervals, available statistical results, e.g. from the use of control charts, from participation in inter-laboratory comparisons or from reviewing own records should be used.

2.2.5 The Increasing Importance of Metrological Traceability

An increasing awareness of the need for metrological underpinning of measurements can be noticed at least in the past years. Several factors may be the reason for this process, including:

- the importance of quality management systems,
- requirements by governments or trading partners that producers have established certified quality management systems and that calibration and testing activities be accredited
- aspects of legal reliability.

In a lot of areas it is highly important that measurement results, e.g. produced by testing laboratories, can be compared with other results produced by other parties at another time and quite often using different methods. This can only be achieved if measurements are based on equivalent physical realisations of units. Traceability of results and reference values to primary standards is a fundamental issue in competent laboratory operation today.

2.3 Statistical Evaluation of Results

Statistics are used for a variety of purposes in measurement science, including mathematical modelling and prediction for calibration and method development, method validation, uncertainty estimation, quality control and assurance, and summarising and presenting results. This section provides an introduction to the main statistical techniques applied in measurement science. A knowledge of the basic descriptive statistics (mean, median, standard deviation, variance, quantiles) is assumed.

2.3.1 Fundamental Concepts

Measurement Theory and Statistics

The traditional application of statistics to quantitative measurement follows a set of basic assumptions related to ordinary statistics:

1. That a given measurand has a value – the value of the measurand – which is unknown and (in general)

unknowable by the measurement scientist. This is generally assumed (for univariate quantitative measurements) to be a single value for the purpose of statistical treatment. In statistical standards, this is the *true value*.

2. That each measurement provides an *estimate* of the value of the measurand, formed from an *observation* or set of observations.
3. That an observation is the sum of the measurand value and an *error*.

Assumption 3 can be expressed as one of the simplest statistical models:

$$x_i = \mu + e_i,$$

in which x_i is the i -th observation, μ is the measurand value and e_i is the error in the particular observation.

The error itself is usually considered to be a sum of several contributions from different sources or with different behaviour. The most common partition of error is

into two parts; one which is constant for the duration of a set of experiments (the *systematic* error) and another, the *random* error, which is assumed to arise by random selection from some distribution. Other partitioning is possible. For example, collaborative study uses a statistical model based on a systematic contribution (method bias), a term which is constant for a particular laboratory (the laboratory component of bias) but randomly distributed among laboratories, and a residual error for each observation. Linear calibration assumes that observations are the sum of a term that varies linearly and systematically with measurand value and a random term; least-squares regression is one way of characterising the behaviour of the systematic part of this model.

The importance of this approach is that, while the value of the measurand may be unknown, studying the distribution of the observations allows inferences to be drawn about the probable value of the measurand. Statistical theory describes and interrelates the behaviours of different distributions, and this provides quantitative tools for describing the probability of particular observations given certain assumptions. Inferences can be drawn about the value of the measurand by asking what range of measurand values could reasonably lead to the observations found. This provides a range of values that can reasonably be attributed to the measurand. Informed readers will note that this is the phrase used in the definition of uncertainty of measurement, which is discussed further below.

This philosophy forms the basis of many of the routine statistical methods applied in measurement, is well

established with strong theoretical foundations, and has stood the test of time well. This chapter will accordingly rely heavily on the relevant concepts. It is, however, important to be aware that it has limitations. The basic assumption of a point value for the measurand may be inappropriate for some situations. The approach does not deal well with the accumulation of information from a variety of different sources. Perhaps most importantly, real-world data rarely follow theoretical distributions very closely, and it can be misleading to take inference too far, and particularly to infer very small probabilities or very high levels of confidence. Further, other theoretical viewpoints can be taken and can provide different insights into, for example, the development of confidence in a value as data from different experiments are accumulated, and the treatment of estimates based on judgement instead of experiment.

Distributions

Figure 2.3 shows a typical measurement data set from a method validation exercise. The tabulated data shows a range of values. Plotting the data in histogram form shows that observations tend to cluster near the centre of the data set. The histogram is one possible graphical representation of the *distribution* of the data.

If the experiment is repeated, a visibly different data distribution is usually observed. However, as the number of observations in an experiment increases, the distribution becomes more consistent from experiment to experiment, tending towards some underlying form. This underlying form is sometimes called the *parent* distribution. In Fig. 2.3, the smooth curve is a plot of a possible parent distribution; in this case, a *normal distribution* with a mean and standard deviation estimated from the data.

There are several important features of the parent distribution shown in Fig. 2.3. First, it can be represented by a mathematical equation – a distribution function – with a relatively small number of parameters. For the normal distribution, the parameters are the mean and population standard deviation. Knowing that the parent distribution is normal, it is possible to summarize a large number of observations simply by giving the mean and standard deviation. This allows large sets of observations to be summarized in terms of the distribution type and the relevant parameters. Second, the distribution can be used predictively to make statements about the likelihood of further observations; in Fig. 2.3, for example, the curve indicates that observations in the region of 2750–2760 mg kg⁻¹ will occur rarely. The distribution is accordingly important in

Fig. 2.3 Typical measurement data. Data from 11 replicate analyses of a certified reference material with a certified value of 2747 ± 90 mg/kg cholesterol. The curve is a normal distribution with mean and standard deviation calculated from the data, with vertical scaling adjusted for comparability with the histogram

both describing data and in drawing inferences from the data.

Distributions of Measurement Data. Measurement data can often be expected to follow a normal distribution, and in considering statistical tests for ordinary cases, this will be the assumed distribution. However, some other distributions are important in particular circumstances. Table 2.1 lists some common distributions, whose general shape is shown in Fig. 2.4. The most important features of each are:

- The normal distribution is described by two independent parameters, the mean and standard deviation. The mean can take any value; the standard deviation any nonnegative value. The distribution is symmetric about the mean, and although the density falls off sharply, is actually infinite in extent. The normal distribution arises naturally from the additive combination of many effects, even, according to the central limit theorem, when those effects do not themselves arise from a normal distribution. (This has an important consequence for means; errors in the mean of even three or four observations can often be taken to be normally distributed even where the parent distribution is not.) Further, since small effects generally behave approximately additively, a very wide range of measurement systems show approximately normally distributed error.
- The lognormal distribution is closely related to the normal distribution; the logarithms of values from a lognormal distribution are normally distributed. It most commonly arises when errors combine multiplicatively, instead of additively. The lognormal distribution itself is generally asymmetric, with positive skew. However, as shown in the figure, the shape depends on the ratio of standard deviation to mean, and approaches that of a normal distribution as the standard deviation becomes small compared to the mean. The simplest method of handling lognormally distributed data is to take logarithms and treat the logged data as arising from a normal distribution. As the standard deviation becomes small relative to the mean, the lognormal distribution tends towards the normal distribution.
- The Poisson and binomial distributions describe counts, and accordingly are *discrete* distributions; they have nonzero density only for integer values of the variable. The Poisson distribution is applicable to cases such as radiation counting; the binomial distribution is most appropriate for systems dominated by sampling, such as the number of defective parts in a batch, the number of microbes in a fixed volume, or the number of contaminated particles in a sample from an inhomogeneous mixture. In the limit of large counts, the binomial distribution tends to the normal distribution; for small probability, it tends to the Poisson. Similarly, the Poisson distribution tends towards normality for small probability and large

Table 2.1 Common distributions in measurement data

Distribution	Density function	Mean	Expected Variance	Remarks
Normal	$\frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{(x-\mu)^2}{2\sigma^2}\right)$	μ	σ^2	Arises naturally from the summation of many small random errors from any distribution
Lognormal	$\frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{(\ln(x)-\mu)^2}{2\sigma^2}\right)$	$\exp\left(\mu + \frac{\sigma^2}{2}\right)$	$\exp\left(2\mu + \sigma^2\right) [\exp(\sigma^2) - 1]$	Arises naturally from the product of many terms with random errors. Approximates to normal for small standard deviation
Poisson	$\lambda^x \exp(-\lambda)/x!$	λ	λ	Distribution of events occurring in an interval; important for radiation counting. Approximates to normality for large λ
Binomial	$\binom{n}{x} p^x (1-p)^{(n-x)}$	np	$np(1-p)$	Distribution of x , the number of successes in n trials with probability of success p . Common in counting at low to moderate levels, such as microbial counts; also relevant in situations dominated by particulate sampling
Contaminated normal	Various			Contaminated normal is the most common assumption given the presence of a small proportion of aberrant results. The <i>correct</i> data follow a normal distribution; aberrant results follow a different, usually much broader, distribution

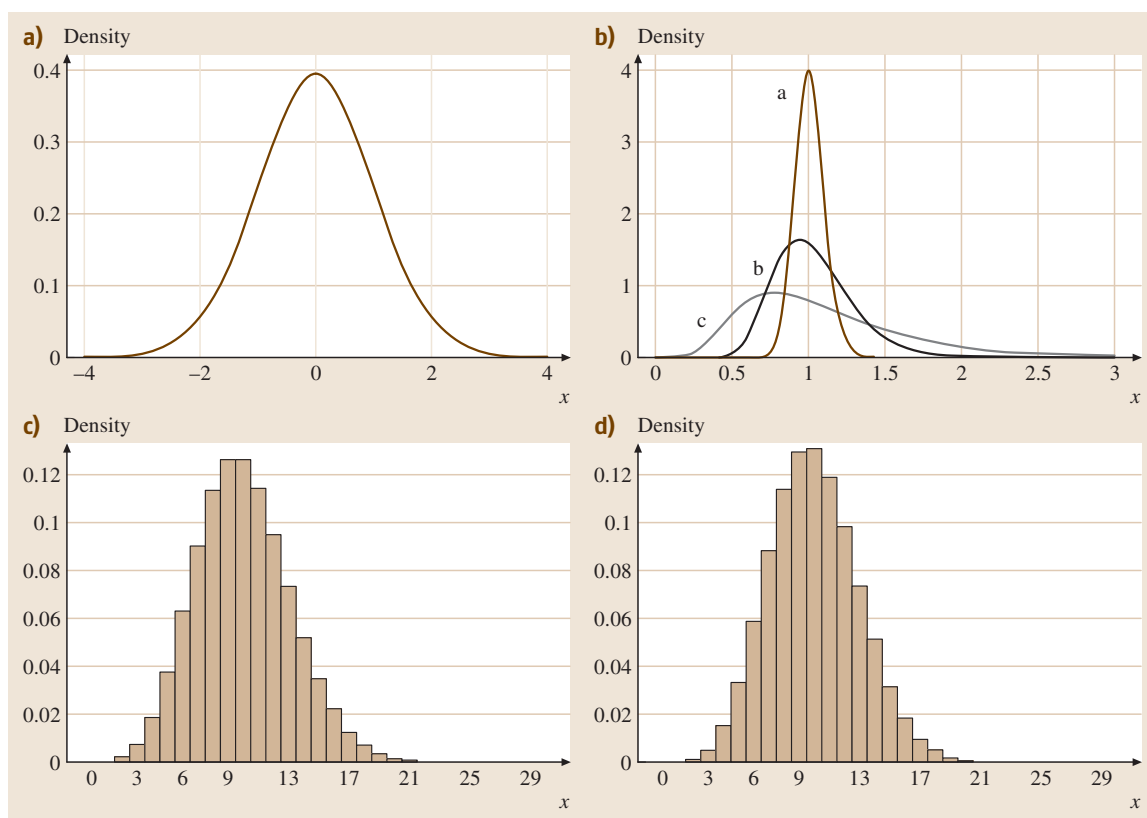

Fig. 2.4a–d Measurement data distributions. Figure 2.4 shows the *probability density function* for each distribution, not the probability; the area under each curve, or sum of discrete values, is equal to one. Unlike probability, the probability density at a point x can be higher than one. **(a)** The standard normal distribution (mean = 0, Standard deviation = 1.0). **(b)** Lognormal distributions; mean on log scale: 0, standard deviation on log scale = a : 0.1, b : 0.25, c : 0.5. **(c)** Poisson distribution: Lambda = 10. **(d)** Binomial distribution: 100 trials, $p(\text{success}) = 0.1$. Note that this provides the same mean as **(c)**

counts. Thus, the Poisson is often a convenient approximation to the binomial, and as counts increase, the normal distribution can be used to approximate either.

Distributions Derived from the Normal Distribution.

Before leaving the topic of distributions, it is important to be aware that other distributions are important in analysing measurement data with normally distributed error. The most important for this discussion are:

- The t -distribution, which describes the distribution of the means of small samples taken from a normal distribution. The t -distribution is routinely used for checking a method for significant bias or for comparing observations with limits;

- The chi-squared distribution, which describes *inter alia* the distribution of estimates of variance. Specifically, the variable $(n - 1)s^2/\sigma^2$ has a chi-squared distribution with $\nu = n - 1$ degrees of freedom. The chi-squared distribution is asymmetric with mean ν and variance 2ν ;
- The F -distribution, which describes the distribution of ratios of variances. This is important in comparing the spread of two different data sets, and is extensively used in analysis of variance as well as being useful for comparing the precision of alternative methods of measurement.

Probability and Significance

Given a particular distribution, it is possible to make predictions of the probability that observations will fall

within a particular range. For example, in a normal distribution, the fraction of observations falling, by chance, within two standard deviations of the mean value is very close to 95%. This equates to the probability of an observation occurring in that interval. Similarly, the probability of an observation falling more than 1.65 standard deviations above the mean value is close to 5%. These proportions can be calculated directly from the area under the curves shown in Fig. 2.4, and are available in tabular form, from statistical software and from most ordinary spreadsheet software.

Knowledge of the probability of a particular observation allows some statement about the significance of an observation. Observations with high probability of chance occurrence are not regarded as particularly significant; conversely, observations with a low probability of occurring by chance are taken as significant. Notice that an observation can only be allocated a probability if there is some assumption or hypothesis about the true state of affairs. For example, if it is asserted that the concentration of a contaminant is below some regulatory limit, it is meaningful to consider how likely a particular observation would be *given this hypothesis*. In the absence of any hypothesis, no observation is more likely than any other. This process of forming a hypothesis and then assessing the probability of a particular observation *given the hypothesis* is the basis of significance testing, and will be discussed in detail below.

2.3.2 Calculations and Software

Statistical treatment of data generally involves calculations, and often repetitive calculation. Frequently, too, best practice involves methods that are simply not practical manually, or require numerical solutions. Suitable software is therefore essential. Purpose-designed software for statistics and experimental design is widely available, including some free and open-source packages whose reliability challenges the best commercial software. Some such packages are listed in the Further Reading 2.10 section at the end of this chapter. Many of the tests and graphical methods described in this short introduction are also routinely available in general-purpose spreadsheet packages. Given the wide availability of software and the practical difficulties of implementing accurate numerical software, calculations will not generally be described in detail. Readers should consult existing texts or software for further details if required.

However, it remains important that the software used is reliable. This is particularly true of some of

the most popular business spreadsheet packages, which have proven notoriously inaccurate or unstable on even moderately ill-conditioned data sets. Any mathematical software used in a measurement laboratory should therefore be checked using typical measurement data to ensure that the numerical accuracy is sufficient. It may additionally be useful to test software using more extreme test sets; some such sets are freely available (see Further Reading 2.10).

2.3.3 Statistical Methods

Graphical Methods

Graphical methods refer to the range of graphs or plots that are used to present and assess data visually. Some have already been presented; the histogram in Fig. 2.3 is an example. Graphical methods are easy to implement with a variety of software and allow a measurement scientist to identify anomalies, such as outlying data points or groups, departures from assumed distributions or models, and unexpected trends, quickly and with minimal calculation. A complete discussion of graphical methods is beyond the scope of this book, but some of the most useful, with typical applications, are presented below. Their use is strongly recommended in routine data analysis.

Figure 2.4 illustrates some basic plots appropriate for reviewing simple one-dimensional data sets. Dot plots and strip charts are useful for reviewing small data sets. Both give a good indication of possible outliers and unusual clustering. Over-interpretation should be avoided; it is useful to gain experience by reviewing plots from random normal samples, which will quickly indicate the typical extent of apparent anomalies in small samples. Strip charts are simpler to generate (plot the data as the x variable with a constant value of y) but overlap can obscure clustering for even modest sets. The stacked dot plot, if available, is applicable to larger sets. Histograms become more appropriate as the number of data points increases. Box plots, or box-and-whisker plots (named for the lines extending from the rectangular box) are useful for summarising the general shape and extent of data, and are particularly useful for grouped data. For example, the range of data from replicate measurements on several different test items can be reviewed very easily using a box plot. Box plots can represent several descriptive statistics, including, for example, a mean and confidence interval. However, they are most commonly based on quantiles. Traditionally, the box extends from the first to the third quartile (that is, it contains the central 50% of the data points). The median is marked as a di-

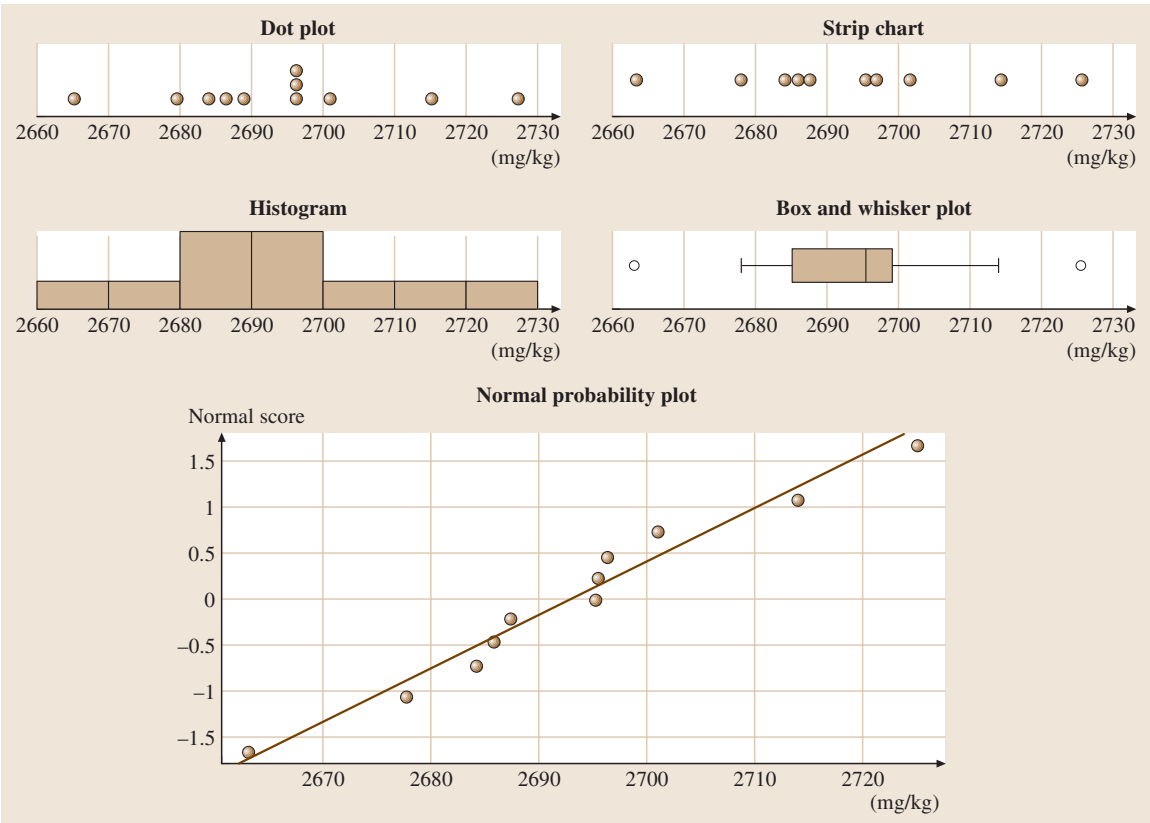

Fig. 2.5 Plots for simple data set review

viding line or other marker inside the box. The *whiskers* traditionally extend to the most distant data point within 1.5 times the interquartile range of the ends of the box. For a normal distribution, this would correspond to approximately the mean ± 2.7 standard deviations. Since this is just beyond the 99% confidence interval, more extreme points are likely to be outliers, and are therefore generally shown as individual points on the plot. Finally, a normal probability plot shows the distribution of the data plotted against the expected distribution assuming normality. In a normally distributed data set, points fall close to the diagonal line. Substantial deviations, particularly at either end of the plot, indicate non-normality.

The most common graphical method for two-dimensional measurement data (such as measurand level/instrument response pairs) is a scatter plot, in which points are plotted on a two-dimensional space with dimensions corresponding to the dimensions of the data set. Scatter plots are most useful in reviewing data

for linear regression, and the topic will accordingly be returned to below.

Planning of Experiments

Most measurements represent straightforward application of a measuring device or method to a test item. However, many experiments are intended to test for the presence or absence of some specific treatment effect – such as the effect of changing a measurement method or adjusting a manufacturing method. For example, one might wish to assess whether a reduction in preconditioning time had an effect on measurement results. In these cases, it is important that the experiment measures the intended effect, and not some external nuisance effect. For example, measurement systems often show significant changes from day to day or operator to operator. To continue the preconditioning example, if test items for short preconditioning were obtained by one operator and for long preconditioning by a different operator, operator effects might be misinterpreted

as a significant conditioning effect. Ensuring that nuisance parameters do not interfere with the result of an experiment is one of the aims of good experimental design.

A second, but often equally important aim, is to minimise the cost of an experiment. For example, a naïve experiment to investigate six possible effects might investigate each individually, using, say, three replicate measurements at each level for each effect; a total of 36 measurements. Careful experimental designs which vary all parameters simultaneously can, using the right statistical methods, reduce this to 16 or even 8 measurements and still achieve acceptable power.

Experimental design is a substantial topic, and a range of reference texts and software are available. Some of the basic principles of good design are, however, summarized below.

1. *Arrange experiments for cancellation*: the most precise and accurate measurements seek to cancel out sources of bias. For example, null-point methods, in which a reference and test item are compared directly by adjusting an instrument to give a zero reading, are very effective in removing bias due to residual current flow in an instrument. Simultaneous measurement of test item and calibrant reduces calibration differences; examples include the use of internal standards in chemical measurement, and the use of comparator instruments in gauge block calibration. Difference and ratio experiments also tend to reduce the effects of bias; it is therefore often better to study differences or ratios of responses obtained under identical conditions than to compare absolute measurements.
2. *Control if you can; randomise if you cannot*: a good experimenter will identify the main sources of bias and control them. For example, if temperature is an issue, temperature should be controlled as far as possible. If direct control is impossible, the statistical analysis should include the nuisance parameter. *Blocking* – systematic allocation of test items to different strata – can also help reduce bias. For example, in a two-day experiment, ensuring that every type of test item is measured an equal number of times on each day will allow statistical analysis to remove the between-day effect. Where an effect is known but cannot be controlled, and also to guard against unknown systematic effects, randomisation should be used. For example, measurements should always be made in random order within blocks as far as possible (although the order should be recorded to

allow trends to be identified) and test items should be assigned randomly to treatments.

3. *Plan for replication or obtaining independent uncertainty estimates*: without knowledge of the precision available, and more generally of the uncertainty, the experiment cannot be interpreted. Statistical tests all rely on comparison of an effect with some estimate of the uncertainty of the effect, usually based on observed precision. Thus, experiments should always include some replication to allow precision to be estimated, or provide for additional information of the uncertainty.
4. *Design for statistical analysis*: “To consult a statistician after an experiment is finished is often merely to ask him to conduct a post-mortem examination. He can perhaps say what the experiment died of.” (*R. A. Fisher, Presidential Address to the First Indian Statistical Congress, 1938*). An experiment should always be planned with a specific method of statistical analysis in mind. Otherwise, despite the considerable range of tools available, there is too high a risk that no statistical analysis will be applicable. One particular issue in this context is that of *balance*. Many experiments test several parameters simultaneously. If more data are obtained on some combinations than others, it may be impossible to separate the different effects. This applies particularly to two-way or higher-order analysis of variance, in which interaction terms are not generally interpretable with unbalanced designs. Imbalance can be tolerated in some types of analysis, but not in all.

Significance Testing

General Principles. Because measurement results vary, there is always some doubt about whether an observed difference arises from chance variation or from an underlying, real, difference. Significance testing allows the scientist to make reliable objective judgements on the basis of data gathered from experiments, while protecting against over-interpretation based on chance differences.

A significance test starts with some hypothesis about a true value or values, and then determines whether the observations – which may or may not appear to contradict the hypothesis – could reasonably arise by chance if the hypothesis were correct. Significance tests therefore involve the following general steps:

1. *State the question clearly, in terms of a null hypothesis and an alternate hypothesis*: in most significance testing, the null hypothesis is that there is no effect of interest. The alternate is always an alternative state

Test objective	Test name	Test Sstatistic	Remarks
Tests on a single observed mean \bar{x} against a reference value or range			
Test for significant difference from the reference value x_0	Student t -test	$ x_0 - \bar{x} / (s / \sqrt{n})$	Hypothesis ($\mu = x_0$). Against alternate ($x_0 \neq \mu$). Use a table of two-tailed critical values
Test for \bar{x} significantly exceeding an upper limit x_0	Student t -test	$(\bar{x} - x_0) / (s / \sqrt{n})$	Hypothesis ($\mu_1 = \mu_2$). Against alternate ($\mu_1 \neq \mu_2$). Use a table of <i>one</i> -tailed critical values. Note that the sign of $x_0 - \bar{x}$ is retained
Test for \bar{x} falling significantly below a lower limit x_0	Student t -test	$(x_0 - \bar{x}) / (s / \sqrt{n})$	
Test for \bar{x} falling significantly outside a range $[x_L, x_U]$	Student t -test	$\max \left[\begin{array}{l} (x_L - \bar{x}) / (s / \sqrt{n}) \\ (\bar{x} - x_U) / (s / \sqrt{n}) \end{array} \right]$	Hypothesis: $x_L \leq \mu \leq x_U$ against the alternate $\mu < x_L$, $x_U < \mu$. Use a table of <i>one</i> -tailed critical values. This test assumes that the range is large compared to s , but $(x_U - x_L) > s$ gives adequate accuracy at the 5% significance level
Tests for significant difference between two means			
(a) With equal variance	Equal-variance t -test	$ \bar{x}_1 - \bar{x}_2 $	Hypothesis $\mu_1 = \mu_2$ against alternate ($\mu_1 \neq \mu_2$)
(b) With significantly different variance	Unequal-variance t -test		Use a table of two-tailed critical values. For equal variance, take degrees of freedom equal to $n_1 + n_2 - 2$. For unequal variance, take degrees of freedom equal to $\frac{(s_1^2/n_1 + s_2^2/n_2)^2}{[(n_1 - 1)/(s_1/n_1)^2 + (n_2 - 1)(s_2/n_2)^2]}$
For testing the hypothesis $\mu_1 > \mu_2$ against the alternative $\mu_1 \leq \mu_2$, where μ_1 is the <i>expected</i> larger mean (not necessarily the larger observed mean), calculated the test statistic using $(\bar{x}_1 - \bar{x}_2)$ instead of $ \bar{x}_1 - \bar{x}_2 $ and use a one-tailed critical value			
Test n paired values for significant difference (constant variance)	Paired t -test	$\frac{ \bar{d} }{(s_d / \sqrt{n})}$, where $\bar{d} = \frac{1}{n} \sum_i x_{1,i} - x_{2,i}$ and $s_d = \frac{1}{n-1} \sum_i (x_{1,i} - x_{2,i})^2$	Hypothesis $\mu_d = 0$ against alternate $\mu_d \neq 0$. The sets must consist of pairs of measurements, such as measurements on the same test items by two different methods.
Tests for standard deviations			
Test an observed standard deviation against a reference or required value σ_0	i) Chi-squared test	i) $(n-1)s^2/\sigma_0$	i) Compared $(n-1)s^2/\sigma_0$ with critical values for the chi-squared distribution with $n-1$ degrees of freedom.
	ii) F -test	ii) s^2/σ_0	ii) Compared s^2/σ_0 with critical values for F for $(n-1)$ and infinite degrees of freedom. For a test of $\sigma \leq \sigma_0$ against $\sigma > \sigma_0$, use the upper one-tailed critical value of chi-squared or F for probability α . To test $\sigma = \sigma_0$ against $\sigma \neq \sigma_0$, use two-tailed limits for chi-squared or compared $\max(s^2/\sigma_0, \sigma_0/s^2)$ against the upper one-tailed value for F for probability $\alpha/2$
Test for a significant difference between two observed standard deviations	F -test	s_{\max}^2/s_{\min}^2	Hypothesis: $\sigma_1 = \sigma_2$ against $\sigma_1 \neq \sigma_2$. s_{\max} is the larger observed standard deviation. Use the upper <i>one</i> -tailed critical value for F for a probability $\alpha/2$ using $n_1 - 1$, $n_2 - 1$ degrees of freedom.
Test for one observed standard deviations s_1 significantly exceeding another (s_2)	F -test	s_1^2/s_2^2	Hypothesis: $\sigma_1 \leq \sigma_2$ against $\sigma_1 > \sigma_2$. Use the upper <i>one</i> -tailed critical value for F for a probability α using $n_1 - 1$, $n_2 - 1$ degrees of freedom
Test for homogeneity of variance among several groups of data	Levene's test	N/A	Levene's test is most simply estimated as a one-way analysis of variance performed on absolute values of group residuals, that is, $ x_{ij} - \hat{x}_j $ where \hat{x}_j is an estimate of the population mean of group j , \hat{x}_j is usually the median, but the mean or another robust value can be used

Table 2.2 Common significance tests for normally distributed data. The following symbols are used: α is the desired significance level (usually 0.05); μ is the (true) value of the measurand; σ = population standard deviation for the population described by μ (not that calculated from the data). \bar{x} is the observed mean; s is the standard deviation of the data used to calculate \bar{x} ; n is the number of data points. x_0 is the reference value; x_U, x_L are the upper and lower limits of a range. $\mu_1, \mu_2, \bar{x}_1, \bar{x}_2, s_1, s_2, n_1, n_2$ are the corresponding values for each of two sets of data to be compared ◀

of affairs such that the two hypotheses are mutually exclusive and that the combined probability of one or the other is equal to 1; that is, that no other situation is relevant. For example, a common null hypothesis about a difference between two values is: *there is no difference between the true values* ($\mu_1 = \mu_2$). The relevant alternate is that *there is a difference between the true values* ($\mu_1 \neq \mu_2$). The two are mutually exclusive (they cannot both be true simultaneously) and it is certain that one of them is true, so the combined probability is exactly 1.0. The importance of the hypotheses is that different initial hypotheses lead to different estimates of the probability of a contradictory observation. For example, if it is hypothesised that the (true) value of the measurand is exactly equal to some reference value, there is some probability (usually equal) of contradictory observations both above and below the reference value. If, on the other hand, it is hypothesised that the true value is less than or equal to the reference value, the situation changes. If the true value may be anywhere below or equal to the reference value, it is less likely that observations above the reference value will occur, because of the reduced chance of such observations from true values very far below the reference value. This change in probability of observations on one side or another must be reflected either in the choice of critical value, or in the method of calculation of the probability.

2. *Select an appropriate test*: different questions require different tests; so do different distribution assumptions. Table 2.4 provides a summary of the tests appropriate for a range of common situations. Each test dictates the method of calculating a value called the *test statistic* from the data.
3. *Calculate the test statistic*: in software, the test statistic is usually calculated automatically, based on the test chosen.
4. *Choose a significance level*: the significance level is the probability at which chance is deemed suf-

ficiently unlikely to justify rejection of the null hypothesis. It is usually the measurement scientist's responsibility to choose the level of significance appropriately. For most common tests on measurement results, the significance level is set at 0.05, or 5%. For stringent tests, 1% significance or less may be appropriate. The term *level of confidence* is an alternative expression of the same quantity; for example, the 5% level of significance is equal to the 95% level of confidence. Mathematically, the significance level is the probability of incorrectly rejecting the null hypothesis given a particular critical value for a test statistic (see below). Thus, one chooses the critical value to provide a suitable significance level.

5. *Calculate the degrees of freedom for the test*: the distribution of error often depends not only on the number of observations n , but on the number of degrees of freedom ν (Greek nu). ν is usually equal to the number of observations minus the number of parameters estimated from the data; $n - 1$ for a simple mean value, for example. For experiments involving many parameters or many distinct groups, the number of degrees of freedom may be very different from the number of observations. The number of degrees of freedom is usually calculated automatically in software.
6. *Obtain a critical value*: critical values are obtained from tables for the relevant distribution, or from software. Statistical software usually calculates the critical value automatically given the level of significance.
7. *Compare the test statistic with the critical value or examine the calculated probability (p-value)*. Traditionally, the test is completed by comparing the calculated value of the test statistic with the critical value determined from tables or software. Usually (but not always) a calculated value higher than the critical value denotes significance at the chosen level of significance. In software, it is generally more convenient to examine the calculated probability of the observed test statistic, or *p-value*, which is usually part of the output. The *p-value* is always between 0 and 1; small values indicate a low probability of chance occurrence. This, if the *p-value* is below the chosen level of significance, the result of the test is significant and the null hypothesis is rejected.

Significance Tests for Specific Circumstances. Table 2.2 provides a summary of the most common significance test used in measurement for normally distributed data. The calculations for the relevant test statistics are in-

cluded, although most are calculated automatically by software.

Interpretation of Significance Test Results. While a significance test provides information on whether an observed difference could arise by chance, it is important to remember that statistical significance does not necessarily equate to practical importance. Given sufficient data, very small differences can be detected. It does not follow that such small differences are important. For example, given good precision, a measured mean 2% away from a reference value may be statistically significant. If the measurement requirement is to determine a value within 10%, however the 2% bias has little practical importance.

The other chief limitation of significance testing is that a lack of statistical significance cannot prove the absence of an effect. It should be interpreted only as an indication that the experiment failed to provide sufficient evidence to conclude that there was an effect. At best, statistical insignificance shows only that the effect is not large compared to the experimental precision available. Where many experiments fail to find a significant effect, of course, it becomes increasingly safe to conclude that there is none.

Effect of Non-constant Standard Deviation. Significance tests on means assume that the standard deviation is a good estimate of the population standard deviation and that it is constant with μ . This assumption breaks down, for example, if the standard deviation is approximately proportional to μ , a common observation in many fields of measurement (including analytical chemistry and radiological counting, although the latter would use intervals based on the Poisson distribution). In conducting a significance test in such circumstances, the test should be based on the best estimate of the standard deviation at the hypothesised value μ , and not that at the value \bar{x} . To take a specific example, in calculating whether a measured value significantly exceeds a limit, the test should be based on the standard deviation at the limit, not at the observed value.

Fortunately, this is only a problem when the standard deviation depends very strongly on μ in the range of interest and where the standard deviation is large compared to the mean to be tested. For s/\bar{x} less than about 0.1, for example, it is rarely important.

Confidence Intervals

Statistical Basis of Confidence Intervals. A confidence interval is an interval within which a statistic (such as

a mean or a single observation) would be expected to be observed with a specified probability.

Significance tests are closely related to the idea of confidence intervals. Consider a test for significant difference between an observed mean \bar{x} (taken from n values with standard deviation s) against a hypothesised measurand value μ . Using a t -test, the difference is considered significant at the level of confidence $1 - \alpha$ if

$$\frac{|\bar{x} - \mu|}{s/\sqrt{n}} > t_{\alpha, v, 2},$$

where $t_{\alpha, v, 2}$ is the two-tailed critical value of Student's t at a level of significance α . The condition for an *insignificant* difference is therefore

$$\frac{|\bar{x} - \mu|}{s/\sqrt{n}} \leq t_{\alpha, v, 2}.$$

Rearranging gives, $|\bar{x} - \mu| \leq t_{\alpha, v, 2}s/\sqrt{n}$ or, equivalently, $-\bar{x} + t_{\alpha, v, 2}s/\sqrt{n} \leq \mu \leq \bar{x} + t_{\alpha, v, 2}s/\sqrt{n}$. Adding \bar{x} and adjusting signs and inequalities accordingly gives

$$\bar{x} - t_{\alpha, v, 2}s/\sqrt{n} \leq \mu \leq \bar{x} + t_{\alpha, v, 2}s/\sqrt{n}.$$

This interval is called the $1 - \alpha$ confidence interval for μ . Any value of μ within this interval would be considered consistent with \bar{x} under a t -test at significance level α .

Strictly, this confidence interval cannot be interpreted in terms of the probability that μ is within the interval $\bar{x} \pm t_{\alpha, v, 2}s/\sqrt{n}$. It is, rather that, in a long succession of similar experiments, a proportion $100(1 - \alpha)\%$ of the calculated confidence intervals would be expected to contain the true mean μ . However, because the significance level α is chosen to ensure that this proportion is reasonably high, a confidence interval does give an indication of the range of values that can reasonably be attributed to the measurand, based on the statistical information available so far. (It will be seen later that other information may alter the range of values we may attribute to the measurand.)

For most practical purposes, the confidence interval is quoted at the 95% level of confidence. The value of t for 95% confidence is approximately 2.0 for large degrees of freedom; it is accordingly common to use the range $\bar{x} \pm 2s/\sqrt{n}$ as an approximate 95% confidence interval for the value of the measurand.

Note that, while the confidence interval is in this instance symmetrical about the measured mean value, this is by no means always the case. Confidence intervals based on Poisson distributions are markedly asymmetric, as are those for variances. Asymmetric confidence

Table 2.3 One-way ANOVA. Analysis of variance table

Source of variation	SS	df	MS	F	P-value	F_{crit}
Between groups	8.85	3	2.95	3.19	0.084	4.07
Within groups	7.41	8	0.93			
Total	16.26	11				

intervals can also be expected when the standard deviation varies strongly with μ , as noted above in relation to significance tests.

Before leaving the topic of confidence intervals, it is worth noting that the use of confidence intervals is not limited to mean values. Essentially any estimated parameter estimate has a confidence interval. It is often simpler to compare some hypothesised value of the parameter with the confidence interval than to carry out a significance test. For example, a simple test for significance of an intercept in linear regression (below) is to see whether the confidence interval for the intercept includes zero. If it does, the intercept is not statistically significant.

Analysis of Variance

Introduction to ANOVA. Analysis of variance (ANOVA) is a general tool for analysing data grouped by some factor or factors of interest, such as laboratory, operator or temperature. ANOVA allows decisions on which factors are contributing significantly to the overall dispersion of the data. It can also provide a direct measure of the dispersion due to each factor.

Factors can be qualitative or quantitative. For example, replicate data from different laboratories is grouped by the qualitative factor ‘laboratory’. This single factor data would require a one-way analysis of variance. In an experiment to examine time and temperature effects on a reaction, the data are grouped by both time and temperature. Two factors require two-way analysis of variance. Each factor treated by ANOVA must take two or more values, or *levels*. A combination of factor levels is termed a *cell*, since it forms a cell in a table of data grouped by factor levels. Table 2.5 shows an example of data grouped by time and temperature. There are two factors (time and temperature)

Table 2.4 One-way ANOVA. Data analysed

Instrument			
A	B	C	D
58.58	59.89	60.76	61.80
60.15	61.02	60.78	60.60
59.65	61.40	62.90	62.50

and each has three levels (distinct values). Each cell (that is, each time/temperature combination) holds two observations.

The calculations for ANOVA are best done using software. Software can automate the traditional manual calculation, or can use more general methods. For example, simple grouped data with equal numbers of replicates within each cell is relatively simple to analyse using summation and sums of squares. Where there are different numbers of replicates per cell (referred to as an unbalanced design), ANOVA is better carried out by linear modelling software. Indeed, this is often the default method in current statistical software packages. Fortunately, the output is generally similar whatever the process used. This section accordingly discusses the interpretation of output from ANOVA software, rather than the process itself.

One-Way ANOVA. One-way ANOVA operates on the assumption that there are two sources of variance in the data: an effect that causes the true mean values of groups to differ, and another that causes data in within each group to disperse. In terms of a statistical model, the i -th observation in the j -th group, x_{ij} , is given by

$$x_{ij} = \mu + \delta_j + \varepsilon_{ij},$$

where δ and ε are usually assumed to be normally distributed with mean 0 and standard deviations σ_b and σ_w , respectively. The subscripts b and w refer to the between-group effect and the within-group effect, respectively. A typical ANOVA table for one-way ANOVA is shown in Table 2.3 (The data analysed are shown, to three figures only, in Table 2.4. The important features are:

- The row labels, between-group and within-group refer to the estimated contributions from each of the two effects in the model. The ‘Total’ row refers to the total dispersion of the data.
- The columns ‘SS’ and ‘df’ are the sum of squares (actually, the sum of squared deviations from the relevant mean value) and the degrees of freedom for each effect. Notice that the total sum of squares and degrees of freedom are equal to the sum of those in

Table 2.5 Example data for two-way ANOVA

Time (min)	Temperature (K)		
	298	315	330
10	6.4	11.9	13.5
10	8.4	4.8	16.7
12	7.8	10.6	17.6
12	10.1	11.9	14.8
9	1.5	8.1	13.2
9	3.9	7.6	15.6

the rows above; this is a general feature of ANOVA and in fact the between-group SS and df can be calculated from the other two rows.

- The ‘MS’ column refers to a quantity called the mean square for each effect. Calculated by dividing the sum of squares by the degrees of freedom, it can be shown that each mean square is an estimated variance. The between-group mean square (MS_b) estimates $n_w\sigma_b^2 + \sigma_w^2$ (where n_w is the number of values in each group); the within-group mean square (MS_w) estimates the within-group variance σ_w^2 .

It follows that if the between-group contribution were zero, the two mean squares should be the same, while if there were a real between-group effect, the between-group mean square would be larger than the within-group mean square. This allows a test for significance; specifically, a one-sided F -test. The table accordingly gives the calculated value for F ($= MS_b/MS_w$), the relevant critical value for F using the degrees of freedom shown, and the p -value, that is, the probability that $F \geq F_{\text{calc}}$ given the null hypothesis. In this table, the p -value is approximately 0.08, so in this instance, it is concluded that the difference is not statistically significant. By implication, the instruments under study show no significant differences.

Finally, one-way ANOVA is often used for inter-laboratory data to calculate repeatability and reproducibility for a method or process. Under inter-laboratory conditions, repeatability standard deviation s_r is simply $\sqrt{MS_w}$. The reproducibility standard deviation

s_R is given by

$$s_R = \sqrt{\frac{MS_b + (n_w - 1)MS_w}{n_w}}.$$

Two-Way ANOVA. Two-way ANOVA is interpreted in a broadly similar manner. Each effect is allocated a row in an ANOVA table, and each main effect (that is, the effect of each factor) can be tested against the within-group term (often called the residual, or error, term in higher-order ANOVA tables). There is, however, one additional feature found in higher-order ANOVA tables, and that is the presence of one or more *interaction terms*.

By way of example, Table 2.6 shows the two-way ANOVA table for the data in Table 2.5. Notice the ‘Interaction’ row (in some software, this would be labelled ‘Time:Temperature’ to denote which interaction it referred to). The presence of this row is best understood by reference to a new statistical model

$$x_{ijk} = \mu + A_j + B_k + AB_{jk} + \varepsilon_{ijk}.$$

Assume for the moment that the factor A relates to the columns in Table 2.5, and the factor B to the rows. This model says that each level j of factor A shifts all results in column j by an amount A_j , and each level k of factor B shifts all values in row k by an amount B_j . This alone would mean that the effect of factor A is independent of the level of factor B . Indeed it is perfectly possible to analyse the data using the statistical model $x_{ijk} = \mu + A_j + B_k + \varepsilon_{ijk}$ to determine these main effects – even without replication; this is the basis of so-called two-way ANOVA without replication. However, it is possible that the effects of A and B are not independent; perhaps the effect of factor A depends on the level of B . In a chemical reaction, this is not unusual; the effect of time on reaction yield is generally dependent on the temperature, and vice versa. The term AB_{jk} in the above model allows for this, by associating a possible additional effect with every combination of factor levels A and B . This is the interaction term, and is the term referred to by the ‘Interaction’ row in Table 2.6. If

Table 2.6 Two-way ANOVA table

Source of variation	SS	df	MS	F	P-value	F_{crit}
Time	44.6	2	22.3	4.4	0.047	4.26
Temperature	246.5	2	123.2	24.1	0.0002	4.26
Interaction	15.4	4	3.8	0.8	0.58	3.63
Within	46.0	9	5.1			
Total	352.5	17	154.5			

it is significant with respect to the within-group, or error, term, it indicates that the effects of the two main factors are not independent.

In general, in an analysis of data on measurement systems, it is safe to assume that the levels of the factors *A* and *B* are chosen from a larger possible population. This situation is analysed, in two-way ANOVA, as a *random effects model*. Interpretation of the ANOVA table in this situation proceeds as follows:

1. Compare the interaction term to the within-group term.
2. If the interaction term is *not* significant, the main effects can be compared directly to the within-group term, as usually calculated in most ANOVA tables. In this situation, greater power can be obtained by pooling the within-group and interaction term, by adding the sums of squares and the degrees of freedom values, and calculating a new mean square from the new combined sum of squares and degrees of freedom. In Table 2.6, for example, the new mean square would be 4.7, and (more importantly) the degrees of freedom for the pooled effect would be 13, instead of 9. The resulting *p*-values for the main effects drop to 0.029 and 3×10^{-5} as a result. With statistical software, it is simpler to repeat the analysis omitting the interaction term, which gives the same results.
3. If the interaction term *is* significant, it should be concluded that even if the main effects are not statistically significant in isolation, their combined effect is statistically significant. Further, the effects are not independent of one another. For example, high temperature and long times might increase yield more than simply raising the temperature or extending the time in isolation. Second, compare the main effects to the interaction term (using an *F*-test on the mean squares) to establish whether each main effect has a statistically significant additional influence – that is, in addition to its effect in combination – on the results.

The analysis proceeds differently where both factors are *fixed effects*; that is, not drawn from a larger population. In such cases, all effects are compared directly with the within-group term.

Higher-order ANOVA models can be constructed using statistical software. It is perfectly possible to analyse simultaneously for any number of effects and all their interactions, given sufficient replication. However, in two-way and higher-order ANOVA, some cautionary notes are important.

Assumptions in ANOVA. ANOVA (as presented above) assumes normality, and also assumes that the within-group variances arise from the same population. Departures from normality are not generally critical; most of the mean squares are related to sums of squares of group means, and as noted above, means tend to be normally distributed even where the parent distribution is non-normal. However, severe outliers can have serious effects; a single severe outlier can inflate the within-group mean square drastically and thereby obscure significant main effects. Outliers can also lead to spurious significance – particularly for interaction terms – by moving individual group means. Careful inspection to detect outliers is accordingly important. Graphical methods, such as box plots, are ideal for this purpose, though other methods are commonly applied (see *Outlier detection* below).

The assumption of equal variance (homoscedasticity) is often more important in ANOVA than that of normality. Count data, for example, manifest a variance related to the mean count. This can cause seriously misleading interpretation. The general approach in such cases is to transform the data to give constant variance (not necessarily normality) for the transformed data. For example, Poisson-distributed count data, for which the variance is expected to be equal to the mean value, should be transformed by taking the square root of each value before analysis; this provides data that satisfies the assumption of homoscedasticity to a reasonable approximation.

Effect of Unbalanced Design. Two-way ANOVA usually assumes that the design is balanced, that is, all cells are populated and all contain equal numbers of observations. If this is not the case, the order that terms appear in the model becomes important, and changing the order can affect the apparent significance. Further, the mean squares no longer estimate isolated effects, and comparisons no longer test useful hypotheses.

Advanced statistical software can address this issue to an extent, using various modified sums of squares (usually referred to as type II, III etc.). In practice, even these are not always sufficient. A more general approach is to proceed by constructing a linear model containing all the effects, then comparing the residual mean square with that for models constructed by omitting each main effect (or interaction term) in turn. Significant differences in the residual mean square indicate a significant effect, independently of the order of specification.

Least-Squares Linear Regression

Principles of Least-Squares Regression. Linear regression estimates the coefficients α_i of a model of the general form

$$Y = \alpha_0 + \alpha_1 X_1 + \alpha_2 X_2 + \dots + \alpha_n X_n,$$

where, most generally, each variable X is a *basis function*, that is, some function of a measured variable. Thus, the term covers both multiple regression, in which each X may be a different quantity, and polynomial regression, in which successive basis functions X are increasing powers of the independent variable (e.g., x , x^2 etc.). Other forms are, of course, possible. These all fall into the class of linear regression because they are linear in the coefficients α_i , not because they are linear in the variable X . However, the most common use of linear regression in measurement is to estimate the coefficients in the simple model

$$Y = \alpha_0 + \alpha_1 X$$

and this simplest form – the form usually implied by the unqualified term linear regression – is the subject of this section.

The coefficients for the linear model above can be estimated using a surprisingly wide range of procedures, including robust procedures, which are resistant to the effects of outliers, and nonparametric methods, which make no distribution assumptions. In practice, by far the most common is simple least-squares linear regression, which provides the minimum variance unbiased estimate of the coefficients when all errors are in the dependent variable Y and the error in Y is normally distributed. The statistical model for this situation is

$$y_i = \alpha_0 + \alpha_1 x_i + \varepsilon_i,$$

where ε_i is the usual error term and α_i are the true values of the coefficients, with estimated values a_i . The coefficients are estimated by finding the values that minimise the sum of squares

$$\sum_i w_i [y_i - (a_0 + a_1 x_i)]^2,$$

where the w_i are weights chosen appropriately for the variance associated with each point y_i . Most simple regression software sets the weights equal to 1, implicitly assuming equal variance for all y_i . Another common procedure (rarely available in spreadsheet implementations) is to set $w_i = 1/s_i^2$, where s_i is the standard deviation at y_i ; this *inverse variance weighting* is the correct weighting where the standard deviation varies significantly across the y_i .

The calculations are well documented elsewhere and, as usual, will be assumed to be carried out by software. The remainder of this section accordingly discusses the planning and interpretation of linear regression in measurement applications.

Planning for Linear Regression. Most applications of linear regression for measurement relate to the construction of a calibration curve (actually a straight line). The instrument response for a number of reference values is obtained, and the calculated coefficients a_i used to estimate the measurand value from signal responses on test items. There are two stages to this process. At the validation stage, the linearity of the response is checked. This generally requires sufficient power to detect departures from linearity and to investigate the dependence of precision on response. For routine measurement, it is sufficient to reestablish the calibration line for current circumstances; this generally requires sufficient uncertainty and some protection against erroneous readings or reference material preparation.

In the first, validation, study, a minimum of five levels, approximately equally spaced across the range of interest, are recommended. Replication is vital if a dependence of precision on response is likely; at least three replicates are usually required. Higher numbers of both levels and replication provide more power.

At the routine calibration stage, if the linearity is very well known over the range of interest and the intercept demonstrably insignificant, single-point calibration is feasible; two-point calibration may also be feasible if the intercept is nonzero. However, since there is then no possibility of checking either the internal consistency of the fit, or the quality of the fit, suitable quality control checks are essential in such cases. To provide additional checks, it is often useful to run a minimum of four to five levels; this allows checks for outlying values and for unsuspected nonlinearity. Of course, for extended calibration ranges, with less well-known linearity, it will be valuable to add further points. In the following discussion, it will be assumed that at least five levels are included.

Interpreting Regression Statistics. The first, and perhaps most important, check on the data is to inspect the fitted line visually, and wherever possible to check a residual plot. For unweighted regression (i.e. where $w_i = 1.0$) the residual plot is simply a scatter plot of the values $y_i - (a_0 + a_1 x_i)$ against x_i . Where weighted regression is used, it is more useful to plot the weighted residuals $w_i [y_i - (a_0 + a_1 x_i)]$. Figure 2.6 shows an example, including: (a) the fitted line and data and (b) the

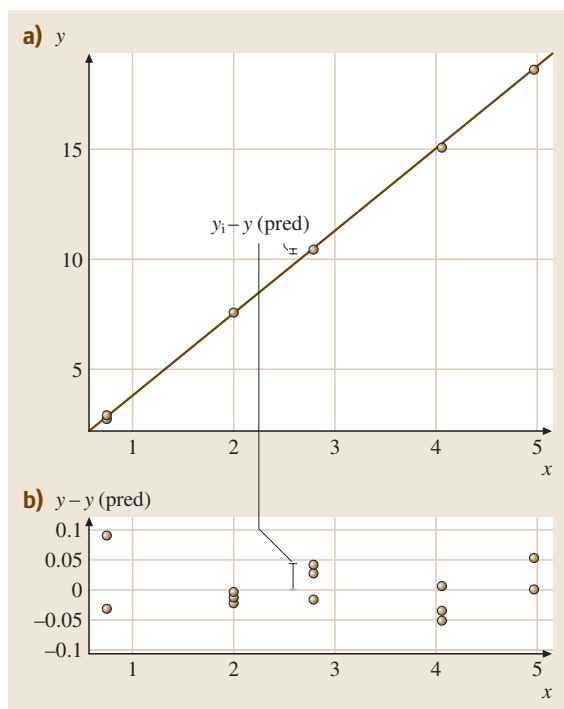

Fig. 2.6 Linear regression

residual plot. The residual plot clearly provides a much more detailed picture of the dispersion around the line. It should be inspected for evidence of curvature, outlying points, and unexpected changes in precision. In Fig. 2.6, for example, there is no evidence of curvature, though there might be a high outlying point at $x_i = 1$.

Regression statistics include the correlation coefficient r (or r^2), a derived correlation coefficient r^2 (adjusted); the regression parameters a_i , and (usually) their standard errors, confidence intervals, and a p -value for each based on a t -test for difference compared to the null hypothesis of zero for each.

The regression coefficient is always in the range -1 to 1 . Values nearer zero indicate a lack of linear relationship (not necessarily a lack of *any* relationship); values near 1 or -1 indicate a strong linear relationship. The regression coefficient will always be high when the data are clustered at the ends of the plot, which is why it is good practice to space points approximately evenly. Note that r and r^2 approach 1 as the number of degrees of freedom approaches zero, which can lead to over-interpretation. The adjusted r^2 value protects against this, as it decreases as the number of degrees of freedom reduces.

The regression parameters and their standard errors should be examined. Usually, in calibration, the intercept a_0 is of interest; if it is insignificant (judged by a high p -value, or a confidence interval including zero) it may reasonably be omitted in routine calibration. The slope a_1 should always be highly significant in any practical calibration. If a p -value is given for the regression as a whole, it indicates, again, whether there is a significant linear relationship; this is usually well known in calibration, though it is important in exploratory analysis (for example, when investigating a possible effect on results).

Prediction from Linear Calibration. If the regression statistics and residual plot are satisfactory, the curve can be used for prediction. Usually, this involves estimating a value x_0 from an observation y_0 . This will, for many measurements, require some estimate of the uncertainty associated with prediction of a measurand value x from an observation y . Prediction uncertainties are, unfortunately, rarely available from regression software. The relevant expression is therefore given below.

$$s_{x_0} = \frac{s_{(y/x)}}{a_1} \left(w_0 + \frac{1}{n} + \frac{(y_0 - \bar{y}_w)^2}{a_1^2 \sum (w_i x_i^2 - n \bar{x}_w^2)} \right)^{1/2},$$

s_{x_0} is the *standard error of prediction* for a value x_0 predicted from an observation y_0 ; $s_{(y/x)}$ is the (weighted) residual standard deviation for the regression; \bar{y}_w and \bar{x}_w are the weighted means of the x and y data used in the calibration; n is the number of (x, y) pairs used; w_0 is a weighting factor for the observation y_0 ; if y_0 is a mean of n_0 observations, w_0 is $1/n_0$ if the calibration used unweighted regression, or is calculated as for the original data if weighting is used; s_{x_0} is the uncertainty arising from the calibration and precision of observation of y_0 in a predicted value x_0 .

Outlier Detection

Identifying Outliers. Measurement data frequently contain a proportion of extreme values arising from procedural errors or, sometimes, unusual test items. It is, however, often difficult to distinguish erroneous values from chance variations, which can also give rise to occasional extreme values. Outlier detection methods help to distinguish between chance occurrence as part of the normal population of data, and values that cannot reasonably arise from random variability.

Graphical methods are effective in identifying possible outliers for follow up. Dot plots make extreme values very obvious, though most sets have at least some ap-

parent extreme values. Box-and-whisker plots provide an additional quantitative check; any single point beyond the whisker ends is unlikely to arise by chance in a small to medium data set. Graphical methods are usually adequate for the principal purpose of identifying data points which require closer inspection, to identify possible procedural errors. However, if critical decisions (including rejection – see below) are to be taken, or to protect against unwarranted follow-up work, graphical inspection should always be supported by statistical tests. A variety of tests are available; the most useful for measurement work are listed in Table 2.7. Grubb's tests are generally convenient (given the correct tables); they allow tests for single outliers in an otherwise normally distributed data set (Fig. 2.7a), and for simultaneous outlying pairs of extreme values (Fig. 2.7b and c), which would otherwise cause outlier tests to fail. Cochran's test is effective in identifying outlying variances; an important problem if data are to be subjected to analysis of variance or (sometimes) in quality control.

Successive application of outlier tests is permitted; it is not unusual to find that one exceptionally extreme value is accompanied by another, less extreme value. This simply involves testing the remainder of the data set after discovering an outlier.

Action on Detecting Outliers. A statistical outlier is only *unlikely* to arise by chance. In general, this is a signal to investigate and correct the cause of the problem. As a general rule, outliers should not be removed from the data set simply because of the result of a statistical test. However, many statistical procedures are seriously undermined by erroneous values, and long experience suggests that human error is the most common cause of extreme outliers. This experience has given rise to some general rules which are often used in processing, for example, inter-laboratory data:

1. Test at the 95% and the 99% confidence level.
2. All outliers should be investigated and any errors corrected.
3. Outliers significant at the 99% level may be rejected unless there is a technical reason to retain them.
4. Outliers significant only at the 95% level should be rejected only if there is an additional, technical reason to do so.
5. Successive testing and rejection is permitted, but not to the extent of rejecting a large proportion of the data.

This procedure leads to results which are not unduly biased by rejection of chance extreme values, but are rel-

Fig. 2.7 Possible outliers in data sets

atively insensitive to outliers at the frequency commonly encountered in measurement work. Note, however, that this objective can be attained without outlier testing by using robust statistics where appropriate; this is the subject of the next section.

Finally, it is important to remember that an outlier is only outlying in relation to some prior expectation. The tests in Table 2.7 assume underlying normality. If the data were Poisson distributed, for example, too many high values would be rejected as inconsistent with a normal distribution. It is generally unsafe to reject, or even test for, outliers unless the underlying distribution is known.

Robust Statistics

Introduction. Instead of rejecting outliers, robust statistics uses methods which are less strongly affected by extreme values. A simple example of a robust estimate of a population mean is the median, which is essentially unaffected by the exact value of extreme points. For example, the median of the data set (1,2,3,4,6) is identical to that of (1,2,3,4,60). The median, however, is substantially more variable than the mean when the data are not outlier-contaminated. A variety of estimators have accordingly been developed that retain a useful degree of resistance to outliers without unduly affecting performance on normally distributed data. A short summary of the main estimators for means and standard deviations is given below. Robust methods also exist for analysis of variance, linear regression and other modelling and estimation approaches.

Robust Estimators for Population Means. The median, as noted above, is a relatively robust estimator, widely available in software. It is very resistant to extreme values; up to half the data may go to infinity without affecting the median value. Another simple robust estimate is the so-called trimmed mean; the mean of the

data set with two or more of the most extreme values removed. Both suffer from increases in variability for normally distributed data; the trimmed mean less so.

The mean suffers from outliers in part because it is a least-square estimate, which effectively gives values a weight related to the square of their distance from the mean (that is, the *loss function* is quadratic). A general improvement can be obtained using methods which use a modified loss function. Huber (see Further Reading) suggested a number of such estimators, which allocate a weight proportional to squared distance up to some multiple c of the estimated standard deviation \hat{s} for the set, and thereafter a weight proportional to distance. Such estimators are called M-estimators, as they follow from maximum likelihood considerations. In Huber's proposal, the algorithm used is to replace each value x_i in a data set with z_i , where

$$z_i = \begin{cases} x_i & \text{if } \hat{X} - c \times \hat{s} < x_i < \hat{X} + c \times \hat{s} \\ \hat{X} \pm c \times \hat{s} & \text{otherwise} \end{cases}.$$

and recalculate the mean \hat{X} , applying the process iteratively until the result converges. A suitable one-dimensional search algorithm may be faster. The estimated standard deviation is usually determined using a separate robust estimator, or (in Huber's proposal 2) iteratively, together with the mean. Another well-known approach is to use Tukey's biweight as the loss function; this also reduces the weight of extreme observations (to zero, for very extreme values).

Robust Estimators of Standard Deviation. Two common robust estimates of standard deviation are based on rank order statistics, such as the median. The first, the median absolute deviation (**MAD**) calculates the median of absolute deviations from the estimated mean value \hat{x} , that is, $\text{median}(|x_i - \hat{x}|)$. This value is not directly comparable to the standard deviation in the case of normally distributed data; to obtain an estimate of the standard deviation, a modification known as **MAD_e** should be used. This is calculated as **MAD**/0.6745. Another common estimate is based on the interquartile range (IQR)

Table 2.7 Tests for outliers in normally distributed data. The following assume an ordered set of data $x_1 \dots x_n$. Tables of critical values for the following can be found in [ISO 5725:1995 part 2](#), among other sources. Symbols otherwise follow those in Table 2.2

Test objective	Test name	Test statistic	Remarks
Test for a single outlier in an otherwise normal distribution	i) Dixon's test	$n = 3 \dots 7 :$ $(x_n - x_{n-1}) / (x_n - x_1)$ $n = 8 \dots 10 :$ $(x_n - x_{n-1}) / (x_n - x_2)$ $n = 10 \dots 30 :$ $(x_n - x_{n-2}) / (x_n - x_3)$	The test statistics vary with the number of data points. Only the test statistic for a high outlier is shown; to calculate the test statistic for a low outlier, renumber the data in descending order. Critical values must be found from tables of Dixon's test statistic if not available in software.
	ii) Grubb's test 1	$(x_n - \bar{x}) / s$ (high outlier) $(\bar{x} - x_1) / s$ (low outlier)	Grubb's test is simpler than Dixon's Test if using software, although critical values must again be found from tables if not available in software
Test for two outlier on opposite sides of an otherwise normal distribution	Grubb's test 2	$1 - \left(\frac{(n-3)[s(x_3 \dots x_n)]^2}{(n-1)s^2} \right)$	$s(x_3 \dots x_n)$ is the standard deviation for the data excluding the two suspected outliers. The test can be performed on data in both ascending and descending order to detect paired outliers at each end. Critical values must use the appropriate tables
Test for two outliers on the same side of an otherwise normal distribution	Grubb's test 3	$(x_n - x_1) / s$	Use tables for Grubb's test 3
Test for a single high variance in l groups of data	Cochran's test	$C_{\bar{n}} = \frac{(s^2)_{\max}}{\sum_{i=1,l} s_i^2}$	$\bar{n} = \frac{1}{l} \sum_{i=1,l} n_i$

of a set of data; a normal distribution has standard deviation $IQR/1.349$. The IQR method is slightly more variable than the MAD_e method, but is usually easier to implement, as quartiles are frequently available in software. Huber's proposal 2 (above) generates a robust estimate of standard deviation as part of the procedure; this estimate is expected to be identical to the usual standard deviation for normally distributed data. ISO 5725 provides an alternative iterative procedure for a robust standard deviation independently of the mean.

Using Robust Estimators. Robust estimators can be thought of as providing good estimates of the parameters for the good data in an outlier-contaminated set. They are appropriate when:

- The data are expected to be normally distributed. Here, robust statistics give answers very close to ordinary statistics.
- The data are expected to be normally distributed, but contaminated with occasional spurious values, which are regarded as unrepresentative or erroneous. Here, robust estimators are less affected by occasional extreme values and their use is recommended. Examples include setting up quality control (QC) charts from real historical data with occasional errors, and interpreting inter-laboratory study data with occasional problem observations.

Robust estimators are not recommended where:

- The data are expected to follow non-normal distributions, such as binomial, Poisson, chi-squared etc. These generate extreme values with reasonable likelihood, and robust estimates based on assumptions of underlying normality are not appropriate.
- Statistics that represent the whole data distribution (including extreme values, outliers and errors) are required.

2.3.4 Statistics for Quality Control

Principles

Quality control applies statistical concepts to monitor processes, including measurement processes, and detect significant departures from normal operation. The general approach to statistical quality control for a measurement process is:

1. Regularly measure one or more typical test items (control materials).

2. Establish the mean and standard deviation of the values obtained over time (ignoring any erroneous results).
3. Use these parameters to set up warning and action criteria.

The criteria can include checks on stability of the mean value, and where measurements on the control material are replicated, on the precision of the process. It is also possible to seek evidence of emerging trends in the data, which might warn of impending or actual problems with the process.

The criteria can be in the form of, for example, permitted ranges for duplicate measurements, or a range within which the mean value for the control material must fall. Perhaps the most generally useful implementation, however, is in the form of a control chart. The following section therefore describes a simple control chart for monitoring measurement processes.

There is an extensive literature on statistical process control and control charting in particular, including a wide range of methods. Some useful references are included in Further Reading.

Control Charting

A control chart is a graphical means of monitoring a measurement process, using observations plotted in a time-ordered sequence. Several varieties are in common use, including cusum charts (sensitive to sustained small bias) and range charts, which control precision. The type described here is based on a Shewhart mean chart. To construct the chart:

- Obtain the mean \bar{x} and standard deviation s of at least 20 observations (averages if replication is used) on a control material. Robust estimates are recommended for this purpose; but at least ensure that no erroneous or aberrant results are included in this preliminary data.
- Draw a chart with date as the x -axis, and a y -axis covering the range approximately $\bar{x} \pm 4s$.
- Draw the mean as a horizontal line on the chart. Add two *warning limits* as horizontal lines at $\bar{x} \pm 2s$, and two further *action limits* at $\bar{x} \pm 3s$. These limits are approximate. Exact limits for specific probabilities are provided in, for example, ISO 8258:1991 *Shewhart control charts*.

As further data points are accumulated, plot each new point on the chart. An example of such a chart is shown in Fig. 2.8.

Fig. 2.8 QC chart example. The figure shows successive QC measurements on a reference material certified for lead content. There is evidence of loss of control at points marked by arrows

Interpreting Control Chart Data

Two rules follow immediately from the action and warning limits marked on the chart.

- A point outside the action limits is very unlikely to arise by chance; the process should be regarded as out of control and the reason investigated and corrected.
- A point between the warning and action limits could happen occasionally by chance (about 4–5% of the time). Unless there is additional evidence of loss of control, no action follows. It may be prudent to remeasure the control material.

Other rules follow from unlikely sequences of observations. For example, two points outside the warning limits – whether on one side or alternate sides – is very unlikely and should be treated as actionable. A string of seven or more points above, or below, the mean – whether within the warning limits or not – is unlikely and may indicate developing bias (some recommendations consider ten such successive points as actionable). Sets of such rules are

available in most textbooks on statistical process control.

Action on Control Chart Action Conditions

In general, actionable conditions indicate a need for corrective action. However, it is prudent to check that the control material measurement is valid before undertaking expensive investigations or halting a process. Taking a second control measurement is therefore advised, particularly for warning conditions. However, it is not sensible to continue taking control measurements until one falls back inside the limits. A single remeasurement is sufficient for confirmation of the out-of-control condition.

If the results of the second check do not confirm the first, it is sensible to ask how best to use the duplicate data in coming to a final decision. For example, should one act on the second observation? Or perhaps take the mean of the two results? Strictly, the correct answer requires consideration of the precision of the means of duplicate measurements taken over the appropriate time interval. If this is available, the appropriate limits can be calculated from the relevant standard deviation. If

not, the following procedure is suggested. First, check whether the difference between the two observations is consistent with the usual operating precision (the results should be within approximately $2.8s$ of one another). If so, take the mean of the two, and compare this with new limits calculated as $\bar{x} \pm 2s/\sqrt{2}$ and $\bar{x} \pm 3s/\sqrt{2}$ (this is conservative, in that it assumes complete independence of successive QC measurements; it errs on the side of action). If the two results do not agree within the expected precision, the cause requires investigation and correction in any case.

2.3.5 Evaluation of Uncertainty

Definitions and Terminology

The definition of the term uncertainty (of measurement) in current use is provided by the ISO guide on the topic (*Guide to the Expression of Uncertainty in Measurement*):

“A parameter associated with the result of a measurement, that characterises the dispersion of the values that could reasonably be attributed to the measurand.”

Notes additionally indicate that the parameter may be, for example, a standard deviation (or a given multiple of it), or the width of a confidence interval, and also that uncertainty of measurement comprises, in general, many components. The *International Vocabulary of Basic and General Terms in Metrology* (VIM) provides further notes.

When expressed as a standard deviation, an uncertainty is known as a *standard uncertainty*, usually denoted by u . For reporting, an *expanded uncertainty*, U , is used. The expanded uncertainty provides an interval within which the value of the measurand is believed to lie with a higher level of confidence.

Approaches to Uncertainty Evaluation

There are two broad approaches to uncertainty evaluation:

1. Studies involving replication of the whole measurement procedure to give a direct estimate of the uncertainty for the final result of the measurement.
2. Studies of individual contributions to the overall uncertainty and combination using an appropriate mathematical model.

The first is typified by inter-laboratory study, in-house validation, or (where available) ongoing quality control data, and is particularly appropriate where individual

effects are poorly understood which, in this context, does not imply lack of knowledge or experience on the measurement scientist's part, only a lack of quantitative theoretical models capable of predicting the behaviour of measurement results. A good and detailed procedure applicable where inter-laboratory study data are available is provided by the document ISO TS 21748:2005. Briefly, this approach takes the reproducibility standard deviation, or some other overall precision estimate, as the basis for an uncertainty estimate, and adds additional contributions as required using the principles of the ISO guide. In many cases, it is found that no additional terms are required, as few are significant compared to reproducibility from inter-laboratory data or long-term within-laboratory precision.

The second approach is most applicable where the major effects on the result can be described by theoretical models; detailed procedures are given in the ISO guide and other related documents. The general approach is:

1. Write a clear description of the quantity to be measured, including any method of calculation for the result (and which should include any corrections for environmental or other factors).
2. For any quantities in the equation, obtain uncertainties from calibration certificates, manufacturer's tolerances, experiments or, where necessary, theoretical models. Make sure that the uncertainty is in the form of a standard deviation (see below for conversion factors).
3. Calculate the combined standard uncertainty $u_c(y)$ from

$$\begin{aligned} u_c[y(x_1, x_2, \dots)] &= \sqrt{\sum_{i=1,n} c_i^2 u(x_i)^2} \\ &= \sqrt{\sum_{i=1,n} u(y, x_i)^2}, \end{aligned}$$

where $y(x_1, x_2, \dots)$ is the function developed at step 1 above, c_i is a sensitivity coefficient evaluated as $c_i = \partial y / \partial x_i$, the partial differential of y with respect to x_i and $u(y, x_i)$ denotes the uncertainty in y arising from the uncertainty in x_i . Each variable's contribution $u(y, x_i)$ is just the square of the associated uncertainty expressed as a standard deviation multiplied by the square of the relevant sensitivity coefficient. These sensitivity coefficients describe how the value of y varies with changes in the parameters x_1, x_2 etc. Sensitivity coefficients may also be evaluated directly by experiment; this is particularly

valuable where no reliable mathematical description of the relationship exists.

Note that the expression above holds only where the uncertainties lead to independent effects on the result. Where they are not independent, the relationship is more complex:

$$u[y(x_i, j, \dots)] = \sqrt{\sum_{i=1, n} c_i^2 u(x_i)^2 + \sum_{i, k=1, n; i \neq k} c_i c_k \cdot u(x_i, x_k)},$$

where $u(x_i, x_k)$ is the covariance between x_i and x_k .

These two approaches should generally be seen as extremes of a range of approaches. In practice, even inter-laboratory study may be unable to explore all the possible effects operating, and in-house studies or theoretical considerations are needed, at least to check some possible effects. At the other extreme, even well-understood systems often need experimental data on, for example, random effects, which can only be obtained by replication experiments.

It is also important that where the second approach is used, the results are checked against actual performance. If a model-based approach estimates uncertainties at 10% and observed performance shows 30–50% variation, the model is almost certainly incomplete. In general, uncertainty calculated using a modelling approach should be consistent with actual performance, and should be not less than the observed dispersion of results over a period of time.

2.4 Validation

The operation of a testing facility or a testing laboratory requires a variety of different prerequisites and supporting measures in order to produce trustworthy results of measurements. The most central of these operations is the actual execution of the test methods that yield these results. At all times it has therefore been vital to operate these test methods in a skilful and reproducible manner that requires not only good education and training of the operator in all relevant aspects of performing a test method, but also the experimental verification that the specific combination of operator, sample, equipment and environment yields results of known and fit-for-purpose quality. For this experimental verification at the testing laboratory the term *validation* (also *validation of test methods*) was introduced some 20 years ago. Herein, test method and test procedure are used synonymously.

Common Conversion Factors for Standard Uncertainty

Uncertainty information on calibration certificates or manufacturer's tolerances is often expressed in the form of limits or confidence intervals. To convert these to an estimated standard uncertainty u , apply the following rules:

- For a tolerance in the form " $x \pm a$ ": $u = a/\sqrt{3}$. This arises as a consequence of an assumed rectangular distribution.
- For a confidence interval in the form " $x \pm d$ at $p\%$ confidence": $u = d/t$, where t is the two-tailed value of Student's t for the relevant level of confidence and the number of degrees of freedom. Where the number of degrees of freedom for the confidence interval is not given, assume t for infinite degrees of freedom. For 95% confidence, $t = 1.96$ (for which 2.0 is a more than adequate approximation for this purpose).

Reporting Measurement Uncertainty

For most purposes, an expanded uncertainty, U , should be reported. U is obtained by multiplying u , the standard uncertainty, by a *coverage factor*, k . The choice of the factor k is based on the level of confidence desired. For an approximate level of confidence of 95%, k is often taken as 2. For exacting requirements, it is calculated using Student's t for the *effective degrees of freedom*, ν_{eff} , for the uncertainty estimate. Detailed procedures for calculating ν_{eff} are provided in the ISO guide.

In the following it is intended to present purpose, rationale, planning, execution and interpretation of validation exercises in testing. We will, however, not give the mathematical and statistical framework employed in validation as this is dealt with in other chapters of the Handbook.

2.4.1 Definition and Purpose of Validation

Definitions

Although in routine laboratory jargon a good many shades of meaning of "validation" are commonly associated with this word, the factual operation of a validation project encompasses the meaning better than words do. Nevertheless a formal definition is offered in the standards, and the following is cited from EN-ISO 9000:2000.

Validation. Confirmation, through the provision of objective evidence, that the requirements for a specific intended use or application have been fulfilled.

Objective Evidence. Data supporting the existence or verity of something.

Requirement. Need or expectation that is stated, generally implied or obligatory.

In ISO 17025 (*General Requirements for the Competence of Testing and Calibration Laboratories*) validation prominently features in Sect. 5.4 on technical requirements, and the definition is only slightly different: “*Validation is the confirmation by examination and the provision of objective evidence that the particular requirements for a specific intended use are fulfilled.*”

Although such definitions tend to be given in a language that makes it difficult to see their ramifications in practice, there are a couple of key features that warrant some discussion. Validation is (done for the purpose of) confirmation and bases this confirmation on objective evidence, generally data from measurements. It can be concluded that in general only carefully defined, planned and executed measurements yield data that will permit a judgement on the fulfilment of requirements. The important point here is that the requirements have to be cast in such a way that permits the acquisition of objective evidence (data) for testing the question whether these requirements are fulfilled.

Verification is frequently used in a manner indistinguishable from validation, so we also want to resort to the official definition in EN-ISO 9000:2000:

Verification. Confirmation, through the provision of objective evidence, that specified requirements have been fulfilled.

The parallels with validation are obvious as verification is also confirmation, also based on objective evidence, and also tested against specified requirements, but apparently without a specific use in mind that is part of the definition of validation. In practice, the difference lies in the fact that validation is cited in connection with test methods, while verification is used in connection with the confirmation of data.

As the formal definitions are not operationally useful, it may be helpful to keep in mind the essentials offered from ISO 17025 that appear to be summarized in Chapt. 5.4.5.3: “*The range and accuracy of the values obtainable from validated methods (e.g. the uncertainty of the results, detection limit, selectivity of*

the method, linearity, limit of repeatability and/or reproducibility, robustness against external influences and/or cross-sensitivity against interference from the matrix of the sample/test object) as assessed for the intended use shall be relevant to the clients’ needs.” This statement makes clear that there must be an assessment for the intended use, although the various figures of merit in parenthesis are inserted in a rather artificial manner into the sentence.

The view of Co-operation International Traceability in Analytical Chemistry (CITAC)/EURACHEM on validation is best summarized in Chapt. 18 of the Guide to Quality in Analytical Chemistry [2.15] where the introductory sentence reads: “*Checks need to be carried out to ensure that the performance characteristics of a method are understood and to demonstrate that the method is scientifically sound under the conditions in which it is to be applied. These checks are collectively known as validation. Validation of a method establishes, by systematic laboratory studies that the method is fit-for-purpose, i. e. its performance characteristics are capable of producing results in line with the needs of the analytical problem . . .*”

At this point we shall leave the normative references and try to develop a general purpose approach to validation in the following.

Purpose

The major purpose in line with the formal definition is confirmation. Depending on the party concerned with the testing the emphasis of such a confirmation may be slightly different.

The (future) operator of a test method has the need to acquire enough skill for performing the method and may also care to optimise the routine execution of this method. The laboratory manager needs to know the limits of operation of a test method, as well as the performance characteristics within these limits. The prospective customer, who will generally base decisions on the outcome of the testing operation, must know the limits and performance characteristics as well, in order to make an educated judgement on the reliability of the anticipated decisions. He/she must be the one to judge the fitness for purpose and this can only be done on the basis of experimental trials and a critical appraisal of the data thereby generated.

In a regulated environment, such as the pharmaceutical or car industry, regulatory agencies are additional stakeholders. These frequently take the position that a very formalised approach to validation assures the required validity of the data produced. In these instances

very frequently every experimental step to be taken is prescribed in detail and every figure to be reported is unequivocally defined, thereby assuring uniform execution of the validation procedures.

On a more general basis one can argue that validation primarily serves the following purposes:

1. derivation of performance characteristics,
2. establishment of short- and long-term stability of the method of measurement, and setting of control limits,
3. fine-tuning of the standard operating procedure (SOP),
4. exploitation of scope in terms of the nature and diversity of samples and the range of the values of the measurand,
5. identification of influence parameters, and
6. proof of competence of the laboratory.

In simple words, validation for a laboratory/operator is about getting to know your procedure.

2.4.2 Validation, Uncertainty of Measurement, Traceability and Comparability

Relation of Uncertainty, Traceability and Comparability to Validation

Validation cannot be discussed without due reference to other important topics covered in this Handbook. We therefore need to shed light on the terms uncertainty, traceability and comparability, in order to demonstrate their relationship to method validation.

The existence of a recognised test method is the prerequisite to the mutual recognition of results. This recognition is based on reproducibility and traceability, whereby traceability to a stated and (internationally) accepted reference is an indispensable aid in producing reproducible results. This links a locally performed measurement to the world of internationally accepted standards (references, scales) in a way that all measurements linked to the same standards give results that can be regarded fractions and multiples of the same unit. For identical test items measured with the same test method this amounts to identical results within the limits of measurement uncertainty. Measurement uncertainty cannot be estimated without due consideration of the quality of all standards and references involved in the measurement; and this in turn necessitates the clear stating of all references that has been defined as traceability earlier in this paragraph. In a way a tight connection of a result to a standard is realised by very well-defined

fractions and multiples, all carrying small uncertainties. Well-defined fractions and multiples are thus tantamount to small measurement uncertainty.

Formal Connection of the Role of Validation and Uncertainty of Measurement

In a certain way validation is linked to measurement uncertainty through optimisation of the method of measurement: validation provides insight into the important influence quantities of a method, these influence quantities are those that generally contribute most to measurement uncertainty. As a result of validation the reduction of measurement uncertainty can be affected in one of two ways: (a) by tighter experimental control of the influence quantity, or (b) by suitable numerical correction of the (raw) result for the exerted influence. By way of example we consider the influence of temperature on a measurement. If this is significant one may control the temperature by thermostating or, alternatively, one can establish the functional dependence of the measurement, note the temperature at the time of measurement and correct the raw result by the correction function established earlier. Both these actions can be regarded as a refinement of the measurement procedure and constitute an improvement over the earlier version of the method (*optimisation*) and necessitate changes in the written SOP.

A good measurement provides a close link of the result to the true value albeit not perfectly so. Prior to validation the result is

$$x_{ijk} = \mu + \varepsilon_{ijk} ,$$

$$x_{ijk} \dots \text{result} ; \mu \dots \text{true value} ; \varepsilon_{ijk} \dots \text{deviation} .$$

The deviation is large and unknown in size and sign, and will give rise to a large uncertainty of measurement. A major achievement in a successful validation exercise is the identification of influence quantities and their action on the result. If, for instance, three (significant) influence quantities are identified, the result can be viewed biased by these effects δ

$$x_{ijk} = \mu + \delta_i + \delta_j + \delta_k + \varepsilon_{ijk} ,$$

and in doing so the residual (and poorly understood) deviation ε_{ijk} is now greatly reduced as the effects of the identified quantities δ are quasi-extracted from the old ε_{ijk} . As the bias is now known in sign and size, δ s can be used for correcting the original x_{ijk} that can after validation be viewed as uncorrected raw result,

$$x_{ijk} - \delta_i - \delta_j - \delta_k = \mu + \varepsilon_{ijk} .$$

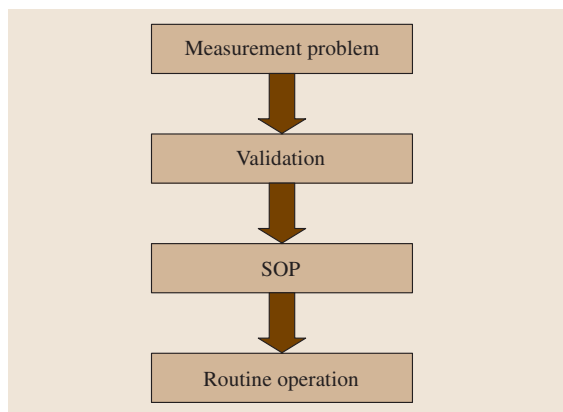

Fig. 2.9 Validation has a central phase in the operation of a test method

Alternatively – as occasionally done in chemistry with recovery – the corrections can be ignored, thus the raw results are left uncorrected.

Figure 2.9 points to the central position of validation in the introduction of a new method of measurement in an testing laboratory.

From a blown-up view of the measurement problem (Fig. 2.10) one can see that in reality it can be broken down into three distinct step, the measurement task as being formulated by the customer, the formulation of the requirements in technical terms derived from the communicated measurement task and the preliminary

method devised from experience and/or literature that will serve as basis for the (first round of) validation.

2.4.3 Practice of Validation

Validation Plan

Prior to validation a plan needs to establish which performance characteristics have to be established. It serves the purpose that in a clear succession of experiments test are applied that ultimately allow the assessment of the performance of the method with respect to the clients' needs.

Therefore a written plan must be laid out for the experiments performed in the course of validation and the criteria to be met by the method in the course of validation must be established in this plan beforehand. It is then immediately obvious whether the method validated is suitable in the particular instance or not.

Validation is frequently planned by senior supervisory personnel or by staff specialised in validation with a good grasp of the clients' needs. In regulated areas, such as pharmacy or food, fixed validation plans may be available as official documents and are not to be altered by laboratory personnel.

In any case it is advisable to have a separate standard operating procedure cover the generic aspects of validation work.

Method Development and Purpose of Basic Validation

For a specified method as practised in a laboratory under routine conditions method validation marks the preliminary end of method development. It served the purpose to establish the performance characteristics of a suitably adapted and/or optimised method also with the purpose of laying down the limitation of reliable operation, limited either through environmental or sample-related conditions. These limits are generally chosen such that the influence of changes in these conditions are still negligible relative to the required or expected measurement uncertainty. In chemical term this makes transparent which analytes (measurands) can be measured with a specific method in which (range of) matrices in presence of which range of potential interferents.

If a method is developed for a very specific purpose, method validation serves to provide experimental evidence, that the method is suitable for this purpose, i.e. for solving the specific measurement problem. In a sense, method validation is interlinked with method development and care must be taken to draw a clear line

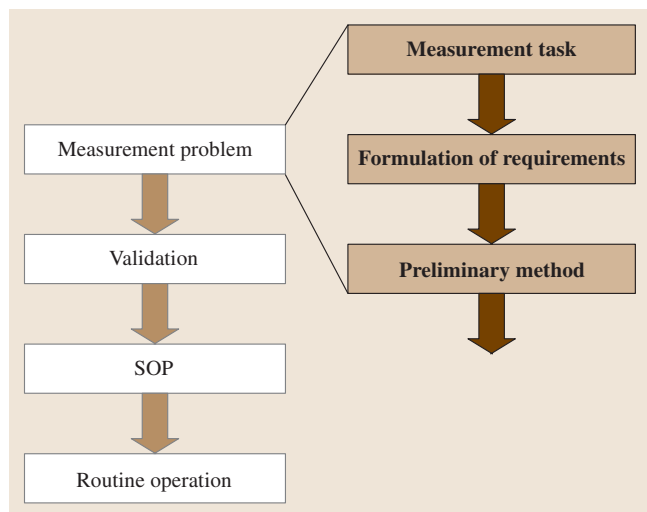

Fig. 2.10 Blown-up view of the measurement problem validation leads from preliminary method to routine operation

experimentally between those steps. The validation plan forms the required delimitation.

Implicitly it is assumed that experiments for the establishment of performance characteristics are executed with apparatus and equipment that operates within permissible specifications, work correctly and are calibrated. Such studies must be made by competent staff with sufficient knowledge in the particular area in order to interpret the obtained results properly and base the required decision regarding the suitability of the method on them.

In the literature there are frequent reports regarding results of inter-laboratory comparison studies being used for the establishment of some method characteristics. There is, however, also found a situation in which a single laboratory requires a specific method for a very special purpose. The Association of Official Analytical Chemists (AOAC), which is a strong advocate of inter-laboratory studies as a basis for method validation, established in 1993 the peer-verified method program [AOAC International, AOAC Peerverified Methods Policies and Procedures, 1993], which serves to validate methods practised by one or a few laboratories only.

For an analytical result to be suitable for the anticipated purpose, it must be sufficiently reliable, so that every decision based on it will be trustworthy. This is the key issue about performing method validation and about estimating measurement uncertainty.

Regardless of how good a method is and how skillfully it is applied, an analytical problem can only be solved by analysing samples that are appropriate for this problem. This implies that sampling can never be disregarded.

Once a specific analytical question is defined by the client, it must be decided whether one of the established (and practised) methods meets the requirements. The method is therefore evaluated for its suitability. If necessary, a new method must be developed/adapted to the point that it is being regarded suitable. This process of evaluating performance (established by criteria such as selectivity, detection limits, decision limits, recovery, accuracy, robustness) and the confirmation of the suitability of a method is the essence of method validation.

The questions influencing the considerations regarding the development of an analytical procedure are multifaceted: is a qualitative or a quantitative statement expected? What is the specific nature of the analyte (measurand)? What matrix is involved? Which is the range of concentrations expected? How large a measurement uncertainty is tolerable? In practice, limitations

of time and money may impose the most stringent requirements.

Confronted with altered or new analytical queries the adaptation of analytical procedures for a new analyte, for a new matrix, for another concentration range or similar variations are frequently required. General analytical trends may also require modifications or new developments of analytical procedures; point in case are trends in miniaturisations as experienced in high-performance liquid chromatography (HPLC), flow photometry, capillary electrochromatography, hyphenation, etc.

Many analytical procedures are described in the scientific literature (books, journals, proceedings, etc.). These sources are frequently an appropriate basis for the development of new procedures. In many cases there are also standards available with a detailed documentation of the experimental procedure. If only general documentation is provided, it might be suitable as a starting point for the development of customised laboratory procedures.

Alternatively, the interchange of ideas with friendly laboratories can give impetus to the development of new or modified analytical procedures. Occasionally a new combination of established analytical steps may lead to a new method.

There is also an increasing need for good cooperation of several disciplines as it is hardly possible for a single person to independently develop complex methods in instrumental analysis. Also, the great flood of data from multichannel detection systems cannot be captured nor evaluated by conventional procedures of data treatment, so that additional interfaces are needed, particularly to information technology.

The basic validation exercise cannot cover the complete validation process, but is concerned mainly with those parts of validation that are indispensable in the course of development of an analytical procedure. Most importantly there must be established the scope of the method, *inter alia* with respect to analytes, matrices and concentration range within which measurements can be made in a meaningful way. In any case, the basic validation comprises the establishment of performance characteristics (also called figures of merit), with a clear emphasis on data supporting the estimation of measurement uncertainty.

Depth and Breadth of Validation

Regarding depth and breadth of validation ISO 17025 states that “validation shall be as extensive as is necessary to meet the needs in the given application or field of application.”

But how does this translate to practical experimental requirements? As already stated earlier it is clear that every analytical method must be available in written form of an SOP. Until the fitness for the intended use is proven through validation all methods must be regarded preliminary. It is not uncommon that the results of validation require a revision of the SOP with regard to the matrix and the concentration range. This can be understood as laboratory procedures are based on a combination of SOP and validation as delimited by matrix, analyte and this particular SOP. Here too, the close connection of SOP and validation is noteworthy.

Besides the type and number of different matrices and the concentration range for the application of the method, the extent of validation also depends markedly on the number of successive operations: for a multi-stage procedure the extent and consequently the effort of validation will be much larger than for a single-stage procedure.

For the time sequence of basic validation there are also no fixed rules, but it seems appropriate to adopt some of the principles of method development for validation:

- Test of the entire working range, starting from one concentration
- Reverse inclusion of the separate stages into validation, starting with the study of the final determination
- Testing of all relevant matrices, starting with the testing of standards

In all phases of validation it must be ascertained that the method is performing satisfactorily, for instance by running recovery checks alongside.

The final step must be the proof of trueness and reproducibility, e.g. on the basis of suitable reference materials.

Performance Characteristics

The importance of performance characteristics have been repeatedly mentioned in this text. These parameters generally serve to characterise analytical methods and – in the realm of analytical quality assurance – they serve to test whether a method is suitable to solve a particular analytical problem or not. Furthermore, they are the basis for the establishment of control limits and other critical values that provide evidence for the reliable performance of the methods on an everyday basis.

The latter use of performance characteristics is a very significant one and it is obvious that these performance characteristics are only applicable if established under

routine conditions and in real matrices, and not under idealised and unrealistic conditions.

The actual selection of performance characteristics for validation depends on the particular situation and requirements. The following Table 2.8 gives an overview of the most relevant ones.

Different emphasis is given to many of these parameters in the various standards. The most significant recent shift in importance is seen in ISO 17025, where the previously prominent figures of merit (*accuracy* and *precision*) are replaced by *uncertainty in measurement*.

The following performance characteristics are specifically emphasised in the CITAC/EURACHEM *Guide to Quality in Analytical Chemistry* of 2002:

- Selectivity and specificity (description of the measurand),
- Measurement range,
- Calibration and traceability,
- Bias/recovery,
- Linearity,
- Limit of detection/limit of quantitation,
- Ruggedness,
- Precision.

In ISO 17025 the performance characteristics are listed exemplarily:

“e.g. the uncertainty of the results, detection limit, selectivity of the method, linearity, limit of repeatability and/or reproducibility, robustness against external influences and/or cross-sensitivity against interference from the matrix of the sample/test object.”

From the wording it can be understood that the actual set of figures must be adapted to the specific problem. Selection criteria for the best set in a given situation will be discussed later.

Some of these performance characteristics are discussed in the following.

Accuracy, Precision and Trueness. There are different approaches for the proof of *accuracy* of results from a particular method. The most common one is by the testing an appropriate reference material, ideally a certified reference material, with certified values uncontested as known and true. A precondition, however, is obviously that such a material is available. It must also be noted that most sampling and some of the sample preparation steps are not subjected to the test in this way.

Numerically the comparison of results of a test method with a certified value is most frequently car-

Table 2.8 Performance characteristics (after *Kromidas* [2.16])

Parameter	Comment
Trueness, accuracy of the mean, freedom from bias	The older English literature does not distinguish between accuracy and trueness
Precision	
– repeatability	
– reproducibility	ISO 5725 series: Accuracy, trueness and precision
Linearity	
Selectivity	
Recovery	
Limit of detection ((LOD)	
Limit of quantification (LOQ)	
Limit of determination (LOD)	
Limit of decision (LOC)	
Robustness, ruggedness	
Range	
Sensitivity	
Stability	
Accuracy	See <i>trueness</i>
Specificity	Often used synonymously with <i>selectivity</i>
Uncertainty of measurement	
expanded uncertainty	
Method capability	
Method stability/process stability	

ried out by a t -test, alternatively the Doerffel test for significant deviations can be applied.

Trueness of results can also be backed up by applying a completely different measurement principle. This alternative method must be a well-established and recognised method. In this approach only those steps are subjected to a serious test for accuracy that are truly independent of each other. For instance, if the same method of decomposition is applied in both procedures, this step cannot be taken as independent in the two procedures and therefore cannot be regarded as having been tested for accuracy by applying the alternative method of measurement.

In practice, the differences between the results from the two procedures are calculated, these differences are averaged and their standard deviation is computed. Finally, a t -value from these results is obtained and compared with a critical t -value from the appropriate table. If the computed t -value is greater than the tabulated one, it can be assumed with a previously determined probability (e.g. 95%) that the difference from the two method is indeed significant.

Other method for checking accuracy are recovery studies (particularly useful for checking separation

procedures), or balancing the analyte, applying mass balances or plausibility arguments.

In all of these considerations there must always be due regard to the fact that trueness and precision are hardly independent from each other.

Precision can be regarded a measure of dispersion between separate results of measurements. The standard deviation under repeatability, reproducibility or intermediate conditions, but also the relative standard deviation and variance can be used as measures of precision. From the standard deviation repeatability or reproducibility limits can be obtained according to ISO 5725.

Which of these measures of precision is actually used is up to the analyst. It is, however, recommended to use the repeatability, reproducibility or intermediate standard deviation according to ISO 5725.

The values of precision and trueness established in practice are always estimates that deviate in the operation of successive inter-laboratory comparison studies or proficiency testing rounds.

Precision can therefore be regarded as a measure of dispersion (typical statistical measure: standard deviation), trueness as a measure of location (typical statistical measure: arithmetic average) adding up to a combined

measure of accuracy as measure of dispersion and location: the deviation of a single value from the true one.

In order to avoid misunderstandings in the practical estimation of trueness and precision the description of the experimental data underlying the computations must be done most carefully. For instance, it is of significant importance to know whether the data used are results of single determinations, or whether they have been obtained from duplicate or triplicate measurements. Equally, the conditions under which these measurements were made must be meticulously documented, either as part of the SOP or independently. Important but neglected parameters might be the temperature constancy of the sample, constant time between single measurements, extraction of raw data, etc.

Calibration and Linearity. Valid calibration can be regarded as a fundamental prerequisite for a meaningful analytical measurement. Consequently, calibration frequently constitutes the first step in quality assurance. In short, the challenge is to find the dependence between signal and amount of substance (or concentration). Preconditions for a reliable calibration are:

- Standards with (almost) negligible uncertainty (independent variable x);
- Constant precision of the entire working range;
- Useful model (linear or curved);
- Random variation of deviations in signals;
- Deviations distributed according to the normal distribution.

These criteria are ranked in the order of decreasing importance. This means, all of analytical work is meaningless unless there is a firm idea about the reliability of standards. Many methods of analysis have a poorer precision at higher concentrations (larger absolute standard deviation) than at lower concentrations. In practice this means that either the working range must be reduced or that the working range is subdivided into several sections each with its own calibration function. Alternatively the increase of standard deviation with increasing concentration can be established and used for a calibration on the basis of weighted regression. In this case a confidence band cannot be given.

In all cases it is advantageous to position the calibration function so that the majority of expected concentrations fall in the middle part of the curve.

The calibration function therefore the mathematical model that best describes the connection between signal

and concentration, and this function can be straight or curved. Linearity of a method of measurement is the range of concentrations within which a straight line is the best description for the dependence of the signal on concentration.

A large deviation from linearity can be visually detected without problems. Alternatively, the dependence of signal on concentration is modelled by appropriate software in a way that best describes this dependence. A statistical F -test then shows deviations from linearity, or the correlation coefficients of the different models can be compared with each other; the closer the value is to 1 the better the fit of the model.

Recovery. Recovery is the ratio of a measured mean value under repeatability conditions to the true value of the analyte in the sample

$$R = \frac{\bar{x}}{x_t} 100,$$

where R is recovery (in %), \bar{x} is the mean value, and x_t is the true value.

Recovery data can be useful for the assessment of the entire method, but in a specific case it is applicable just for the experimental conditions, the matrix, etc. for which the mean value was determined.

If R is sufficiently well established, it can also be used for the correction of the results.

The following are the most important procedures for determining recoveries.

- **Certified reference materials:** the certified value is used as the true value in the formula above.
- **Spiking:** this procedure is widely practised either on a blank sample or on a sample containing the analyte.
- **Trueness:** if spiking is used at several concentration levels or if several reference materials are available over the concentration range of interest, R can be estimated from a regression line by testing trueness by a plot of true values (spiked values) versus measured values.
- **Mass balance:** tests are conducted on separate fractions of a sample. The sum of the results on each fraction constitute 100%. This tedious method is applied only in special cases.

Robustness. A method is robust (also called rugged) if minor variations in the practice of the method do not lead to changes in the quality of data. Robustness therefore is the degree of independence of the results from changes

Table 2.9 Purpose of a method of measurement and the relevant performance characteristics in validation

	(a) Qualitative	(b) Main component/assay	(c) Trace analysis	(d) Phys.-chem. properties
Trueness		×	×	×
Precision		×	×	×
Linearity/working range		×	×	×
Selectivity	×	×	×	
Limit of detection	×		×	
Limit of determination			×	
Robustness	×	×	×	×

in the different influence factors. It is easily seen that robustness is becoming a very major issue in routine operation of analytical methods.

For the determination of robustness two different approaches are feasible.

Inter-laboratory studies: the basic reasoning behind the usefulness of inter-laboratory studies for robustness testing is the fact, that the operation of a specific method in a sufficiently large number of laboratories (≥ 8) will always lead to random deviations in the experimental parameters.

Experimental design in a single laboratory: in a carefully designed study the relevant experimental parameters are varied within foreseen or potential tolerances and the effect of these perturbations on the results are recorded:

- Experimental parameters (also called factors), that are most likely to have an influence on the result, are identified.
- For each experimental parameter the maximum deviation from the nominal value that might be seen in routine work is laid down.
- Experiments were run under these perturbed conditions.
- The results are evaluated in order to identify the truly influential experimental parameters.
- A strategy is devised to optimise the procedure with respect to the identified influences.

Relationship Between the Objective of a Method and the Depth of Validation

In order to present the basic considerations considered so far in a concrete form it is useful to classify the analytical methods according to their main purposes:

1. methods for qualitative analysis,
2. methods for measuring main components, assaying,
3. methods for trace analysis,
4. methods for the establishment of physicochemical properties.

The requirements for validation that follow for different classes of applications are given in the Table 2.9.

These performance characteristics have already been described in an earlier part of the chapter and do not require further discussion. It should be stressed, however, that selectivity must be demonstrated in the course of validation by accurate and reliable measurements on real samples. A test of selectivity is at the same time a test of the influence of interferents on the results.

Particular attention should also be drawn to the fact that the working range of a method of analysis is never larger than tested on real samples in the course of validation. Extrapolation to smaller or to larger values cannot be tolerated.

In practice this leads to a definition of the limit of determination by the sample with the smallest content where data on trueness and precision are available. The lower limit of the working range therefore also defines the limit of determination; the upper limit of the working may sometimes be extended by suitable dilutions.

Frequency of Validation

The situation regarding the frequency of validation is comparable to the situation for the appropriate amount of validation; there are no firm and generally applicable rules, only recommendations can be offered that help the person responsible for validation with a competent assessment of the particular situation. Some such recommendations can also be found in ISO 17025 Chap. 5.4.5. Besides those cases where a basic validation is in order, e.g. at the beginning of the life cycle of a method, there is the recommendation to validate “*standard methods used outside their intended scope, and amplifications and modifications of standard methods to confirm that the methods are fit for the intended use*”, and “*when some changes are made in the validated non-standard methods, the influence of such changes carried out should be documented and if appropriate a new validation should be carried out*”.

Table 2.10 Event driven actions in revalidation adapted from [2.17]

Event	Action taken for revalidation
A new sample	Internal standard Standard additions Duplicate analysis
Several new samples (a new batch)	Blank(s) Recalibration Measurement of a standard reference material or a control check sample
New operator	Precision Calibration Linearity Limit of detection Limit of determination Control check sample(s)
New instrument	General performance check Precision Calibration Limit of detection Limit of determination Control check samples
New chemicals/standards	Identity check for critical parameters Laboratory standards
New matrix	Interlaboratory comparisons New certified reference material Alternative methods
Small changes in analytical methodology	Proof of identical performance over the concentration range and range of matrices (<i>method comparison</i>)

In routine work regular checks are required to make sure that the fitness for the intended use is not compromised in any way. In practice this is best done by control charts.

It is fair to state that in essence the frequency and the extent of a revalidation depends on the problem and on the magnitude of changes applied to previously validated methods. In a way it is therefore not time, but a particular event that triggers the quest for revalidation. For a simple orientation and overview some typical examples are addressed in Table 2.8.

If a new sample is analysed this might constitute the simplest event calling for validation measures. Depending on the method applied this might be accomplished by adding an internal standard, or by the method of standard additions or by calling for duplicate measurements. If a new batch of samples is to be analysed it may be appropriate to take some additional actions, and it is easily seen that the laboratory supervisory personnel must incorporate flexibility in the choice of the appropriate revalidation action.

A special case is the training of new laboratory personnel, as the workload necessary may be significant,

for instance if difficult clean-up operations are involved. It may be advisable to have a back-up operator trained in order to have a smooth transition from one operator to another one without interruption of the laboratory work flow.

System Suitability Test

A system suitability test (SST) is an integral part of many analytical methods. The idea behind an SST is to view equipment, electronics, analytical operations and samples as one system that can therefore be evaluated in total. The particular test parameters of an SST therefore critically depend on the type of method to be validated. In general an SST must give confidence that the test system is operating without problem within specified tolerances. An SST is being practice with real samples, and it therefore cannot pinpoint problems of a particular subsystem.

Details can be found in pharmaceutical sciences, particularly in pharmacopoeia. In the literature there are several examples for SST, e.g. for HPLC.

If an SST is applied regularly, it is generally laid down in a separate standard operating procedure.

Report of Validation and Conclusions

Around the globe millions of analytical measurements are performed daily in thousands of laboratories. The reasons for doing these measurements are extremely diverse, but all of them have in a common the characteristic that the cost of measurement is high, but the decisions made on the basis of the results of these measurements involve yet higher cost. In extreme cases they can lead to fatal consequences; points in case are measurements in the food, toxicological and forensic fields.

Correct results from analytical measurements are truly of foremost importance throughout life and demonstrate the underlying responsibility. Validation is an appropriate means to demonstrate that the method applied is truly fit for the purpose. For every method

applied, a laboratory will have to rely on validation for confidence in the operation of this method.

The elements of validation discussed in this chapter must ascertain that the laboratory produces, in every application of a method, data that are well defined with respect to trueness and precision. The basics of quality management aid in providing this confidence. Therefore, every laboratory should be prepared to demonstrate its competence on the basis of internal data not only for methods it has devised itself, but also for standard methods of analysis. Revalidation will eventually be required for all methods to keep this data up to date.

A laboratory accredited according to **ISO 17025** must be able, at any time, to demonstrate the required performance by well-documented validation results.

2.5 Inter-laboratory Comparisons and Proficiency Testing

Inter-laboratory comparisons (**ILCs**) are a valuable quality assurance tool for measurement laboratories since they allow direct monitoring of the comparability of measurement and testing results. Proficiency tests (**PTs**) are inter-laboratory comparisons that are organised on a continuing or ongoing basis. **PTs** and **ILCs** are therefore important components in any laboratory quality system. This is recognised increasingly by national accreditation bodies (**NABs**) in all parts of the world, who are increasingly demanding that laboratories participate in **PTs** or **ILCs** where these are available and appropriate.

PTs and **ILCs** enable laboratories to benchmark the quality of their measurements. Firstly, in many **ILCs**, a laboratory's measurement results may be compared with reference, or true, values for one or more parameters being tested. Additionally, where applicable, the associated measurement uncertainties may also be compared. These reference values will be the best estimate of the true value, traceable to national or international standards or references. Reference values and uncertainties are determined by expert laboratories; these will often be national measurement institutes (**NMIs**).

However, not all **ILCs** and **PTs** will be used to determine reference values. In most of these cases, a laboratory will only be able to benchmark their results against other laboratories. In these situations, a consensus value for the true value will be provided by the organiser, which will be a statistical value based upon the results of the participating laboratories or a value derived from extended validation.

2.5.1 The Benefit of Participation in PTs

The primary benefit from participating in **PTs** and **ILCs** for a laboratory is the ability to learn from the experience. Organisers of **PTs** and **ILCs** usually see themselves in the role of teachers rather than policemen. **PTs** and **ILCs** are therefore viewed as educational tools, which can help the participating laboratories to learn from their participation, regardless of how successful the participation is.

There are many quality assurance tools available to laboratories, including:

- Appropriate training for staff;
- Validation of methods for testing and calibration;
- Use of certified reference materials and artefacts;
- Implementation of a formal quality system and third-party accreditation;
- Participation in appropriate **PTs** and **ILCs**.

It is usually recommended that all these tools should be used by measurement laboratories. However, laboratories are now recognising the particular importance of participation in **PTs** and **ILCs** as a quality tool. Of the tools listed above, it is the only tool that considers a laboratory's outputs, i.e. the results of its measurements. The other tools are input tools, concerned with quality assurance measures put in place to provide the infrastructure necessary for quality measurements.

As a consequence of this, appropriate use of participation in **PTs** and **ILCs** is of great value to laboratories in assessing the validity of the overall quality manage-

ment system. Appropriate participation in **PTs** and **ILCs** can highlight how the quality management system is operating, where any problems may be found that have an effect on the measurement results expected. Regular participation can therefore form a continuous feedback mechanism, to enable the quality management system to be monitored and improved on an ongoing basis. In particular, following poor performance in a **PT** or **ILC**, laboratories should institute an investigation, which may result in corrective action being taken. This corrective action may involve changes to the quality management system and its documentation.

2.5.2 Selection of Providers and Sources of Information

There are literally thousands of **PTs** and **ILCs** offered during any year, across all measurement sectors, by reputable organisations across the world. Laboratories can gain information about available **PTs** and **ILCs** from a number of sources. These include:

- The European Proficiency Testing Information System (EPTIS);
- National accreditation bodies (**NABs**);
- International accreditation bodies [e.g. the Asian Pacific Accreditation Cooperation (APLAC), **ILAC**, and the European Cooperation for Accreditation (EA)];
- Peer laboratories.

National accreditation bodies (**NABs**) will hold, as part of their normal laboratory surveillance and assessment activities, a great deal of information about **PTs** and **ILCs** (or organisations that run **ILCs**). They will have noted, during laboratory surveillance visits, what these **PTs** and **ILCs** cover, how they operate, and how relevant they are to the laboratory's needs. **NABs** are therefore in a good position to provide information about available and appropriate **PTs** and **ILCs** and, in some cases, may advise on the suitability and quality of these. Some **NABs** also accredit **PT** providers, usually against ISO guide 43 part 1 (1997) [2.18] and **ILAC** guide G13 (2000) [2.19]. These **NABs** will therefore have more detailed information regarding accredited **PTs**, which they can pass on to laboratories.

International accreditation bodies such as APLAC, **ILAC** or EA will also have a significant body of information regarding international, or regional **PTs** and **ILCs**. Additionally they may organise **PTs** and **ILCs** themselves, or associate themselves with specific **PTs**

and **ILCs**, which they use for their own purposes, such as monitoring the efficacy of multilateral agreements (MLAs) or multi-regional agreements (**MRAs**). APLAC, for example, associate themselves with a number of **ILCs**, which are usually organised by member accreditation bodies. EA may be involved with independent **PT** and **ILC** organisers, such as the Institute of Reference Materials and Measurements (IRMM) in Geel, Belgium, who organise the International Measurement Evaluation Programme (IMEP) series of **ILCs**.

The European Proficiency Testing Information System (EPTIS) is the leading international database of **PTs** and **ILCs**. EPTIS was originally set up with funding from the European Commission, and is now maintained by the German Federal Institute of Materials Testing (**BAM**) in Berlin. EPTIS contains over 800 **PTs** and **ILCs** across all measurement sectors excluding metrology. Although originally established as a database for the pre-May 2004 countries within the European Union, plus Norway and Switzerland, it has now been extended to include the new European Union (EU) countries, the United States of America, as well as other countries in South and Central America and Asia. EPTIS now enjoys the support of the International Laboratory Accreditation Conference (**ILAC**), and has the goal of extending its coverage to include potentially all providers of **PTs** and **ILCs** throughout the world. The database, however, is searchable by anyone, anywhere in the world. It is accessed online at www.eptis.bam.de. It can be searched for **PTs** by country, test sample type, measurement sector, or determinand. The details contained on EPTIS of each **PT** and **ILC** are comprehensive. These include:

- Organiser
- Frequency
- Scope
- Test samples
- Determinands
- Statistical protocol
- Quality system
- Accreditation status
- Fees payable.

Many of the entries also contain a link to the home page of the provider so that more in-depth information can be studied.

EPTIS also provides more general information on the subject of proficiency testing. Any laboratory wishing to find a suitable **PT** or **ILC** in which to participate is strongly advised to search EPTIS first. One warning

must, however, be given. Although there is no cost to PT providers to have an entry on EPTIS, it is voluntary and therefore there are a small number of PTs in the countries covered by EPTIS which are not listed.

Peer laboratories are a good source of information about available and appropriate PTs and ILCs. A laboratory working in the same field as your own may be a good source of information, particularly if they already participate in a PT, or have investigated participation in a PT or ILC. Although such laboratories may be commercial competitors, a PT or ILC that is appropriate for them is very likely to be appropriate for all similar laboratories in that measurement sector.

When a laboratory has obtained the information about available ILCs and PTs, there may be a need to make a decision:

- Are there more than one available ILC/PT? If so, which is the most appropriate for my laboratory?
- There is only one ILC/PT that covers my laboratory's needs. Is it appropriate for my laboratory to participate?

There are many issues that are appropriate to both the above questions. In order to make the correct decision, there are a number of aspects of the ILCs/PTs that must be understood. To select the most appropriate ILC or PT, or determine if an ILC or PT is appropriate for a specific laboratory, the following factors need to be considered:

- Test samples, materials or artefacts used;
- Measurands, and the magnitude of these measurands;
- What is the frequency of distribution for a PT scheme?
- Who are the participants?
- What quality system is followed by the organiser?
- In which country is the ILC or PT organised, and what language is used?
- What is the cost of participation?

We should consider these factors individually.

Test Samples, Materials or Artefacts Used

The laboratory must satisfy itself that the test samples, materials or artefacts used in the PT or ILC are appropriate to their needs. The test materials should be of a type that the laboratory would normally or routinely test. They should be materials that are covered by the scope of the laboratories test procedures. If the materials available in the PT or ILC are not fully appropriate

– they may be quite similar but not ideal – the laboratory must make a judgement as to whether participation would have advantages. The laboratory could also contact the PT or ILC organiser to ask if the type of material appropriate to them could be included.

Measurands and the Levels of these Measurands

If the test materials in the PT or ILC are appropriate for the laboratory, then the question of the measured properties (measurands) needs to be taken into consideration. The measurands available should be the same as the laboratory would routinely measure. Of course, for those materials where many tests could be carried out, the PT or ILC may not routinely provide all of these. Again, the laboratory must make a judgement about whether the list of tests available is appropriate and fits sufficiently well with the laboratory's routine work to make participation worthwhile.

The origin of the samples is also important to many laboratories. The laboratory needs to know where and how they are prepared, or from which source they were obtained.

For example, it is important to know if are they tested for homogeneity and/or stability. If so, where there is more than one measurand required for that material, the laboratory needs to know for which measurands. A good-quality PT or ILC will prepare sufficient units so that surplus samples are available for participants later, particularly those who need them following poor performance.

What is the Frequency of Distribution for a PT Scheme?

For PT schemes, rather than ILCs, the frequency of distributions, or rounds, is important. The frequency of PTs does vary from scheme to scheme and from sector to sector. Most PTs are distributed between two and six times a year, and a frequency of three or four rounds per year is quite common. The frequency is important for laboratories, in case of unsatisfactory performance in a PT, when the efficacy of corrective actions must be studied to ensure any problem has been properly corrected.

Who are the Participants?

For any PT or ILC, it is important that a laboratory can compare its results with peer laboratories. Peer laboratories may not always be those who carry out similar tests.

Laboratories in different countries may have different routine test methods – these may be specified by

regulation. In some cases, these test methods will be broadly equivalent technically, but in other cases their performance may be significantly different. In fact, in this case, this situation may not be recognised by laboratories or expert sectoral bodies. Comparison to results generated using such methods will be misleading.

Even within any individual country, there may be differences in the test methods used by laboratories. The PT or ILC organiser should be able to offer advice on which test methods may be used by participants, how these vary in performance, and what steps the organiser takes to take these into account when evaluating the results.

The type of laboratories participating in a PT or ILC is also important. For a small nonaccredited laboratory, comparison with large, accredited laboratories or national measurement institutes (NMIs), may not be appropriate. The measurement capabilities of these different types of laboratories, and the magnitude of their estimated measurement uncertainties will probably be significantly different. The actual end use of results supplied by different types of laboratories to their customers will usually determine the level of accuracy and uncertainty to which these laboratories will work.

What Quality System is Followed by the Organiser?

For laboratories who may rely significantly on participation in PTs or ILCs, or if they are accredited and are required to participate by their national accreditation body (NAB), as a major part of their quality system, it is important that the schemes they use are of appropriate quality. This gives laboratories a higher degree of confidence in the PT or ILC, and hence the actions they may need to take as a result of participating.

In recent years the concept of quality for PTs has gained more importance. ISO/IEC guide 43 parts 1 and 2 were reissued in 1997, and many PT and ILC organisers claim to follow this. In practice, this guide is very generic, but compliance with it does confer a higher level of quality. The development of the ILAC guide G13:2000 has, however, enabled many accreditation bodies throughout the world (including in countries such as The Netherlands, Australia, The United Kingdom, Spain, Sweden and Denmark) to offer accreditation of PT scheme providers as a service. Most accreditation bodies who offer this service accredit the providers against a combination of ISO/IEC guide 43 and ILAC G13. Guide G13 is a considerably more detailed document and is generally used as an audit

protocol. Not all NABs accredit PT and ILC organisers using these documents; some NABs in Europe prefer the approach of using ISO/IEC 17020, considering the PT or ILC organisers to be inspection bodies. In Europe, the policy of EA is that it is not mandatory for NABs to provide this service, but that if they do they should accredit using a combination of ISO guide 43 part 1 (1997) and the ILAC guide G13:2000, which is also the preferred approach within APLAC.

Information on quality is listed on EPTIS, and now information on accreditation status is also included, at the request of ILAC.

Laboratories need to make a judgement on whether an accredited scheme is better than a nonaccredited scheme where a choice is available.

The quality of a PT or ILC is important, as the operation of such an intercomparison must fit well with the requirements of participating laboratories. All PTs and ILCs should have a detailed protocol, available to all existing and potential participating laboratories. The protocol clearly illustrates the *modus operandi* of the PT or ILC, including timescales, contacts and the statistical protocol. The statistical protocol is the heart of any intercomparison, and should comprehensively show how data should be reported (e.g. number of replicates and reporting of measurement uncertainty), how the data is statistically evaluated, and the results of the evaluation reported to participating laboratories. Laboratories need to understand the principles of the statistical protocol of any PT or ILC in which they participate. This is necessary in order to understand how their results are evaluated, which criteria are used in this evaluation, and how these fit with the laboratory's own criteria for the quality and fitness for purpose of results. It is therefore important to find a PT or ILC that asks for data in an appropriate format for the laboratory and evaluates the data in a way that is broadly compatible with the laboratory's own procedures.

In which Country is the ILC or PT Organised, and what Language is Used?

Where a laboratory has a specific need which cannot be met by a PT or ILC in their own country, or where a choice between PTs or ILCs exists where one or more of these are organised in countries outside their own, the country of origin may be important.

The *modus operandi* of many PTs and ILCs may vary significantly between countries, particularly with regard to the statistical evaluation protocol followed. This may be important where a laboratory wants to take part in

a **PT** or **ILC** that fits well with their own internal quality procedures.

More important for many laboratories is the language in which the **PT** or **ILC** documentation is written. A number of **PTs** or **ILCs** may be aimed mainly laboratories in their own country and will use only their native language. Laboratories wishing to participate in such a **PT** or **ILC** will need to ensure that they have members of staff who can use this language effectively. Other **PTs** and **ILCs** are more international in their nature, and may use more than one language. In particular, many of these will issue documents in English as a second language.

What is the Cost of Participation?

If a laboratory has researched the available **PTs** and **ILCs** and has found more than one of these that could be appropriate, the final decision may often be made on the basis of cost.

Some laboratories see participation in **PTs** and **ILCs** as another cost that should be minimised. Some accredited laboratories see participation as an extra cost on top of what they already pay for accreditation.

Therefore, cost is an important factor for some laboratories. However, it should be noted that a less-expensive scheme may not always provide the quality or service that is required for all the many benefits of participation in **PTs** and **ILCs** to be realised.

Some laboratories successfully negotiate with the organisers where cost is a real issue for them (e.g., very small laboratories, university laboratories, laboratories in developing economies, etc.). Laboratories should note that the cost of participation is not just the subscription that is paid to the organiser. The cost in time and materials of testing **PT** and **ILC** test materials or samples also needs to be taken into account.

What if there is no Appropriate **PT** or **ILC** for a Laboratory's Needs?

When the right **PT** or **ILC** does not exist, a laboratory can participate in one which is the best fit, or decide not to participate at all. In this case, reliance on other quality measures will be greater. A laboratory can approach a recognised organiser of **PTs** and **ILCs** to ask if an appropriate intercomparison can be organised. Also, a laboratory may collaborate with a group of laboratories with similar needs (these groups will nearly always be quite small, otherwise a **PT** or **ILC** will probably already have been organised), to organise small intercomparisons between themselves.

2.5.3 Evaluation of the Results

It is important for laboratories, when they have participated in any **PT** or **ILC**, to gain the maximum benefit from this. A major aspect of this is in the interpretation of the results from a **PT** or **ILC**, and how to use these results to improve the quality of measurements in the laboratory.

There are a number of performance evaluation procedures used in **PT** schemes. Two of the most widely used of these are outlined here:

1. Z -scores;
2. E_n numbers.

Z -scores are commonly used in many **PT** schemes across the world, in many sectors. This performance evaluation technique is probably the most widely used on an international basis.

E_n numbers incorporate measurement uncertainty and are used in calibration studies, and many **ILCs** where the measurement uncertainty is an important aspect of the measurement process. E_n numbers are therefore used more commonly in physical measurement **ILCs** and **PTs** where the measurement uncertainty concept is much better understood.

More examples of performance evaluation techniques can be found in the **ISO** standard for statistics used in proficiency testing, **ISO 13528** (2005).

Z -Scores

Z -scores are calculated according to the following equation:

$$Z = (x_I - X)/s,$$

where x_I is the individual result, X is the assigned or true value, and s is a measure of acceptability.

For example, s can be a percentage of X : if X is 10.5, then if results should be within 20% of this to be awarded a satisfactory Z -score, the s will be 10% of 10.5, i.e. 1.05. It could also be a value considered by the organiser to be appropriate from previously generated precision data for the measurement. s may also be a statistically calculated value such as the standard deviation, or a robust measure of the standard deviation.

The assigned value can be either a *reference* value or a *consensus* value. Reference values are traceable, and can be obtained, for example, from:

- formulation (the test sample is prepared in a quantitative manner so that its properties and/or composition are known),

- reference measurement (the test sample has been characterised using a primary method, or traceable to a measurement of a certified reference material of a similar type).

Consensus values are obtained from the data submitted by participants in a **PT** or **ILC**.

Most schemes will classify Z-scores as:

- Satisfactory ($|Z| \leq 2$);
- Questionable ($2 > |Z| > 3$);
- Unsatisfactory ($|Z| \geq 3$).

These are broadly equivalent to internal quality control charts, which give warning limits – equivalent to a “questionable” result, and action limits – equivalent to an “Unsatisfactory” result.

E_n numbers

The equation for the calculation of E_n numbers is:

$$E_n = \frac{x - X}{\sqrt{U_{\text{lab}}^2 + U_{\text{ref}}^2}},$$

where the assigned value X is determined in a reference laboratory, U_{ref} is the expanded uncertainty of X , and U_{lab} is the expanded uncertainty of a participant's result x .

E_n numbers are interpreted as follows

- Satisfactory ($E_n \leq 1$);
- Unsatisfactory ($E_n > 1$).

Laboratories are encouraged to learn from their performance in **PTs** and **ILCs**. This includes both positive and negative aspects.

Action should be considered:

- when an unsatisfactory performance evaluation has been obtained (this is mandatory for laboratories accredited to **ISO/IEC 17025**); or
- when two consecutive questionable results have been obtained for the same measurement; or
- when nine consecutive results with the same bias against the assigned value, for the same measurement, have been obtained. This would indicate that, although the measurements may have been very precise, there is a clear bias. Deviations from this situation could easily take the measurements out of control.

The above guidelines should enable laboratories to use **PT** and **ILC** results as a way of monitoring measurement quality and deciding when action is necessary.

When interpreting performance in any **PT** or **ILC**, there are a number of factors that need to be considered to enable the performance to be placed into a wider context.

These include:

- the overall results in the intercomparison from all participating laboratories;
- the performance of different testing methods;
- any special characteristics or problems concerning the test sample(s) used in the intercomparison;
- bimodal distribution of results;
- other factors concerning the **PT** or **ILC** organisation.

It is always advisable to look at any unsatisfactory performance in the context of all results for that measurement in the intercomparison.

For example, if the majority of the results have been evaluated as satisfactory, but one single result has not, then this is very serious. However, if many participating laboratories have also been evaluated as unsatisfactory, then for each laboratory with an unsatisfactory performance, there is still a problem but it is less likely to be specific to each of those laboratories.

It is also a good idea to look at how many results have been submitted for a specific measurement. When there are only a few results, and the intercomparison has used a consensus value as the assigned value for the measurement, the confidence in this consensus value is much reduced. The organiser should provide some help in interpreting results in such a situation and, in particular, should indicate the minimum number of results needed.

2.5.4 Influence of Test Methods Used

In some cases, an unsatisfactory performance may be due, at least in part, to the test method used by the laboratory being inappropriate, or having lower performance characteristics than other methods used by other laboratories in the intercomparison.

If the **PT** or **ILC** organiser has evaluated performance using the characteristics of a standard method, which may have superior performance characteristics, then results obtained using test methods with inferior performance characteristics will be more likely to be evaluated as unsatisfactory. It is always suggested that in such situations participating laboratories should compare their results to other laboratories using the same test method.

Some PTs and ILC will clearly differentiate between the various test methods used in the report, so the performance of each test method can be compared in order to see if there is a difference in precision of these test methods, and any bias between test methods can also be evaluated. The performance of all participating laboratories using the same test method can be studied, which should give laboratories information about both the absolute and relative performance of that test method in that intercomparison.

As has been previously stated, the test samples used in PTs and ILCs should be as similar to those routinely measured by participating laboratories. A PT scheme may cover the range of materials appropriate to that scheme, so some may be unusual or extreme in their composition or nature for some of participating laboratories. Such samples or materials should ideally be of a type seen from time to time by these laboratories. These laboratories should be able to make appropriate measurements on these test samples satisfactorily, if only to differentiate them from the test samples they would normally see. These unusual samples can, however, present measurement problems for laboratories when used in a PT or ILC, and results need to be interpreted accordingly.

In some cases, the value of the key measurands may be much higher or lower than what is considered to be a normal value. This can cause problems for laboratories and results need to be interpreted appropriately, and lessons should be learned from this. If the values are in fact outside the scope of a laboratory's test methods, then any unsatisfactory performance may not be surprising, and investigation or corrective actions do not always need to be carried out.

One consequence of divergence of performance of different test methods, which may not necessarily be related to the test samples, is that a bimodal distribution of results is obtained. This is often caused by two test methods which should be, or are considered by experts in the appropriate technical sector to be, technically equivalent showing a significant bias. This could also arise from two different interpretations of a specific test method, or the way the results are calculated and/or reported. Problems that are typically encountered with reporting include the units or number of significant figures. When the assigned value for this measurement is a consensus value, this will have a more significant effect on result evaluation. Automatically, any smaller group of laboratories will be evaluated as unsatisfactory, regardless. In extreme cases, the two distributions will contain the same number of results, and then the consensus value will lie

between them and probably most, if not all, results will be evaluated as unsatisfactory.

In these cases, the organiser of the PT or ILC should take action to ensure that the effect of this is removed or minimised, or no evaluation of performance is carried out in order that laboratories do not misinterpret the evaluations, and carry out any unnecessary investigations or corrective actions.

Although organisers of PTs and ILCs should have a quality system in place, occasionally some problems will arise that affect the quality of the evaluation of performance that they carry out. These can include, for example:

- transcription errors during data entry,
- mistakes in the report,
- software problems,
- inappropriate criteria for evaluation of performance being used.

In these cases, the evaluation of the performance of participating laboratories may be wrong, and the evaluation must either be interpreted with caution or, in extreme situations, ignored. The organiser of the PT or ILC should take any necessary corrective once the problem has been identified.

2.5.5 Setting Criteria

In setting the criteria for satisfactory performance in a PT or ILC, the organiser, with the help of any technical steering group, may need to make some compromises in order to set the most appropriate criteria that will be of value to all participating laboratories. These criteria should be acceptable and relevant to most laboratories, but for a small minority these may be inappropriate. From a survey carried out by the author in 1997, some laboratories stated that they chose to use their own criteria for performance evaluation, rather than those used by the PT or ILC organiser. For most of these laboratories, the criteria they chose were tighter than those used in the PT or ILC.

Laboratories are normally free to use their own criteria for assessing their PT results if those used by the scheme provider are not appropriate since the PT provider can obviously not take any responsibility for participating laboratories' results. These criteria should be fit for purpose for the individual laboratory's situation, and should be applied consistently. Interpretation of performance using these criteria should be carried out in the same manner as when using the criteria set by the PT or ILC organiser.

2.5.6 Trends

It is very useful to look at trends in performance in a **PT** that is carried out regularly. This is particularly useful when a laboratory participates at a relatively high frequency (e.g., once every three months).

Performance over time is the major example of this. The example above shows how this may be illustrated graphically. This approach is recommended by experts rather than using statistical procedures, which may produce misleading information or hide specific problems.

The chart shows an example from an Laboratory of the Government Chemist (LGC) **PT** scheme of a graph showing performance over time.

Z-scores for one measurement are plotted against the round number. In this case, the laboratory has reported results using three different test methods. This graph can be used to assess trends, and ascertain whether problems are individual in nature, or have a more serious underlying cause.

Where more than one test method has been used, these can also be used to see if there is a problem with any individual method, or whether there is a calibration problem, which could be seen if more than one test method is showing a similar trend.

In many **PTs** and **ILCs** there may be measurements that are requested to be measured using the same method, or are linked to each other technically in some way. Where all results for such linked measurements are unsatisfactory, the problem is likely to be generic and only one investigation and corrective action necessary.

Laboratory managers can gain information about the performance of individual staff on **PT** or **ILC** test samples. Information on each member of staff can be collated from **PT** and **ILC** reports and interpreted together with the information they should hold about which member of staff carried out the measurements.

Alternatively, where the test sample is of an appropriate nature, the laboratory manager can give the **PT/ILC** test sample(s) to more than one member of staff. Only one set of results needs to be reported to the organiser, but the results of appropriate members of staff can then be compared when the report is published.

Samples provided by the organiser should be tested in the same way as routine samples in order to get optimum feedback on performance. If this is not done, the educational benefit will be limited.

2.5.7 What Can Cause Unsatisfactory Performance in a **PT** or **ILC**?

There are many potential causes of unsatisfactory performance in any **PT** or **ILC**. These fall into two distinct categories:

- Analytical problems with the measurement itself;
- Non-analytical problems that usually occur after the measurement has been made.

Analytical errors include:

- problems with calibration (e.g., the standard materials prepared to calibrate a measurement, or the accuracy/traceability of the calibration material);
- instrument problems (e.g. out of specification);
- test sample preparation procedures not being carried out properly;
- poor test method performance. These may be due to problems with the member of staff carrying out the measurement, or the appropriateness of the test method itself.

Non-analytical errors include:

- calculation errors,
- transcription errors,
- use of the wrong units or format for the reported result.

Any result giving rise to an unsatisfactory performance in a **PT** or **ILC** indicates that there is a problem in the laboratory, or a possible breakdown of the laboratory's quality system. It does not matter if the cause of this unsatisfactory result was analytical or non-analytical as the result has been reported. At this point, it must be remembered that **PT** or **ILC** organiser is acting in the role of the laboratory's customer and is providing a service to examine the laboratory's quality system thoroughly by means of an intercomparison.

The author's own experience of the organisation of **PTs** over 10 years has shown that between 35 and 40% of unsatisfactory results are due to non-analytical errors.

2.5.8 Investigation of Unsatisfactory Performance

Participation in appropriate **PTs** and **ILCs** is strongly recommended by most national accreditation bodies for accredited laboratories and those seeking accreditation. Some **NABs** will stipulate that participation is mandatory in certain circumstances. Additionally, some regulatory authorities and, increasingly, customers of

laboratories, will also mandate participation in certain PT and ILCs in order to assist in the monitoring of the quality of appropriate laboratories.

It is mandatory under accreditation to ISO/IEC 17025 that an investigation should be conducted for all instances of unsatisfactory performance in any PT or ILC, and to implement corrective actions where these are considered appropriate. All investigations into unsatisfactory performance in an intercomparison, and what, if any, corrective actions are implemented must be fully documented.

Some measurement scientists believe that unsatisfactory performance in any PT or ILC is in itself a noncompliance under ISO/IEC 17025. This is not true, although there are a few exceptions in regulatory PTs where participation is mandatory and specified performance requirements are stated. However, the failure to investigate an unsatisfactory result is certainly serious noncompliance for laboratories accredited to ISO/IEC 17025.

It is generally recommended to follow the policy for the investigation of unsatisfactory performance in PTs and ILCs given by most national accreditation bodies, and the subsequent approach to taking corrective actions. All investigations should be documented, along with a record of any corrective actions considered necessary and the outcome of the corrective action(s).

There are a number steps that it is recommended should be taken when investigating unsatisfactory performance in any intercomparison. This should be done in a logical manner, working backwards.

Firstly, you should check that the PT or ILC organiser not at fault. This should be done by ensuring that the report is accurate, they have not entered any of the laboratory's data incorrectly, and have carried out all performance evaluations appropriately.

If the organiser has not made any errors, then the next check is to see that the result was properly reported. Was this done accurately, clearly and in the correct units or format required by the PT or ILC?

If the result have been reported correctly and accurately, the next check is on any calculations that have been carried out in producing the result.

If the calculations are correct, the next aspect to check is the status of the member of staff who carried out the measurement. In particular, was he or she appropriately trained and/or qualified for this work, and were the results produced checked by their supervisor or manager?

This should identify most sources of non-analytical error. If no non-analytical errors can be found, then an-

alytical errors must be considered. When it appears that an unsatisfactory result has arisen due to analytical problems, there are a number of potential causes that should be investigated, where appropriate.

Poor calibration can lead to inaccurate results, so the validity of any calibration standards or materials must be checked to ensure that these are appropriate, within their period of use, and that the calibration values have been correctly recorded and used.

If the measurement has been made using an instrument – which covers many measurements – the status of that instrument should be checked (i.e., is it within its calibration period, when was it last checked?). It is also recommended to check that the result was within the calibration range of the instrument.

Any CRM, RM or other QC material measured at the same time as the PT test sample should be checked, with the result. If the result for such a material is acceptable, then a calibration or other generic measurement problem is unlikely to be the cause of the unsatisfactory performance.

Finally, the similarity of the test sample to routine test samples or, where appropriate, other samples tested in the same batch, should be noted.

This is not an exhaustive list, but covers the main causes.

When an investigation into unsatisfactory performance has indicated a potential cause, one or more corrective actions may need to be implemented.

These include:

- Modifying a test method – which may then need revalidating;
- Recalibration or servicing of an instrument;
- Obtaining new calibration materials;
- Changing the procedure for checking and reporting test results;
- Considering whether any members of staff need further training, or retraining in particular test methods or techniques.

2.5.9 Corrective Actions

Corrective actions are not always necessary. Investigation of the situation may in fact conclude that:

- no problem can be readily identified, and that the unsatisfactory result is just a single aberration – this needs monitoring, however to ensure that this is not the beginning of a trend,
- there is a problem external to the laboratory – for example with the organisation of the PT or ILC,

Fig. 2.11 Example of graphical presentation of performance over time

- the test sample from the PT or ILC is very unusual for the laboratory compared with the test samples they normally receive so that any corrective action will be of little or no value.

In some cases, it can prove very difficult for a laboratory to find the causes of unsatisfactory performance. Many PT and ILC organisers provide help to laboratories in such situations. It is always recommended to contact the organiser to ask for confidential help to solve such a problem. Many organisers have the expertise to give valuable advice, or can obtain the advice in strictest confidence from third parties.

Whatever is – or is not – done should be documented fully.

When corrective actions have been implemented, the laboratory needs to know that the actions have been successful. The corrective actions therefore need to be validated. The easiest way is to reanalyse the PT or ILC test sample. (If there is none remaining, some organisers will be able to provide another sample.) This will not, of course, be appropriate for checking non-analytical errors. If the result from retesting agrees with the assigned value in the report, the corrective action can be considered to be successful. Alternatively (this is particularly true for more frequent PTs), it may be more appropriate to wait for the next round to be distributed, carry out the testing of the sample, so the efficacy of the corrective action can be assessed when the report is received. Doing both is the ideal situation, where appropriate, and will give greater confidence that the corrective action has been effective.

In some cases, the nature of the problem is such that there must be a significant doubt about the quality of

results made for the test under investigation, and that this problem may have existed for some weeks or months. In fact, the problem will certainly have occurred since the last PT or ILC where satisfactory performance for the test had been obtained.

The investigation in such a situation therefore needs to be deeper in order to ascertain which results within this time frame have a high degree of confidence, and which may be open to questions as to their validity.

There are other, secondary, benefits from participation in appropriate PTs or ILCs. These include:

- help with method validation,
- demonstration of competence to internal and external customers, accreditation bodies, regulatory bodies,
- evaluation of technical competence of staff, which can be used in conjunction with a staff training programme.

2.5.10 Conclusions

Participation in PTs and ILCs is a very good way for a laboratory to demonstrate its competence at carrying out measurements. This may be for internal use – giving good news and confidence to senior management, for example, or giving positive feedback to the staff who carried out the measurements. Alternatively it may be used externally. Accreditation bodies, of course, will ask for evidence of competence from the results from PTs and ILCs. Regulatory authorities may ask for a level of PT or ILC performance from laboratories carrying out measurements in specific regulated areas. Customers of laboratories may require evidence of PT or ILC performance as part of their contractual arrangements. The laboratory can also be proactive in providing data to existing and potential customers to show their competence.

PT can also be used effectively in the laboratory as a tool for monitoring the performance of staff. This is particularly valuable for staff undergoing training, or who have been recently trained. The results obtained in an intercomparison can be used for this purpose, and appropriate feedback can be given. Where performance has been good, these results can be used as a specific example in a training record, and positive feedback should be given to the individual. Where performance has been less than satisfactory, it should be used constructively to help the individual improve, as part of any corrective action.

To conclude, **PTs** and **ILCs** are very important quality tools for laboratories. They can be used very effectively in contributing to the assessment of all aspects

of a laboratory's quality system. The most valuable use of **PTs** and **ILC** participation is in the educational nature of proficiency testing.

2.6 (Certified) Reference Materials

2.6.1 Introduction and Definitions

Role of Reference Materials in Quality Assurance, Quality Control and Measurement

Reference materials (**RM**s) are widely used for the calibration of equipment and the validation of measurement procedures, e.g. in chemical analysis or materials testing. They may be characterised for *identity* (e.g. chemical structure, fibre type, microbiological species etc.) and for *property values* (e.g. hardness etc.). According to the recent draft revision of the International Vocabulary of Basic and General Terms in Metrology (VIM), the term *property value* is better described as *quantity*. In this document the term property value is maintained in order to maintain the alignment with the existing **ISO** guides. The measurand needs to be clearly defined and the property values need to be, where possible, traceable to the SI units of measurement, or to other internationally agreed references such as the values carried by certified reference material [2.20].

The key characteristics of **RM**s and therefore the characteristics whose quality needs to be assured include the following: definition of the measurand, metrological traceability of the assigned property values, measurement uncertainty, stability and homogeneity.

Users of reference materials require reliable information concerning the **RM** property values, preferably in the form of a certificate. The user and accreditation bodies will also require that the **RM** has been produced by a competent body [2.21, 22].

The producers of reference materials must be aware that the values they supply are invariably an indispensable link in the traceability chain. They must implement all procedures necessary to provide evidence internally and externally (e.g. by peer review, laboratory intercomparison studies, etc.) that they have met the conditions required for obtaining traceable results at all times.

There are a number of authoritative and detailed texts on various aspects of reference materials and these are listed in Sect. 2.3.4. Reference materials are an important tool in realising a number of aspects of measurement quality and are used for method validation, calibration, estimation of measurement uncertainty, training and

for internal quality control (**QC**) and external quality assurance (**QA**) (proficiency testing) purposes.

Different types of reference materials are required for different functions. For example, a certified reference material would be desirable for method validation but a working-level reference material would be adequate for **QC** [2.21].

Definition of RM and CRM

Reference materials (**RM**s) are materials or substances on or more of whose *property values* are sufficiently homogeneous and well established to be used for calibration of an apparatus, the assessment of a measurement method, or for assigning values to materials [2.20].

Certified reference materials (**CRMs**) are reference materials, accompanied by a certificate, one or more of whose property values are certified by a procedure which establishes *traceability* to an accurate realisation of the unit in which the property values are expressed, and for which each certified value is accompanied by an uncertainty at a stated level of confidence [2.20].

Related Terms

Traceability is the property of result of measurement or the value of a standard whereby it can be related to stated references, usually national or international standards, through an unbroken chain of comparisons all having stated uncertainty [2.23].

A *reference material producer* is a technically competent body (organisation or firm, public or private) that is fully responsible for assigning the certified or property values of the reference materials it produces and supplies which have been produced in accordance with **ISO** guides 31 and 35 [2.24].

A *calibrator* is a measurement standard used in the calibration of a measurement system (VIM) [2.25] – or is a pure analyte in a suitable solvent or matrix, used to prepare the calibration curve (ST/NAR/26, 1995) [2.21].

A *European reference material* (**ERM**) is a new standard in certified reference materials issued by three European reference materials producers (IRMM, **BAM**, LGC).

In-house reference material is a material whose composition has been established by the user laboratory by several means, by a reference method or in collaboration with other laboratories [2.26].

The *primary method* [2.27] is a method having the highest metrological qualities, whose operation can be completely described, and understood, and for which a complete uncertainty statement can be written down in terms of SI units. A primary direct method measures the value of an unknown without reference to a standard of the same quantity. A primary ratio method measures the ratio of an unknown to a standard of the same quantity; its operation must be completely described by a measurement equation. The methods identified as having the potential to be primary methods are: isotope dilution mass spectrometry; gravimetry, covering gravimetric mixtures and *gravimetric analysis*; titrimetry; coulometry; determination of freezing point depression; differential scanning calorimetry and nuclear magnetic resonance spectroscopy. Other methods such as chromatography, which has extensive applications in organic chemical analysis, have also been proposed.

Standard reference materials (SRMs) are certified reference materials issued by the National Institute of Standards and Technology (NIST) of the USA. SRM is a trademark.

The *uncertainty of measurement* [2.25] is a parameter associated with the result of a measurement that characterises the dispersion of the values that could reasonably be attributed to the measurand [2.25].

Validation is confirmation, through the provision of objective evidence, that the requirements for a specific intended use or application have been fulfilled [2.28].

2.6.2 Classification

Principles of Categorization

Physical, chemical character:

- Gases, liquids, solutions
- Metals, organics,
- Inorganics

Preparation:

- Pure compounds, code of reference materials
- Natural or synthetic mixtures
- Artifacts and simulates
- Enriched and unenriched real-life samples

Function:

- Calibration of apparatus and measurement systems
- Assessment of analytical methods
- Testing of measurement devices
- Definition of measuring scales
- Inter-laboratory comparisons
- Identification and qualitative analysis
- Education and training

Application field (this principle is mainly used in the catalogues of RM-producers):

- Food and Agriculture (meat, fish, vegetable etc.)
- Environment (water, soil, sediment etc.)
- Biological and clinical (blood, urine etc.)
- Metals (ferrous, nonferrous etc.)
- Chemicals (gas, solvents, paints etc.)
- Pure materials (chromatography, isotopes etc.)
- Industrial raw materials and products (fuels, glass, cement etc.)
- Materials for determination of physical properties (optical, electrical properties etc.)

Metrological qualification CMC:

- Primary, secondary, tertiary standards
- Reference, transfer and working standards
- Amount of substance standards
- Chemical composition standards
- Gases, electrochemistry, inorganic chemistry, organic chemistry

Reliability:

1. Certified reference materials of independent institutions (NIST, IRMM, BAM, LGC)
2. CRM traceable from (1) of reliable producers (Merck, Fluka, Messer-Griesheim)
3. Reference Materials derived from (1) or (2) (in-house RM, dilution, RM preparations)

2.6.3 Sources of Information

CRM Databases

Information about reference materials is available from a number of sources. The international database for certified reference materials Code d'Indexation des Matériaux de Référence (COMAR) contains information on about 10500 CMC from about 250 producers in 25 countries. It can be accessed via the internet [2.29]. Advisory services assist users identify the type of material required for their task and identify a supplier. A number of suppliers provide a comprehensive range of materials

including materials produced by other organisations and aim to provide a one-stop shop for users. An additional internet database of natural matrix reference materials is published by the International Atomic Energy Agency (IAEA) [2.30].

Calibration and Measurement Capabilities (CMC) of the BIPM [2.31]

In 1999 the member states of the meter convention signed the mutual recognition arrangement (MRA) on measurement standards and on calibration and measurement certificates issued by national metrology institutes. Appendix C of the CIPM MRA is a growing collection of the calibration and measurements capabilities (CMC) of the national metrology institutes. The CMC database is available for everyone on the website of the Bureau International des Poids et Mesures (BIPM) and includes reference materials as well as references methods.

The methods used are proved by key comparisons between the national metrology institutes. For chemical measurements the Comité Consultative pour la Quantité de Matière (CCQM) has been established. CMC database provides a reliable service for customers all over the world to establish traceability.

Conferences and Exhibitions (Election)

- PITTCON: annual, biggest conference and exhibition of RM in USA,
- ANALYTICA: biannual, Munich,
- BERM: biannual, biological and environmental RM.

Guides (Selection)

- ISO guide 30:1992 – Terms and definitions used in connection with reference materials [2.20]
- ISO guide 31:2000 – Contents of certificates of reference materials [2.32]
- ISO guide 32:1997 – Calibration of chemical analysis and use of certified reference materials
- ISO guide 33:2000 – Uses of certified reference materials
- ISO guide 34:2000 – General requirements for the competence of reference material producers [2.24]
- ISO guide 35:1989 – Certification of reference materials-General and statistical principles
- ISO/REMCO (ISO-Committee on Reference Materials) document N 330 – List of producers of certified reference materials, information by task group 3 (promotion)
- 4E-RM guide (B. King) – Selection and use of reference materials [2.21]

- European Commission document BCR/48/93 (Dec. 1994) – Guidelines for the production and certification of Bureau Communautaire de Reference (BCR) reference materials
- ISO/REMCO – List of producers of certified reference materials
- RM report (RMR) (www.rmreport.com)
- European Commission document BCR/48/93 (Dec. 1994) – Guidelines for the production and certification of BCR reference materials
- NIST publication 260-100 (1993) – Standard reference materials – handbook for SRM users
- IUPAC orange book – Recommended reference materials for the realisation of physicochemical properties, ed. K.N. Marsh, Blackwell Scientific, 1987
- World Health Organisation (WHO) – Guidelines for the preparation and characterisation and establishment of international and other standards and reference reagents for biological substances, technical report series no. 800 (1990)

2.6.4 Production and Distribution

Requirements on RM producers [2.24]

All or some of the following activities can be crucial in RM production and their quality assessment can be crucial to the quality of the final RM:

- Assessment of needs and specification of requirements;
- Financial planning and cost-benefit analysis;
- Subcontracting and selection of collaborators;
- Sourcing of materials including synthesis;
- Processing of materials including purification, grinding, particle size separation, etc.;
- Packaging, storage and design of dispatch processes;
- Homogeneity and stability testing;
- Development, validation of measurement methods, including consideration; of the traceability and measurement uncertainty of measurement results;
- Measurement of property values, including evaluation of measurement uncertainty;
- Certification and sign off of the RM;
- Establishment of shelf life;
- Promotion, marketing and sales of RM;
- Post-certification stability monitoring;
- Post-certification corrective action;
- Other after-sales services;
- QC and QA of quality systems and technical aspects of the work.

Certification Strategies [2.33]

Inter-laboratory Cooperation Approach. The producer organises inter-laboratory comparisons of selected experienced laboratories, contributing by independent measurements. Systematic uncertainties can be identified and minimised.

Elite Group Method Approach. Only a few qualified laboratories contribute to the certification by validated, independent measurement methods.

Primary Method Approach. Only primary methods (CIPM definition [2.27]) are used for certification. A blunder check is recommended.

Most BCR, BAM and EURONORM reference materials are certified by the inter-laboratory cooperation approach. NIST prefers however the latter methods.

Homogeneity and Stability [2.32]

The homogeneity of an RM has to be estimated and noted on the certificate. It describes the smallest amount (of a divisible material) or the smallest area (of a reference object) for which the certified values are accurate in the given uncertainty range.

The stability of a RM has to be stated in the certificate and has to be tested by control measurements (e.g. control charts). Time-dependent changes of the certified values within the uncertainty range are tolerated.

List of Suppliers (Examples)

Institutes. NIST (USA), LGC (United Kingdom), NPL (Natal Physical Laboratory, United Kingdom), LNE (Laboratoire d'Essais, France), BAM (Germany), PTB (Germany), NMU (Japan), NMI (Netherlands Measurement Institute, Netherlands), NRC-CRM (National Research Center for Certified Reference Materials, China), UNIM (Russia), CANMET (Canadian Centre for Mineral and Energy Technology, Canada), SABS (South African Bureau of Standards, South Africa), OMH (Orzajos Meresugyi Hivatal, Hungary), SMU (Slovenski Metrologický Ústav, Slovak), SP (Swedish National Testing and Research Institute, Sweden), GUM (Główny Urząd Miar, Poland), IRMM (Europe)

Associations. Pharmacopoeia, the European Network of Forensic Science (ENFS), BCR (Bureau Communautaire de Référence), ECISS (European Committee for Iron and Steel Standardization), Codex Alimentarius Committee (food standard program), EPA (Environmental Protection Agency) (environment), UBA

(Bundesumweltamt) (environment), GDMB, VDEh (Verein Deutscher Eisenhüttenleute)

Companies (Branches). Sigma-Aldrich, LGC-Promochem, Merck, Fluka, Polymer Standard Service GmbH, Ehrenstorfer, Brammer Standard Company, Messer-Griesheim (gas), Linde (gas)

2.6.5 Selection and Use

Requirements on RM

Generally the demand for reference materials exceeds supply in terms of the range of materials and availability. It is rare to have a choice of alternative RMs and the user must choose the most suitable material available. It is important therefore that users and accreditation bodies understand any limitations of reference materials employed.

There are, however, several hundred organisations producing tens of thousands of reference materials worldwide. Producers include internationally renowned institutions such as NIST, collaborative government sponsored programs such as the EU BCR program, semi-commercial sectoral or trade associations such as the American Oil Chemicals Association and an increasing number of commercial organisations. The distinction between government institutes and commercial businesses is disappearing with the privatisation of a number of national laboratories.

Not all materials that are used as reference materials are described as such. Commercially available chemicals of varying purity, commercial matrix materials and products from research programs are often used as standards or reference materials. In the absence of certification data provided by the supplier it is the responsibility of the user to assess the information available and undertake further characterisation as appropriate. Guidance on the preparation of reference materials is given in ISO guides 31, 34 and 35 and guides on the preparation of working-level reference materials are also available.

The suitability of a reference material depends on the details of the analytical specification. Matrix effects and other factors such as concentration range can be more important than the uncertainty of the certified value as detailed. The factors to consider include:

- Measurand, including analyte;
- Measurement range (concentration);
- Matrix match and potential interferences;
- Sample size;

- Homogeneity and stability;
- Measurement uncertainty;
- Value assignment procedures (measurement and statistical);
- The validity of the certification and Uncertainty data;
- Track record of both;
- Availability of certificate.

The validity of the certification and uncertainty data, including conformance to key procedures with ISO guide 35 and other ISO requirements.

Track record of both the producer and the material. For example, when an RM in use has been subjected to an inter-laboratory comparison, cross-checked by the use of different methods, or there is experience of use in a number of laboratories over a period of years. Availability of a certificate and report conforming to ISO guide 31.

All or some of the requirements may be specified in the customer and analytical specification, but often it will be necessary for the analyst to use professional judgement. Finally, quality does not necessarily equate to small uncertainty and fitness-for-purpose criteria need to be used [2.21].

Certificates and Supporting Reports. Ideally, a certificate complying with ISO guide 31 and a report covering the characterisation, certification and statistical analysis procedures, complying with ISO guide 35, will be available. However, many RM, particularly older materials and materials not specifically produced as RM, may not fully comply with ISO guides 31 and 35. Alternative, equivalent information in whatever form available and that provides credible evidence of compliance can be considered acceptable. Examples include the following: technical reports, trade specifications, papers in journals or reports of scientific meetings and correspondence with suppliers.

Assessment of the Suitability of Reference Materials. Laboratories must be able to explain and justify the basis of selection of all RMs and of course any decision not to use an RM. In the absence of specific information it is not possible to assess the quality of an RM. The rigour with which an assessment needs to be conducted depends on the criticality of the measurement, the level of the technical requirement and the expected influence of the particular RM on the validity of the measurement. Only where the choice of RM can be expected to affect measurement results significantly is a formal suitability assessment required.

Requirements of ISO/IEC 17025 on Laboratories Measurement Traceability (§ 5.6 of ISO/IEC 17025) General (§ 5.6.1). All equipment used for tests and/or calibrations, including equipment for subsidiary measurements (e.g. for environmental conditions) having a significant effect on the accuracy or validity of the result of the test, calibration or sampling shall be calibrated before being put into service. The laboratory shall have an established programme and procedure for the calibration of its equipment.

Note that such a programme should include a system for selecting, using, calibrating, checking, controlling and maintaining measurement standards, reference materials used as measurement standards, and measuring and testing equipment used to perform tests and calibrations.

Specific Requirements (§ 5.6.2) Calibration (§ 5.6.2.1).

- § 5.6.2.1.1. For calibration laboratories, the programme for calibration of equipment shall be designed and operated so as to ensure that calibrations and measurements made by the laboratory are traceable to the International System of Units [système international d'unités (SI)].
- § 5.6.2.1.2. There are certain calibrations that currently cannot be strictly made in SI units. In these cases calibration shall provide confidence in measurements by establishing traceability to appropriate measurement standards such as: the use of certified reference materials provided by a competent supplier to give a reliable physical or chemical characterisation of a material; the use of specified methods and/or consensus standards that are clearly described and agreed by all parties concerned. Participation in a suitable programme of inter-laboratory comparisons is required where possible.

Testing (§ 5.6.2.2).

- § 5.6.2.2.1. For testing laboratories, the requirements given in § 5.6.2.1 apply for measuring and test equipment with measuring functions used, unless it has been established that the associated contribution from the calibration contributes little to the total uncertainty of the test result. When this situation arises, the laboratory shall ensure that the equipment used can provide the uncertainty of measurement needed. Note that the extent to which the requirements in § 5.6.2.1 should be followed depends on the relative contribution of the calibration uncertainty to the total uncertainty. If calibration is the dominant factor, the requirements should be strictly followed.

- § 5.6.2.2.2. Where traceability of measurements to SI units is not possible and/or not relevant, the same requirements for traceability to, for example, certified reference materials, agreed methods and/or consensus standards, are required as for calibration laboratories (see § 5.6.2.1.2). (e.g. breath alcohol, pH-value, ozone of air)

Reference Standards and Reference Materials (§ 5.6.3).

- Reference standards (§ 5.6.3.1). The laboratory shall have a programme and procedure for the calibration of its reference standards. Reference standards shall be calibrated by a body that can provide traceability as described in § 5.6.2.1. Such reference standards of measurement held by the laboratory shall be used for calibration only and for no other purpose, unless it can be shown that their performance as reference standards would not be invalidated. Reference standards shall be calibrated before and after any adjustment.
- Reference materials (§ 5.6.3.2). Reference materials shall, where possible, be traceable to SI units of measurement, or to certified reference materials. Internal reference materials shall be checked as far as is technically and economically practicable.

Assuring the Quality of Test and Calibration Results (§ 5.9 of ISO/IEC 17025). The laboratory shall have quality control procedures for monitoring the validity of tests and calibrations undertaken. The resulting data shall be recorded in such a way that trends are detectable and, where practicable, statistical techniques shall be applied to the reviewing of the results. This monitoring shall be planned and reviewed and may include, but not be limited to, the following:

1. Regular use of certified reference materials and/or internal quality control using secondary reference materials;
2. Participation in inter-laboratory comparison or proficiency testing programmes;
3. Replicate tests or calibrations using the same or different methods;
4. Retesting or recalibration of retained items; correlation of results for different characteristics of an item.

Note that the selected methods should be appropriate for the type and volume of the work undertaken.

Application Modes

Method Validation and Measurement Uncertainty. Estimation of bias (the difference between the meas-

ured value and the true value) is one of the most difficult elements of method validation, but appropriate RMs can provide valuable information, within the limits of the uncertainty of the RM certified value(s) and the uncertainty of the method being validated. Although traceable certified values are highly desirable, the estimation of bias differences between two or more methods can be established by use of less rigorously certified RM. Clearly the RM must be within the scope of the method in terms of matrix type, analyte concentration etc. and ideally a number of RM covering the full range of the method should be tested. Where minor modifications to a well-established method are being evaluated then less-rigorous bias studies can be employed.

Replicate measurement of the RM, covering the full range of variables permitted by the method being validated, can be used to estimate the uncertainty associated with any bias, which should normally be corrected for.

The uncertainty associated with an RM should be no greater than one third of that of the sample measurement [2,20,34].

Verification of the Correct Use of a Method. The successful application of a valid method depends on its correct use, both with regard to operator skill and suitability of equipment, reagents and standards. RM can be used for training, for checking infrequently used methods and for trouble-shooting when unexpected results are obtained.

Calibration. Normally a pure substance RM is used for calibration of the measurement stage of a method. Other components of the test method, such as sample digestion, separation and derivatisation are, of course, not covered and loss of analyte, contamination and interferences and their associated uncertainties must be addressed as part of the validation of the method. The uncertainty associated with RM purity will contribute to the total uncertainty of the measurement. For example, an RM certified as 99.9% pure, with an expanded uncertainty $U(k=2)$ of 0.1% will contribute an uncertainty component of 0.1% to the overall measurement uncertainty budget. In the case of trace analysis, this level of uncertainty will rarely be important, but for assay work, it can be expected to be significant.

Some other methods, such as X-ray-fluorescence (XRF) analysis, use matrix RM for calibration of the complete analytical process. In addition to a close matrix match, the analyte form must be the same in the samples and RM, and the analytical concentrations of the RM must span that of the samples.

ISO guide 32 provides additional useful information.

Quality Control and Quality Assurance (QC and QA). RM should be characterised with respect to homogeneity, stability, and the certified property value(s). For in-house QC, however, the latter requirement can be relaxed, but adequate homogeneity and stability are essential. Similar requirements apply to samples used to establish how well or badly measurements made in different laboratories agree. In the case of proficiency testing, homogeneity is essential and sample stability within the time scale of the exercise must be assessed and controlled. Although desirable, the cost of certifying the property values of proficiency testing samples often prohibits this being done and consensus mean values are often used instead. As a consequence, there often remains some doubt concerning the reliability of assigned values used in proficiency testing schemes. This is because, although the consensus mean of a set of data has value, the *majority* is not necessarily correct and as a consequence the values carry some undisclosed element of uncertainty. The interpretation of proficiency testing data thus needs to be carried out with caution.

Errors and Problems of RM – use Election of RM.

- certificate not known,
- certificate not complete,
- required uncertainty unknown,
- contribution of calibration to total uncertainty of measurement unknown,
- wrong matrix simulation,
- precision of measurement higher than precision of certification of RM,
- no need for a certified RM.

Handling of RM.

- amount of RM too small,
- stability date exceeded,
- wrong preparation of in-house RM,
- wrong preparation of the sample,
- matrix of sample and RM differ too much.

Assessment of values.

- wrong correction of matrix effect,
- use of incorrect quantities (e.g., molality for unspecified analyte),
- uncertainty budget wrong.

2.6.6 Activities of International Organisations

Standardisation Bodies

ISO. The International Organisation for Standardisation (ISO) is a worldwide federation of national standards bodies from some 130 countries. The scope of the ISO covers standardisation in all fields except electrical and electronic standards, which are the responsibility of the IEC (see below).

IEC. The International Electrotechnical Commission (IEC), together with the ISO form a specialised system for worldwide standardisation – the world's largest nongovernmental system for voluntary industrial and technical collaboration at the international level.

ISO REMCO. REMCO is ISO's committee on reference materials, responsible to the ISO technical management board [2.35]. The objectives of REMCO are:

- to establish definitions, categories, levels and classification of reference materials for use by ISO.
- to determine the structure of related forms of reference materials.
- to formulate criteria for choosing sources for mention in ISO documents (including legal aspects).
- to prepare guidelines for technical committee for making reference to reference materials in ISO documents.
- to propose, as far as necessary, action to be taken on reference materials required for ISO work.
- to deal with matters within the competence of the committee, in relation with other international organisations and to advise the technical management board on action to be taken.

ASTM. The American Society for Testing and Materials (ASTM) is the US standardisation body with international activities. The committees of the ASTM are also involved in determine reference materials, providing cross-media standards and working in other associated fields.

Accreditation Bodies

ILAC. International Laboratory Accreditation Cooperation (ILAC) and the International Accreditation Forum (IAF) are international associations of national and regional accreditation bodies. ILAC develops guides for production, selection and use of reference materials.

EA. The European Co-operation for Accreditation (EA) is the regional organisation for Europe. EA is directly contributing to the international advisory group on reference materials.

Metrology Organisations

BIPM. In 1875, a diplomatic conference on the metre took place in Paris where 17 governments signed a treaty (*The Metre Convention*). The signatories decided to create and finance a scientific and permanent institute, the Bureau International des Poids et Mesures (BIPM).

CIPM. The Comité Internationale des Poids et Mesures (CIPM) supervises the BIPM and supplies chairmen for the consultative committees.

CCQM. The consultative committee for amount of substance (CCQM) is a subcommittee of the CIPM. It is responsible for international standards in chemical measurements, including reference materials.

OIML. The International Organisation of Legal Metrology (OIML) was established in 1955 on the basis of a convention in order to promote the global harmonisation of legal metrology procedures. OIML collaborates with the Metre Convention and BIPM on the international harmonisation of legal metrology.

User Organisations (Users of RM)

EUROLAB. The European Federation of national Associations of Measurement, Testing and Analytical Laboratories (EUROLAB) promotes cost-effective services, for which the accuracy and quality assurance requirements should be adjusted to actual needs. EUROLAB contributes to the international advisory group on reference materials.

EURACHEM. The European Federation of national Associations of analytical laboratories (EURACHEM) promotes quality assurance and traceability in chemical analysis. EURACHEM also contributes to the international advisory group on reference materials.

CITAC. The Cooperation for International Traceability in Analytical Chemistry (CITAC), a federation of

international organisations, coordinates activities of international comparability of analytical results, including reference materials.

IAGRM. The international advisory group on reference materials (IAGRM) is the successor of the 4E/RM group (selection and use of reference materials). It coordinates activities of users, producers and accreditation bodies in the field of reference materials. IAGRM published guides and policy papers. Presently the accreditation of reference materials producers according to ISO guide 34 is being discussed.

AOAC International. The Association of Official Analytical Chemists (AOAC) International also has a reference materials committee to develop RM for analytical chemistry.

IFCC. The International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) develops concepts for reference procedures and reference materials for standardisation and traceability in laboratory medicine.

Pharmacopeia. Pharmacopeia (European and USP (United States (of America) Pharmacopeia)) provides analyst and researchers from the pharmaceutical industry and institutes with written standards and certified reference materials.

Codex Alimentarius Commission. This commission of the Food and Agriculture Organisation (FAO) of the United Nations and the World Health Organisation (WHO) deals with safety and quality in food analysis, including reference materials.

ENFSI. The Network of Forensic Science Institutes (ENFSI) recommends standards and reference materials for forensic analysis.

BCR. The Bureau Communautaire de Référence (BCR) of the European Commission has, since 1973, set up programs for the development of reference materials needed for European directives. The Institute of Reference Materials and Measurement (IRMM) in Geel is responsible for distribution.

2.7 Reference Procedures

2.7.1 Framework: Traceability and Reference Values

Establishing *traceability* of measurement results (Sect. 2.2) is a shared activity. A laboratory performing measurements of materials properties has to:

- identify all the laboratory references that are relevant for a given result, e.g. *specify the working standard used for calibrating the measuring system*,
- specify the relationship between the result and any laboratory reference used, e.g. *specify how the value of the working standard is used in a correction*,
- ensure that all those laboratory references are fit for purpose, e.g. *check the calibration status and the uncertainty of the working standard*.

As a complementary activity, the provider of a laboratory reference (e.g. *a calibration laboratory, performing calibration of working standards against reference standards*) has to:

- ensure that the specification of the laboratory reference is valid, e.g. *operate a quality control program for the calibration of working standards*,
- establish traceability of the laboratory reference to a primary reference, e.g. *ensure traceability of the reference standard used for calibrating working standards against a primary standard*.

Laboratory references are by no means restricted to measurement standards used for calibration, reference materials used for bias investigation and the like. Rather than relating measurement results to devices or materials, traceability relates measurement results to *reference values*, which may be associated with devices or materials but may also be of other origin. They include any data except for those generated in the measurement process and subsidiary measurements (e.g. for control of environmental conditions) which are utilised explicitly or implicitly in any stage of the measurement process, from preparation of measuring objects to data evaluation, and whose values are taken for granted.

Traceability relates measurement results to reference values.

Having raised the issue of a reference value, here are two current definitions.

- Definition 1: Quantity value, generally accepted as having a suitably small measurement uncertainty, to be used as a basis for comparison with values of quantities of the same kind. (VIM, draft revision April 2004 [2.36])
- Definition 2: Value of a characteristic of a specified material or product that has been determined with an accuracy fit for use as a source of traceability for test results obtained on comparable materials or products. (Eurolab document 2004 [2.37])

While originating from different fields – metrology and testing – these definitions are in fact very close, with complete agreement concerning the basic requirement: the uncertainty of reference values must be known and fit for the intended use. Given this, the relevance of reference values with regard to the accuracy of specified measurements may be assessed as follows: a reference value is relevant to a measurement result, if the uncertainty associated with the reference value contributes significantly to the overall uncertainty of the measurement result.

Reference values need specified uncertainties!

Depending on the type of material and the property under consideration, there are three basic sources of reference values for materials properties: *reference data compilations*, *reference materials* (Sect. 2.5) and *reference procedures*.

- For
 - well-defined and commonly available materials (e.g. pure copper), and
 - well-investigated quantities (e.g. thermophysical)
 reference values may be taken from a recognised reference data compilation.
- For
 - certified reference materials (e.g. a copper alloy CRM CuZn37), and
 - certified properties (e.g. the mass fraction of Nickel)
 reference values may be taken from the certificate of the reference material.
- For
 - real-life materials (e.g. a sample from a batch of raw copper), and
 - well-defined quantities (for the purpose at hand)

reference values may be measured using a reference procedure, if available.

As a remark in passing, uncertainty statements in reference data compilations are generally poor. Strategies for improving the situation are:

- *New measurements* – Example: in the framework of a Japanese national project [2.38] new measurements were made on thermophysical property data of key industrial materials to generate reference data with state-of-the-art uncertainty.
- *Reevaluation of original measurements* – Example: for an international standardisation project [2.39], publications on measurements of virial coefficients of pure gases were reevaluated to estimate the uncertainty of virial coefficient data used in a previous standard.

2.7.2 Terminology: Concepts and Definitions

Unlike for reference materials (Sect. 2.5), there are currently no internationally harmonised terminology, fundamental concepts and basic requirements for reference measurements. Before reviewing current concepts and definitions for the notion of a reference procedure, there is an obvious question to address first: why use the term procedure instead of the more common term method?

Method – procedure: according to current perception, a measurement method provides a generic description of measurements, specifying the kind of

equipment to be used, the kind of measuring objects and a sequence of operations, while a measurement procedure provides a detailed description of how to actually carry out measurements according to a given method using specified equipment on specified measuring objects. This distinction is not yet part of standard terminology and is often disregarded even in current publications.

Method – procedure: a subtle but important difference!

In the scientific/technical literature various different definitions of the term reference procedure are in use, falling into three main categories as follows:

1. Measurement procedure with established high quality of results, which can be used for the assessment of other measurement procedures; *... results obtained using the procedure (proper implementation and validation assumed) serve as a benchmark for alternative procedures.*
2. Measurement procedures defining a quantity subject to measurement; *... the property under consideration is in fact defined by the procedure.*
3. Measurement procedure prescribed by legal regulations for specific measurements; *... to obtain valid results for regulatory purposes, the procedure must be used.*

In the last decade approach (1) has clearly become the dominant concept, and in this section the term reference procedure is used in this sense. Below are three definitions with international scope [2.20, 40, 41].

Reference procedure	Reference measurement procedure	Reference method
Procedure of testing, measurement or analysis, thoroughly characterised and proven to be under control, intended for quality assessment of other procedures for comparable tasks, or characterisation of reference materials including reference objects, or determination of reference values. The uncertainty of the results of a reference procedure must be adequately estimated and appropriate for the intended use. (Euromet Guide [6])	Thoroughly investigated measurement procedure shown to have an uncertainty of measurement commensurate with the intended use, especially in assessing the trueness of other measurement procedures for the same quantity and in characterising reference materials. (ISO 15195 [12])	Thoroughly investigated method, clearly and exactly describing the necessary conditions and procedures, for the measurement of one or more property values that has been shown to have accuracy and precision commensurate with its intended use and that can therefore be used to assess the accuracy of other methods for the same measurement, particular in permitting the characterisation of a reference material. (ISO Guide 30 [13])

Irrespectively of their widely different origins – metrology, laboratory medicine and reference materials – these definitions are very close and agree completely with respect to scope and requirements.

The term “reference procedure” has a wide range of connotations.

Obviously the term reference procedure applies equally to measurement, testing and chemical analysis, i. e. all procedures for determining quantitative properties of materials, but the concept may also be extended to other fields:

Qualitative testing, i. e. determination of qualitative properties: qualitative properties are expressed by membership to one of several specified classes, and the uncertainty of a qualitative test result is an estimate of the probability that the result is incorrect.

Preparation of reference materials or reference objects: for example, the gravimetric preparation of mixtures of pure substances as reference materials of chemical composition, or the preparation of reference defects by spark erosion on metal specimens to be used as reference objects for nondestructive testing of pressure vessels.

Procedures for data evaluation: for example, uncertainty propagation, i. e. the calculation of combined standard uncertainty according to the GUM, is based on approximations that may not always be valid in practice. In case of doubt, Monte Carlo simulation may be used as a reference procedure to investigate whether uncertainty propagation is valid [2.42].

According to the definitions above, reference procedures for materials measurements can be used to

- Validate (or calibrate) other measurement procedures that are used for a similar task and to determine their uncertainty;
- Determine reference values for material properties that are embodied by a reference material or a reference object;
- Determine reference data of materials properties for reference data compilations.

Another application of reference procedures could be measurements as the basis for important decisions, e.g. for authoritative evidence.

It should be noted that there are a number of alternative terms with a similar meaning. The term *primary method of measurement* has been developed for use in the Consultative Committee for Amount of Substance (CCQM), i. e. the international committee of the Meter

Convention for metrology in chemistry. The term *definitive method* originates from the International Union of Pure and Applied Chemistry (IUPAC).

Primary Method of Measurement

A method having the highest metrological qualities, whose operation can be completely described and understood, and for which a complete uncertainty statement can be written down in terms of SI units (*Milton & Quinn*) [2.43].

Definitive Method of Measurement

A method of exceptional scientific status that is sufficiently accurate to stand alone in the determination of a given property for the certification of a reference material. Such a method must have a firm theoretical foundation so that systematic error is negligible relative to the intended use. The property values must be measured directly in terms of the base units of measurement, or indirectly related through sound theoretical equations (adapted from IUPAC [2.44]).

2.7.3 Requirements: Measurement Uncertainty, Traceability and Acceptance

The definition of a reference procedure presumes the existence of several procedures for a specified task. Given this, a reference procedure is qualified by the uncertainty of results that are proven to be fit for the purpose of providing reference values of the property under consideration.

Before addressing requirements for measurement quality, the basic condition that the procedure be one among several procedures for the same task requires a second thought. For measurement of *rationaly defined properties*, i. e. properties that are defined independently of the method of measurement, the concept is clear. There is a variety of measurement techniques available, and a reference procedure implements the best available technique, i. e. that with the capability of providing the most reliable results with the best available uncertainty.

Reference procedures for operationally defined properties?

However, the concept is also applicable to operationally defined properties, i. e. properties that are (to a significant degree) defined by a particular measurement method, often specified in a standard. In this case a reference procedure is a *reference implementation* of the

defining measurement method, used to provide reference values for benchmarking *routine implementations*.

The scope of reference procedures implies a number of key requirements, concerning *measurement uncertainty*, *measurement traceability* and *acceptance*, as follows. In addition to these, measurement quality control must be designed and executed at an appropriate level that is commensurate with provision of reliable reference values.

1. *The uncertainty of measurement results must be known.* The uncertainty of measurement is evaluated and specified in accordance with the GUM [2.45]. This entails that the uncertainty attributed to a measurement result accounts for all significant sources of uncertainty, and that every effort is taken to ensure that there is no significant residual bias that could compromise measurement results. The uncertainty of measurement may be evaluated using any of the following approaches or combinations thereof:
 - Propagation of input uncertainties, based on a detailed mathematical model of the measurement process, as specified in the GUM [2.45];
 - Utilising data from inter-laboratory method-validation studies according to ISO 5725 [2.46];
 - Utilising data from within-laboratory method-validation studies [2.47].
2. *The validity of the uncertainty claim must be demonstrated by inter-laboratory comparisons.* Comparison with results obtained by other proficient laboratories, preferably using reference procedures based on independent measurement techniques, is generally accepted as the best way to challenge the uncertainty claimed for the results of a reference procedure. Agreement is taken to support the claim. Disagreement requires further action to identify the reason, e.g. underestimation of the uncertainty or significant bias not detected so far. As a recent example, the so-called key comparisons (KC) provide the basis for the acceptance of calibration and measurement capability (CMC) claims of national metrology institutes in the various peer reviews prior to publication; see Sect. 2.7.6.
3. *The uncertainty of measurements results must be commensurate with their intended use as reference values.* The traditional policy concerning the use of reference values, e.g. in calibration, has been: the uncertainty of reference values (e.g. the uncertainty of a reference standard used to calibrate working standards) should be negligible compared with the target uncertainty of the result under consideration (e.g. the

uncertainty of a working standard) and must not exceed 1/3 of that target uncertainty. The rationale for this requirement is unknown to the author but, as a conjecture, the driver behind this requirement may have been the lack of techniques for the statistical evaluation of data with specified uncertainty, e.g. least-squares regression with uncertainties in the independent variable. When using techniques designed for data without uncertainty on data with an associated uncertainty, one has to make sure that they still give valid results. To this end, the uncertainty associated with the data has to be negligible against the relevant statistical variability. Similarly the 1:3 rule mentioned above may be justified using the root-sum-of-squares addition of standard uncertainties:

$$\sqrt{u^2 + (u/3)^2} = \sqrt{1.11u^2} = 1.05u \approx u.$$

Fitness for purpose concerning requirements on measurement uncertainty.

Given appropriate techniques for uncertainty-based data evaluation, there is no need to require that the uncertainty of reference values be negligible. Instead, their contribution to the uncertainty of the final result may be determined, and limits on the uncertainty of reference values may be derived from target uncertainties.

4. *Measurement results must be traceable to recognised references.* Reference values constitute the endpoint of within-laboratory traceability chains. Unless a reference value happens to be a primary reference that is recognised by the relevant community, its traceability to an appropriate higher-level reference value has to be established. Reference measurements carried out by national metrology institutes according to measurement capabilities specified in the BIPM data base (Sect. 2.7.6) are internationally recognised as providing traceability to SI units. Traceability of reference values embodied by certified reference materials (CRM) is currently under debate in various fora, concerning technical issues such as the traceability of consensus values from inter-laboratory certification studies and quality management issues such as third-party assessments of CRM quality and accreditation of CRM producers. The BIPM database contains a number of entries for CRMs provided by national metrology institutes, which may therefore be utilised as internationally recognised sources of traceability.

5. *Reference procedures must be accepted as such by the relevant target groups.* Reference procedures have the potential to stand alone in the provision of reference values for the property in question. Reference procedures are qualified as such in a validation study, where the performance of the procedure is investigated in appropriate detail, and the values of the relevant performance characteristics – in particular measurement uncertainty – are determined. However, as an equally important requirement, the relevant target groups have to be convinced of the merits of a candidate reference procedure before it can be used as such. These target groups will normally include customers of reference measurements, laboratories, research institutes and technical associations in the respective field, but may also involve accreditation bodies and regulators. Results of appropriate inter-laboratory comparisons will normally be the most convincing arguments in favour of a newly proposed reference procedure.

2.7.4 Applications for Reference and Routine Laboratories

Developing and maintaining a reference procedure often requires significant effort, money and manpower, and the costs for operating a reference procedure are often significantly higher than for other procedures for the same task. Therefore reference procedures are most often operated by reference laboratories (see Appendix), e.g. for the provision of reference measurement services, the determination of reference data and the characterisation of reference materials or reference objects. However, it may also be profitable for laboratories engaged in routine measurement and testing to operate a reference procedure for dedicated tasks such as validation or calibration of routine procedures.

The key qualification of reference procedures is their potential to stand alone in the determination of reference values for the property in question. This is due to

- the high capability of the particular measurement technology, with respect to trueness (absence of bias), precision, robustness to interfering effects (measuring conditions and measuring objects), and
- the high level of performance evaluation, in particular concerning measurement uncertainty, and ongoing internal and external quality control for the reference procedure developed using this technology.

The main fields of application for reference procedures were already mentioned in the various definitions (Sect. 2.7.2):

Euromet Guide [2.40]:

- Quality assessment of other procedures for comparable tasks,
- Characterisation of materials, including reference objects,
- Determination of reference values.

ISO 15195 [2.41]:

- Assessing the trueness of other measurements procedures for the same quantity,
- Characterising reference materials.

ISO Guide 30 [2.48]:

- Assessing the accuracy of other methods for the same measurement,
- Characterisation of a reference material.

Reference Data

Determination of reference data for materials property databases is a typical reference laboratory activity, requiring reference procedures with established uncertainty and traceability of measurement, and an appropriate level of measurement quality control.

Reference Measurements

An increasingly important application of reference procedures is the provision of reference values for proficiency testing samples or specimens, as an activity for a single reference laboratory or a small group of reference laboratories. Utilising traceable reference values with specified uncertainty as the target values in proficiency tests (PT) has the advantage of providing information to the participants about their level of measurement bias while PTs using a consensus value of the participants results only provide information about their comparability.

Reference values for proficiency testing: a key application field.

The International Measurement Evaluation Programme (IMEP) of the IRMM, *Geel* [2.46] is a prominent example of a proficiency test utilising reference values. Recently, provision of reference values for PT samples or specimens has become a major activity for national metrology institutes for the dissemination of their measurement capabilities (Sect. 2.7.6).

Reference Materials

Reference materials are often characterised in inter-laboratory studies that include a major number of expert laboratories utilising a broad range of different measurement techniques. Alternative approaches include a small group of reference laboratories, or even a single reference laboratory, utilising appropriate reference procedures as follows:

- Stand-alone determination of the property value under consideration in a single laboratory, utilising an appropriate reference procedure, with check measurements using an independent method as a safeguard against blunders. In the chemistry field, this approach is often advocated by national metrology institutes, using primary methods of measurement such as isotope-dilution mass spectrometry.
- Collaborative determination, in a single laboratory using several independent reference procedures or several laboratories, using a reference procedure each. Given agreement within uncertainty limits, the results are combined into a mean value and an associated uncertainty.

Further information on strategies and procedures for the characterisation of reference materials is given in Sect. 2.6.

Validation of Routine Procedures

As another major field of application, reference procedures may be used to validate routine procedures for the same task. Similarly, routine procedures may be calibrated against reference procedures for the same task. To this end, measurements using the routine procedure and the reference procedure are carried out in parallel on appropriate samples or specimens, and the results are compared. The great benefit of this approach is that real-life samples may be used, thus avoiding the problem of mismatch between calibrants and measuring objects, which is often encountered using reference materials.

Validation and calibration of routine procedures: an alternative to the use of reference materials.

When validating a routine procedure against a reference procedure, the task is to investigate whether the results of the routine procedure agree with those of the reference procedure. For this purpose, measurements using both procedures are carried out on a series of samples or specimens S_1, S_2, \dots, S_N with varying values of the property under consideration, yielding paired results

$(y_1, x_1), (y_2, x_2), \dots, (y_N, x_N)$. These data are examined to see whether they are compatible with a straight line $y = x$. To this end, a straight line $y_i = ax_i + b$ is fitted to the calibration data (y_i, x_i) using e.g. the method of least squares, and the joint confidence region for the slope a and the intercept b is determined. If this confidence region contains the point $(a = 1, b = 0)$, the test is positive, i.e. the results obtained using the routine procedure and reference procedure are compatible with a straight line $y = x$. This means that the routine procedure is not significantly biased against the reference procedure, thus both procedures measure the same quantity – although most often with different uncertainties.

Calibration of Routine Procedures

Calibration of a routine procedure against a reference procedure makes use of the same experimental design, with a slightly different task: the measurement results are utilised to derive a correction for the results of the routine procedure, and to evaluate the uncertainty for the corrected results.

Often calibration is performed for a narrow measuring range, using a single sample or specimen S . With x_S denoting the result of the reference procedure and y_S that of the routine procedure, the difference $\Delta_S = y_S - x_S$ may be utilised to correct the results obtained using the routine procedure on similar samples or specimens according to $y_{\text{corr}} = y_{\text{meas}} - \Delta_S$. The uncertainty of the corrected result can be calculated by combining the precision of the routine procedure and the uncertainty associated with the correction. The latter uncertainty includes the measurement uncertainty of the reference procedure.

For extended measuring ranges calibration often requires parallel measurement of several samples or specimens S_1, S_2, \dots, S_N . The results are used to derive a correction curve, e.g. by way of fitting a straight line $y_i = ax_i + b$ to the calibration data (y_i, x_i) and subsequent inversion according to $y_{\text{corr}} = (y_{\text{meas}} - a)/b$. The uncertainty of the corrected results may be calculated from the precision of the routine procedure and the uncertainty associated with the parameters of the calibration line. The latter uncertainty includes contributions from the measurement uncertainty of the reference procedure.

The approach outlined above is also applicable to another type of calibration, where, instead of a correction, the input/output behaviour of a measuring system is determined. Here the task is to establish the relationship between the target quantity and the response (output) of the measuring system, e.g. temperature and current

in case of a thermoelement. To this end, measurements using the procedure subject to calibration and the reference procedure are carried out in parallel on appropriate samples or specimens. A calibration curve is fitted to the calibration data, and this is used to convert measured responses into values of the target quantity. Again the advantage of using a reference procedure instead of reference materials or reference objects is that calibration can be carried out on real-life samples or specimens.

2.7.5 Presentation: Template for Reference Procedures

When dealing with a range of measurement or test procedures, it is useful to have the most important characteristics presented in a standard format. Most often

these standards are sector specific, as e.g. ISO 78-2 [2.49], which specifies the presentation of procedures for chemical analysis. A generic template for the presentation of reference procedures was developed at the Federal Institute for Materials Research and Testing (BAM), Germany and is utilised in their catalogue [2.50].

BAM Catalogue of reference procedures.

According to this template, reference measurement procedures are presented as follows:

- *Title* – the title of the procedure.
- *Key words* – key words for the procedure.

X-ray Photoelectron Spectroscopy for Chemical Analysis of Surfaces (ESCA / XPS): Precise Determination of Binding Energies on Non-conducting Samples			
Key words			
Binding energy, ESCA, surface, chemical analysis, gold particle			
Quantities and items tested			
Binding energies of photoelectrons in non-conducting samples			
Testing range		Uncertainty of results	
0 eV to 1040 eV		from 0.3 eV	to 1.0 eV
Fields of application			
Quality assessment of other procedures for the determination of photoelectron binding energies of non-conducting samples. Determination of reference values of binding energies for users of the ESCA method in surface analysis laboratories.			
Methodology and instrumentation			
Determination of the static charge by using the Au 4f 7/2 photoemission signal of nm gold particles as a reference. With the help of the static charge value the ESCA spectrum is corrected. The identification of chemical species is now possible. The binding energy of the Au 4f 7/2 photoemission signal is given by ISO 15472. Traceability of ESCA measurements is possible by using this method.			
Qualification and quality assurance			
Traceability to SI units, Organisation of inter-laboratory tests. Participation in inter-laboratory tests. The uncertainty of results was determined by a world-wide inter-laboratory test launched under the auspices of the Versailles Project on Advanced Materials and Standards (VAMAS).

Fig. 2.12 Example for the presentation of a reference procedure

- *Quantities and items measured* – the quantities measured, the kind of objects that can be investigated and important measuring conditions.
- *Measuring range and uncertainty of measurement* – the range of values, i. e. the working range as a reference procedure, for each quantity measured, and an associated uncertainty range. Uncertainty of measurement is an expanded uncertainty according to the GUM [2.45] for an approximate confidence level of 0.95 (coverage factor $k = 2$), expressed as a relative uncertainty in % or as an absolute uncertainty in units of the quantity measured. For expressing an uncertainty range, different conventions may be used:
 - referring to the lower and upper limit of the measuring range, respectively, or
 - specifying best-case and worst-case uncertainty.
- *Fields of application* – the kind of tasks for which the procedure is currently in use, or may be utilised as a reference: quality assessment of other procedures, characterisation of reference materials and objects, determination of reference values and other high-level tasks.
- *Methodology and instrumentation* – the method of measurement and essentials of the measuring system.
- *Qualification and quality assurance* – supporting evidence for the critical figures of merit, in particular measurement uncertainty (e.g. successful participation in inter-laboratory comparisons), and efforts taken for measurement quality control.
- *Further information* – free-style presentation of additional information, in particular including pictures, diagrams and references.

This template is also applicable to reference procedures for testing, even in cases of qualitative characteristics. Figure 2.12 shows an example taken from the BAM catalogue [2.50].

2.7.6 International Networks: CIPM and VAMAS

One of the main services of national metrology institutes is to calibrate reference standards against national standards. Typically, these calibrations are performed by reference measurements, i. e. measurements using reference procedures of measurement.

On 14 October 1999 a multilateral agreement (the so-called **CIPM MRA**) was signed in Paris between 38 member states of the Meter Convention as well as two international organisations (the IAEA and IRMM).

This agreement had been drawn up by the International Committee of Weights and Measures (**CIPM**), its subject being the mutual recognition of national measurement standards and of the calibration and measurement certificates issued by national metrology institutes. The mutual recognition of the national traceability systems is to create a secure technical foundation for wider agreements in international trade, commerce and regulatory affairs.

This mutual recognition is far more than a formal act. The national measurement institutes concerned have to prove their competence and the reliability of their results in international intercomparisons – so-called key comparisons (**KC**) – and must operate an appropriate quality management system. For maximum transparency the results of these intercomparisons are published with free access on the Internet [2.51] by the International Office of Weights and Measures (**BIPM**) in Paris. In addition, the BIPM publishes another (freely accessible) Internet database [2.52] specifying the reference measurement services of the national metrology institutes – the so-called calibration and measurement capabilities (**CMC**).

BIPM data bases for intercomparisons and reference measurements.

These activities take place in close cooperation with the national metrology institutes and related designated institutes in the respective committees of the **CIPM**, the so-called consultative committees (**CCs**), one associated with each base quantity of the SI. Further information on the Meter Convention and the BIPM is given in Sect. 1.3.

Currently the **CMC** database contains some 18,000 entries, specifying reference measurement procedures of the national metrology institutes and designated institutes for various metrology areas:

- *Acoustics, ultrasound and vibration*;
- *Electricity and magnetism*, including direct-current (**DC**) and alternating-current (**AC**) measurements, impedance, electric and magnetic fields, radio frequencies and measurements on materials;
- *Length*, including laser frequencies and dimensional metrology;
- *Mass and related quantities*, including mass standards, force, pressure, density, hardness, torque, gravity, viscosity and fluid flow;
- *Photometry and radiometry*, including fibre optics and properties of detectors, sources and materials;
- *Amount of substance*, including high-purity chemicals, inorganic solutions, organic solutions, gases, water, metals and metal alloys, advanced mater-

ials, biological materials, food, fuels, sediments, soils, ores and particulates, other materials, pH, electrolytic conductivity;

- *Ionising radiation*, including dosimetry, radioactivity and neutron measurements;
- *Thermometry*, including temperature, humidity and thermophysical quantities;
- *Time and frequency*.

In several of these CMC directories, entries for reference measurements of materials properties can be found. However, the reference procedures for materials measurements are a long way from covering the needs of materials metrology. Therefore an initiative was recently taken by some of the leading national materials research institutes towards the International Committee of Weights and Measures, proposing to consider dedicated activities in the field of materials metrology.

A well-known international network for materials research and technology is the Versailles project on advanced materials and standards(VAMAS). VAMAS was founded in 1985, as a follow-up action from a G7 economic summit in Versailles, to provide a framework for international collaboration on pre-standardisation materials research, with scope to provide a technical basis for agreement on methodologies prior to the formal development of standards.

The Versailles Project on Advanced Materials and Standards.

The main objective of VAMAS is to support trade in high-technology products through international collaborative projects aimed at providing the technical basis for drafting codes of practice and specifications for advanced materials. The scope of the collaboration embraces all agreed aspects of science and technology concerned with advanced materials including materials technology, test methods, design methods and materials

data bases that are required as a precursor to the drafting of standards.

Current member countries are Canada, France, Germany, Italy, Japan, United Kingdom, USA and also the EC, but VAMAS is open to organisations from other countries to participate in research activities.

Technical work is done in various working groups, the so-called technical work areas (TWA), of which there are 19 currently:

- Wear test methods
- Surface chemical analysis
- Ceramics for structural applications
- Polymer composites
- Computerised materials data
- Low-cycle fatigue
- Metal–matrix composites
- Superconducting materials
- Cryogenic structural materials
- Statistical techniques for inter-laboratory studies
- Measurement of residual stress
- Mechanical measurements for hardmetals
- Mechanical property measurement of thin films and coatings
- Performance-related properties for electroceramics
- Creep/fatigue crack growth in components
- Full-field optical stress and strain measurement
- Characterisation methods for ceramic powders and green bodies
- Quantitative mass spectrometry of synthetic polymers
- Materials properties at the nanoscale

Currently VAMAS are considering the need of, and options for activities on materials metrology, covering collaborative studies for the validation of reference test procedures. Further information about VAMAS activities may be obtained from the VAMAS web site [2.53].

Reference (testing) laboratory	Reference measurement laboratory	Reference laboratory
Testing laboratory providing, by arrangement with a specified laboratory community in a specified technical field, reference values for use as references or sources of traceability of test results, whose quality is fit for this use. (Eurolab document 2004 [5])	Laboratory that performs a reference measurement procedure and provides results with stated uncertainties. (ISO 15195 [12])	Laboratory that assigns reference values to test objects. (ISO Guide 43-1 [14])

2.7.7 Appendix: Related Terms and Definitions

In Sect. 2.7.4 the term reference laboratory was introduced and utilised without any further explanation. Similarly to the term reference procedure, the term reference laboratory has recently been used on an increasing scale, but a widely accepted definition is not available yet. Here are three definitions, originating from rather different fields: testing, laboratory medicine and proficiency testing [2.37, 41, 54].

The concept of reference laboratories, as defined above, has a lot of similarity with that of calibration laboratories and may be seen as a generalisation. Unfortunately, the author is not aware of any officially designated reference laboratories in the field of materials measurements. Examples from other fields include:

- EU community and national reference laboratories for regulatory residue analysis of veterinary drugs,
- Reference laboratories for clinical measurements.

The concept of reference laboratories could become a key issue in the future development of ISO/IEC 17025, but this will require comprehensive discussion in various fora. In the author's opinion, the concept should designate functions rather than a formal status, with functions centred about the provision of reference values. This could include provision of:

- reference measurements/tests, preferably using reference procedures,
- reference materials and reference objects,
- proficiency testing schemes.

Another basic term that is intimately related to many of the issues of this section is that of a measurement standard. Here are two definitions from the International Vocabulary of Basic and General Terms in Metrology (VIM):

Standard (of Measurement). Material measure, measuring instrument, reference material or measuring system intended to define, realise, conserve or reproduce a unit or one or more values of a quantity to serve as a reference (VIM 1993 [2.55]).

Measurement Standard. Realisation of the definition of a given quantity, with stated value and measurement uncertainty, used as a reference (VIM, draft revision April 2004 [2.36]).

The concept of a measurement standard embraces both reference materials and reference procedures (of measurement). Currently the notion of national measurement standards maintained and disseminated by national metrology institutes is moving away from tangible objects to measurement service delivery capabilities.

2.8 Accreditation and Peer Assessment

2.8.1 Accreditation of Conformity Assessment Bodies

Accreditation is the formal recognition that laboratories and other conformity assessment bodies such as inspection bodies and bodies certifying products, quality management systems, environmental management systems or personnel are competent to perform specified tasks such as tests or measurements.

Modern technologies in processing goods, just-in-time manufacturing of goods, subcontracting or out-sourcing of activities to specialised organisations are demanding an established system to demonstrate competence and reliability of testing laboratories.

The word *accreditation* comes from the Latin *credere* (to believe, to be confident in) in which the word *dare*, meaning to give or to offer, is found. Accreditation therefore means *to give confidence*. People must be confident that accredited bodies provide their services with competence and reliability.

Accreditation should be understood as a system to maintain and continuously develop laboratory's competence through competent assessments provided by accreditation bodies. It is designed to be a transparent process in which all the interested parties should have the possibility to become involved effectively. In this context processes should also be understood as a host of small innovative steps with the goal of causing something new to arise. (For more about processes see Sect. 2.9.)

Accreditation is defined in standards that are developed by ISO/CASCO. CASCO is the ISO committee on conformity assessment. ISO is the International Standards Organisation and CASCO is its conformity assessment cooperation. These standards specify the accreditation body's competence as well as the laboratory's competence. While accreditation bodies work according to the ISO/IEC 17011 standard, laboratories operate according to the ISO/IEC 17025 standard. In some special fields, such as in the field of the medical laboratories sector, specific standards have been developed as well.

In other cases sector-specific criteria is given in annexes to ISO/IEC 17025.

The goal of the all these standards is to insure that the respective organisations are competent technically to perform well-defined services and that they have an adequate management system in place to ensure daily quality as defined by their clients.

Competence according to the spirit of all of these standards can be assured in the long term only when the accredited companies – and the accreditation bodies themselves – including all the persons involved, go through a permanent and conscious process.

It is obvious that conformity assessment bodies that continuously develop their competence in a systematic way have a large advantage in an increasingly competitive market. Accreditation recognises the constant development of their competence and service quality. So far, accreditation should be seen as a structure to implement processes leading to competence, quality and efficiency.

The task of an accreditation service is to assess whether a conformity assessment body (CAB) has the necessary technical competence and infrastructure to provide reliable services. The CAB's procedures should be clearly structured and controlled in a defined way. CABs need specialised know-how and to develop an adapted structure to allow systematic decisions and learning processes.

Having a look at how accreditation works makes the significance of this evident. Let us take cable transportation plants and operators as an example:

- Accredited calibration laboratories calibrate measuring equipment for material testing;
- Accredited testing laboratories test mechanical, hydraulic and electronic system components and assess their quality;
- Accredited inspection bodies inspect the critical technical installations for final approval of cable transportations;
- Accredited certification bodies for products certify security components of cable transportation. In delivering credible conformity certificates they recognise compliance of such components with security requirements;
- Accredited certification bodies evaluate quality and environmental management systems of cable transportation manufacturers and operators,
- Accredited certification bodies for personnel examine training and technical competence of specialists.

2.8.2 Measurement Competence: Assessment and Confirmation

Measurement and testing are important elements of conformity assessment, the formal recognition that a material or a product conforms with specified requirements. The institutions performing conformity assessment tasks are called conformity assessment bodies (CABs). CABs are organisations providing the following conformity assessment services: calibration, testing, inspection, management system certification, personnel certification and product certification. Accreditation is a third-party attestation related to a conformity assessment body conveying formal demonstration of its competence to carry out specific conformity assessment tasks. An authoritative body that performs accreditation is called an accreditation body (AB, ISO/IEC 17011). The goal of accreditation is:

- to assess and confirm the competence and service quality of conformity assessment bodies;
- to ensure worldwide acceptance of their reports and certificates through a highly reliable confidence-building process;
- to support the competitiveness of accredited bodies on the national and global market.

In the entire chain of production and services one must have confidence that accredited testing and conformity assessment bodies provide their services in a competent and reliable manner.

The following examples illustrate the tasks fulfilled by accredited bodies:

- Measuring instruments of manufacturers and service providers have to be calibrated in order to allow correct measurements. *Accredited calibration laboratories* execute this task with the required precision and traceability to the international system of units (ISO 31).
- In their daily life, consumers depend on reliable analyses and tests, e.g. in the fields of food products, electrotechnical appliances and medical diagnostic analyses. *Accredited testing laboratories* carry out these analyses and tests in a reliable manner.
- Inspections have to be carried out in order to detect safety oversights in food products, medicine and technical installations at a given moment. *Accredited inspection bodies* fulfil these tasks reliably.
- Consumers and industry depend on the compliance of products with defined requirements. *Accredited*

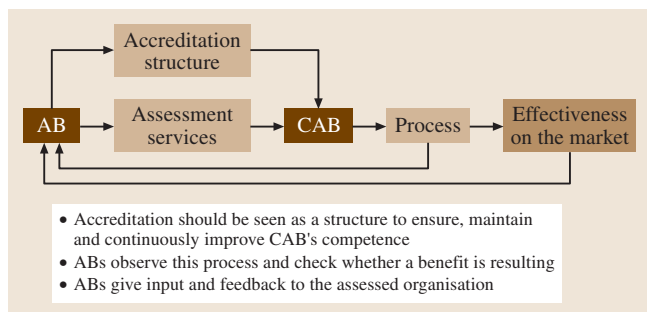

Fig. 2.13 Accreditation should be seen as a structure to implement processes leading to competence quality and efficiency

Fig. 2.14 Organisations of accreditation bodies in the regions and worldwide

certification bodies for products attest to this conformity, after evaluation, in a credible way.

- *Accredited certification bodies for quality systems* deliver conformity certificates attesting to the conformity of quality systems to the standard requirements. This allows clients to be confident that these firms have structures and working procedures at their disposal that ensure a service that respects deadlines and corresponds to the agreed quality.
- *Accredited certification bodies for environmental management systems* attest through their conformity certificates that firms present the necessary conditions in order to continuously improve their environmental performance.
- A large number of firms depend on recognised specialists whose competence has to comply with defined criteria. Amongst these specialists we find welders, auditors, business consultants and project managers. *Accredited certification bodies for personnel* attest to their technical competence so the economy can rely on these specialists.

In the light of the considerable costs of assessments and the long-term acceptance of accreditation as tools to

build confidence in reports and certificates, accreditation bodies are fully aware of the fact that the necessary added value can only be achieved if:

- assessments are aimed at real objectives and values and not at formalism of standards;
- assessors are able to provide useful feedback to the ongoing processes in a competent and independent way.

Today trade has become global and export trade is vital to the development of any country's economy. The increasing development of globalisation, the reduction of technical barriers to trade (TBTs) and the recognition of conformity certificates world wide is leading to increasing competition not only between companies, but also between market places and economic regions. Governments, the industry, and the whole economy is challenged to face this situation. Specialist knowledge, the use of modern technologies, experience and competence in management and in the realisation of modern scientific technical solutions is the way to face this development.

The technical barriers to trade (TBT) agreement encourages members of the World Trade Organisation (WTO) to enter into mutual recognition agreements (MRAs) to enable assessments carried out in one country to be recognised in the other, based on reliable conformity assessments.

"Members shall ensure, whenever possible, that results of conformity assessment procedures in other Member's states are accepted, even when those procedures differ from their own, provided they are satisfied that those procedures offer an assurance of conformity with applicable technical regulations or standards equivalent to their own procedures. It is recognized that prior consultations may be necessary in order to arrive at a mutually satisfactory understanding (TBT, Article 6)."

The TBT agreement was one of the reasons for the establishment of accreditation bodies in the major trade groupings of the world (Fig. 2.12):

ILAC: International Laboratory Accreditation Co-operation (covers the field of laboratory accreditation and, together with the IAF, the field of accreditation of inspection bodies).

IAF: International Accreditation Forum (covers the field of the accreditation of certification bodies and together with **ILAC** the field of accreditation of inspection bodies).

EA: European Cooperation for Accreditation.

IAAC: Inter American Cooperation for Accreditation.

PAC: Pacific Accreditation Cooperation (active in the field of accreditation of certification bodies).

APLAC: Asian Pacific Accreditation Cooperation (active in the field of laboratory accreditation).

These agreements help to eliminate major technical barriers to trade and, at the same time, reduce costs by removing the need for duplicate testing of products by both exporters and importers. Similar provisions, consistent with the TBT agreement, are being encouraged by regional trade groupings such as e.g. the European Union (EU), the European Free Trade Association (EFTA) the Asia-Pacific Economic Cooperation (APEC) or the North America Free Trade Association (NAFTA) and the ASEAN (Association of South-East-Asian Nations) Free Trade Association (AFTA).

MRAs may be *bilateral* or *multilateral*. Over the past 20 years, a network of bilateral and multilateral MRAs have been established between laboratory accreditation bodies throughout the major trade regions.

An example illustrates this: within the framework of the *new and global approach concept* of the European Union, the national standards are replaced by harmonised European directives, which define the fundamental requirements, especially with regard to the safety of a product. Products in compliance with these requirements are marked with the Communauté Européenne (CE) logo. They can be put into free circulation in the European Economic Area. In order to implement and maintain this concept globally, all states that participate need an infrastructure of competent and reliable calibration, testing, inspection and certification bodies.

Multilateral Agreements. These agreements within accreditation bodies within regional trade groupings such as Europe (Fig. 2.15) ensure the worldwide harmonisation of accreditation. They create the basis for the international recognition of testing reports and conformity certificates, especially on the technical level. Therefore, an important task of each country's accreditation bodies is to maintain the interests of the respective country in view of international organisations such as the European cooperation for Accreditation (EA) in Europe, the International Laboratory Accreditation Cooperation (ILAC) and the International Accreditation Forum (IAF). Together with all their stakeholders these organisations continuously establish recommendations and guidance for the harmonisation of accreditation criteria and evaluation testing procedures in order to en-

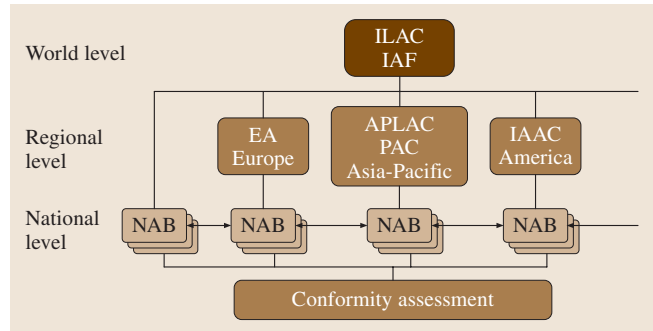

Fig. 2.15 The structure of the MLAs: The competence of the regional organisations is evaluated by ILAC and IAF, the regional organisations evaluate the national accreditation bodies, and these accredit the conformity assessments bodies

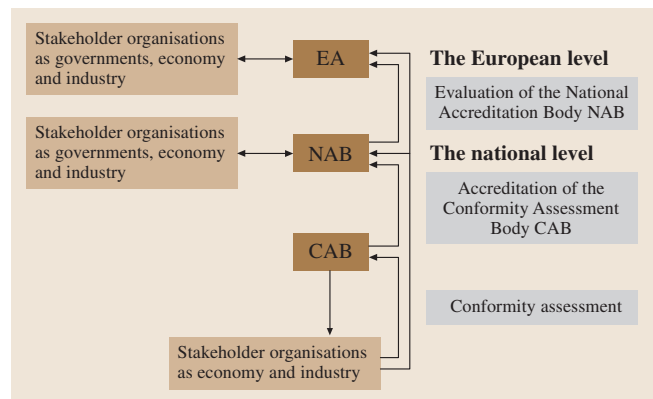

Fig. 2.16 Accreditation, an infrastructure offered to all the interested parties

sure the worldwide reliability and recognition of testing reports and conformity certificates.

As a result, accreditation benefits from professional input and provides a structure to all the interested parties in order to:

- establish confidence in testing reports and conformity certificates,
- develop competence in a continuous way,
- allow mutual recognition of testing reports and conformity certificates.

2.8.3 Peer Assessment Schemes

Peer assessment schemes follow basically the same goal as the accreditation process. Peer assessments schemes are private agreements with the aim of mu-

tually assessing each other's competence. They are normally designed and performed by professional organisations in order to build confidence in their members' services.

By definition such peer assessments schemes are second-party recognition schemes while accreditation is clearly designed as a third-party recognition scheme. However they can provide a big help for its members.

2.8.4 Certification or Registration of Laboratories

The ISO 9001 standard is the well-known standard in the field of quality management systems QMS certification. This standard deals with quality management as generally applied to any types of companies. The ISO/IEC 17025 standard and laboratory accreditation are concerned with competence and quality and is specific for laboratories. An official communiqué

(IAF/ILAC JWG/129) characterises the differences between accreditation and certification as follows:

Certification

- means compliance with a standard or specification
- uses management system auditors who are certified by an independent body that meets internationally agreed criteria
- considers the total activities of an organisation, and the scope of recognition is general.

Accreditation

- is the recognition of specific competence and its scope is normally highly specific
- evaluates people skills and knowledge
- uses assessors who are recognised specialists in their fields
- evaluates the supporting management system for a specific activity
- involves practical tests as appropriate (proficiency testing and measurement audits).

2.9 Human Aspects in a Laboratory

2.9.1 Processes to Enhance Competence – Understanding Processes

Continuous development of the technical competence of all staff necessitates processes that leads to creative and innovative solutions. Such processes must be understood in such a way that continuous progress at all levels and for all functions in an organisation is self-evident.

Clients expect from laboratories services, and solutions taking into account the latest developments in a respective technical field. Only competent laboratories will be able to perform such services in an economic and reliable way. Materials testing is very seldom based on routine testing. Often, methods have to be developed or adapted to

- new materials,
- new questions to be answered,
- special problems to be solved.

Validation plays a big role, as testing methods must be adapted to given tasks and be proved suitable for these tasks. To prove the fitness for purpose of testing methods in order to achieve highly reliable results, which can in special cases be very complex, requires the continuous development of specialised knowledge. Such knowledge consists not only of the details of the testing methods that one plans to use but also the knowledge about what cus-

tomers are planning to do with the results and a general knowledge about the materials tested.

In very rare cases the required competence can be organised from outside. Competence must be developed by all people involved in a laboratory, who are faced with the daily questions and problems. This requires staff who are highly motivated and deeply engaged in their daily tasks.

The long-term safeguarding of competence requires the use of processes at all levels of an organisation. Processes involving people consist of a host of small steps with the goal of creating something new. Competence, e.g. according to the spirit of the standards relevant for accreditation, can be assured in the long term only if their implementation is considered as an ongoing learning process. Learning processes are highly dependent on management structures, and on the provisions to make sure that the whole staff can feel full responsibility for their work.

We all undergo processes, whether we want to or not, be it consciously or unconsciously, simply because of all the information that reaches us and daily interactions. In the function of a head of an organisation it is important to ask for the following questions:

- What kind of processes are going on in the entire company, in parts of it and within individual people?

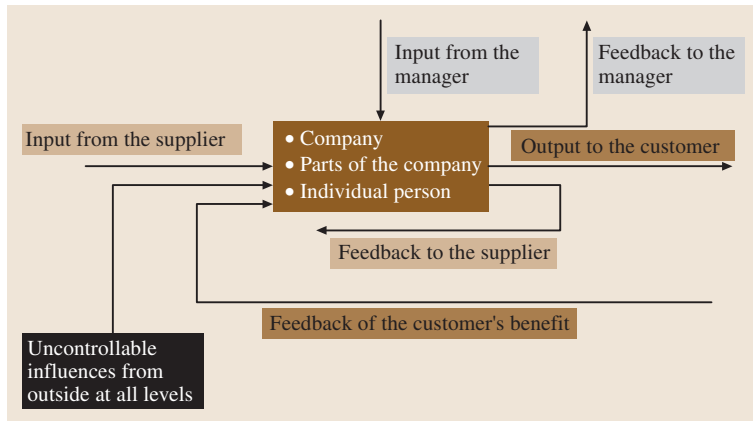

Fig. 2.17 The principle of the systematically controlled input and output

- Which of them are important for me, and how can I recognise them?
- What can I do to support processes leading to engaged staff with good motivation and loyalty?
- What is the driving force for enthusiasm in my organisation?

To find answers it is important that

- communication principles are discussed regularly,
- conflicts are treated and solved systematically,
- internal audits are carried out in such a way that aspects of the management system and procedures that could hinder learning processes or lead to internal conflicts are discovered.

Being process-orientated means that each staff member may bring in his/her competence and his/her creativity for

- planning procedures
- putting procedures into effect

and therefore participates in the ongoing innovative process.

This is also a reply to those who perceive management systems as limiting, restrictive and conservative, and that, at best, they are able to optimise something already existing, but in no case to create something new and innovative.

Management systems should therefore always, and particularly in the case where the aim is the long-term safeguarding of competence and quality, be implemented in such a way that creativity plays an important role. Creativity also depends on how responsibilities are allocated and on the functional behaviour of all individ-

uals in an institution; this means that each staff member must have the possibility to take on his or her responsibility fully and be assured of the protection required to provoke unconventional ideas.

2.9.2 The Principle of Controlled Input and Output

Functional behaviour therefore necessitates a clear definition of responsibilities. This means that everyone assumes responsibility and respects the responsibility of people who come above or below them in the hierarchy and of colleagues at the same hierarchical level. If this is not the case, good processes will be blocked and creativity cannot arise. Clear structures in a laboratory's management system therefore have of an important prerequisite. This structure should ensure that client's requests will lead to respective reactions at all levels: the individual staff level, the subunit level and at the whole organisation. Of course it is important that these reactions are fully controllable and controlled, without taking responsibility away from the individual staff.

The First Control Circle: Input from and Feedback to the Manager (Superior Person)

Input should be given regularly e.g. by defining targets to be achieved. This can be done on daily, weekly or monthly bases and requires regular feedback from the collaborator. Input and feedback should be systematically planned and given in a structured way. Respected responsibility means that each collaborator has the freedom to organise and to arrange their own activities within his defined frame of responsibility.

The Second Control Circle: Input from and Feedback to the Supplier

All internal and external institutions (parts of a company), and individual people performing the activities prior to and in support of ones own activities should be considered as suppliers and treated as such. Input and feedback should be defined, planned and given in a structured way.

The Third Control Circle: Input from and Feedback to the Customer

All internal and external institutions (parts of a company) and individual persons benefiting from own activities should be considered as customers and treated as such. Output and feedback should be well defined, planned and given in a structured way.

The principle of systematically controlled input and output should be valid for the whole organisation, for parts of it and for the individual staff. Each element, the whole organisation, parts of it or individual staff members have to deal with information from clients, from customers, and from superiors. If such a system is applied, it will greatly assist the development of staff entrepreneurship. The system will distinguish between those who are prepared to take responsibility as an entrepreneur and those who are not. It is obvious that staff feeling like entrepreneurs will undergo learning processes to develop the technical and personal skills needed to take the responsibility linked to given hierarchical competences.

The principle of systematically controlled input and output will automatically lead to intensive interaction of the individuals involved, the team and the subject and the involved environment and therefore provide good bases for the implementation of management systems such as that defined in the standard ISO/IEC 17025.

2.9.3 The Five Major Elements for Consideration in a Laboratory

Quality management starts with the individual. If the principle of systematically controlled input and output is applied strictly, each entrepreneur in the organisation will feel responsible for the quality of his or her product or performed service. The following five elements will help to assure reliable performance at all hierarchical levels, the laboratory, the subunits and the individual staff:

1. Systematic estimation of the chances and the corresponding risks;

2. Leadership and ability to lead at all levels;
3. Traceability of all decisions; decisions should be comprehensive;
4. Periodic evaluation of the effectiveness of the organisation, procedures etc.
5. A general system to limit damage; corresponding procedures should be laid down in the overall quality management system.

Regardless of the quality system applied, internal audits should preferably be used to monitor how these five elements are implemented at all the hierarchical levels mentioned above.

2.9.4 Internal Audits

Internal audits are a very helpful tool to observe whether good processes are being carried out. However they should not be used to establish a hidden supervision of the staff and their activities. To audit means to observe if the structure of the management system is developed in such a way, that conscious processes at all levels in a company are possible and provide feedback. This means that auditors have to take into account

- the people,
- their processes,
- the structure of the organisation and the management system.

Auditors have to respect the functions and the corresponding hierarchical competences in an organisation. The staff should therefore always be included in the audit teams and be responsible for those audits that are performed within their own area of responsibility. Audit teams should include the following team members:

- The individual persons responsible for a given activity or task;
- The superior who wants to gain trust in the work of his collaborator;
- A person having the necessary communication skills and who is familiar with
 - the quality system,
 - its structure and procedures and
 - the audit techniques.

To audit an organisation, parts of it or an individual person means to observe and to learn how the management system is implemented, whether it enables conscious processes at all levels in a company and to give feedback.

The most important point is that auditors are trained to observe learning processes and to this end they need

to know more about human beings and behaviour. If international standards, such as the ISO/IEC 17000 series of standards, are implemented and audits are used to verify if these standards are implemented correctly, auditors should not only look at how these standards are translated into action but if this translation is of benefit to the company, parts of it and the individual staff. This means audits must concentrate on the effects of the defined measures and after an audit the audited organisation or persons should be able to explain what they discovered during the audit, e.g. in the audit report, which is – in the best case – provided by the audited people or the people who are responsible for the audited part of the organisation.

2.9.5 Conflicts

Conflicts are normal and will occur in all situations. Conflicts result from disagreements or different opinions. Conflicts can occur if engaged people are convinced about their own solutions or ideas. To be in conflict with somebody is not bad behaviour; bad behaviour is not to solve these conflicts. Unsolved conflicts lead to situations where learning processes are no longer possible and later where cooperation between staff members becomes nearly impossible.

It is therefore good practice to establish a system to solve conflicts, even the smallest one, in statu nascendi and in a systematic way. This can e.g. be done using the following principles:

1. All the staff (including the general manager) are required to declare a conflict (even a possible one) as soon as it is recognised, to the person(s) with which a potential conflict exists. The person who recognises the conflict can be considered as the client, the other conflicting person as the supplier.
2. The client should discuss this potential conflict as soon as possible with the supplier, while this is possible and with the least emotion as possible.
3. If the client and the supplier are not able to solve the conflict, it is important that they involve a third person to act as an arbitrator. Arbitration in an organisation should not be considered as a tribunal, but as a good way to translate to one another different opinions that obviously cannot be understood. It is important that the arbitrator does not rate the opinions of the conflicting persons. On the other hand he

is obliged to explain what is already fixed, e.g. in the management system or in technical procedures.

4. Both conflicting people (client and supplier) should afterwards express their wish for future solutions in a comprehensive way such that it is clear what the other person is expecting. The arbitrator ensures that this discussion remains factual.
5. Having learned from each other, both conflicting partners explain to the other person the next steps to realising good solutions in the future.
6. All three partners explain what they have learned in the process. If one of the partners does not have trust in the solution by the other partner, he will announce this and clarify remaining points immediately.
7. The supplier will minute the discussions, especially the agreed conclusions about the next steps.

It is recommended to lay down such a procedure in the corresponding management system of an organisation. This will ensure that conflicts do not remain untouched and that the necessary learning steps are taken; this is an important aspect to maintain the necessary competence of all the staff.

2.9.6 Conclusions

The increasing development of globalisation, the European and worldwide reduction of technical barriers to trade and the recognition of conformity certificates worldwide is leading to increasing competition not only between companies, conformity assessment bodies and laboratories, but also between market places and economic regions. Specialised knowledge, the use of modern technologies, experience and competence in the management and realisation of innovative scientific technical solutions is the way to face this development.

Considering human aspects is of utmost important, especially in laboratories where there is a clear need to continuously develop technical competence. Technical competence can only be continuously developed and improved, if the management can base this on engaged staff. There are a few basic principles that must be respected to support the development of engagement. It is highly recommended to invest into these principles. Such investments should be treated in the same way as investments in technical equipment or scientific developments. They are at least of similar importance.

3. Materials and Their Characteristics: Overview

In its most general context, the term *materials measurements* denotes principles, techniques and operations to distinguish qualitatively and to determine quantitatively the characteristics of materials. As materials comprise all natural and synthetic substances and constitute the physical matter of products and systems, such as

- machines, devices, commodities
- power plants and energy supplies
- means of habitation, transport, and communication,

it is clear that materials characterization methods have a wide scope and impact for science, technology, the economy and society. Whereas in the preceding chapters the principles of metrology,

the science of measurement, are outlined, in this chapter an overview on the basic features of materials is given as a basis for the classification of the various methods used to characterize materials by analysis, measurement, testing, modelling and simulation.

Materials measurements are aimed at characterizing the features of materials quantitatively; this is often closely related to the analysis, modelling and simulation, and the qualitative characterization of materials through testing [3.1], see Fig. 3.1.

Generally speaking, measurement begins with a definition of the *measurand*, the quantity that is to be measured [3.2], and it always involves a comparison of the *measurand* with a known quantity of the same kind. Whereas the general metrological system is based on the

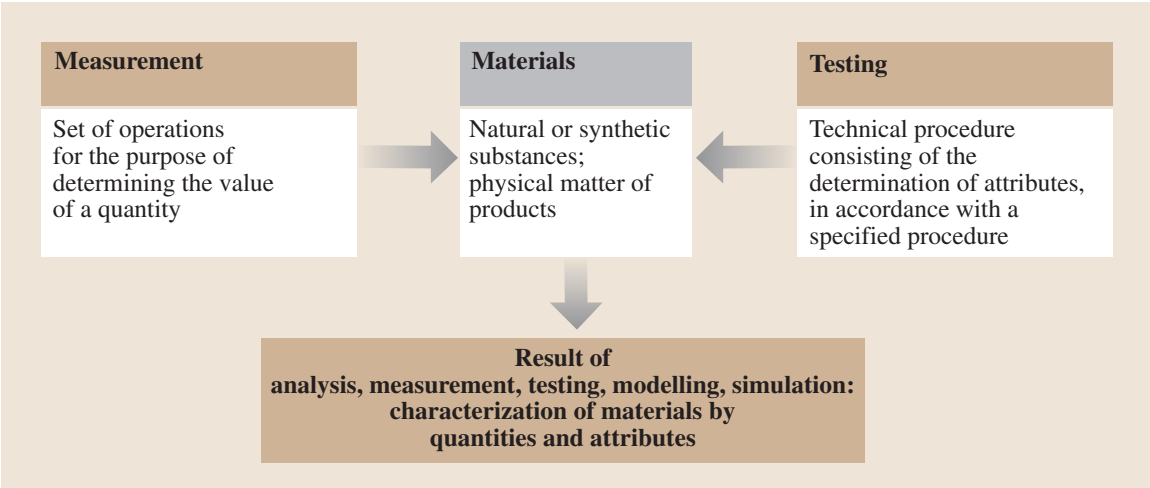

Fig. 3.1 Scheme for the characterization of materials

well-defined SI-Units (see Chapt. 1 of this handbook), for materials there is a broad spectrum of “material measurands”. This is due to the variety of materials, their intrinsic chemical and physical nature, and the many attributes, which are related to materials with respect to composition, structure, scale, synthesis, properties and applications. Some of these attributes can be expressed – in a metrological sense – as numbers, like density

or thermal conductivity; some are Boolean, such as the ability to be recycled; some, like resistance to corrosion, may be expressed as a ranking (poor, adequate, good, for instance) and some can only be captured with text and images [3.3]. As a background for the materials measurement system and the classification of materials characterization methods, in this chapter the basic features of materials are briefly reviewed.

3.1 Basic Features of Materials

Materials can be of natural origin or synthetically processed and manufactured. According to their chemical nature they are broadly grouped traditionally into inorganic and organic materials. Their physical structure can be crystalline, or amorphous. Composites are combinations of materials assembled together to obtain properties superior to those of their single constituents. Composites are classified according to the nature of their matrix: metal, ceramic or polymer composites, often designated MMCs, CMCs and PMCs, respectively. Figure 3.2 illustrates with characteristic examples the spectrum of materials between the categories natural, synthetic, inorganic, and organic.

3.1.1 Nature of Materials

From the view of materials science [3.4], the fundamental features of a solid material are described as follows.

Materials Atomic Nature. The atomic elements of the periodic table which constitute the chemical composition of a material.

Materials Atomic Bonding. The type of cohesive electronic interactions between the atoms (or molecules) in a material, empirically categorised into the following basic classes:

- Ionic bonds form between chemical elements with very different electron-negativity (tendency to gain electrons), resulting in electron transfer and the formation of anions and cations. Bonding occurs through electrostatic forces between the ions.
- Covalent bonds form between elements that have similar electron-negativities, the electrons are localised and shared equally between the atoms, leading to spatially directed angular bonds.

- Metallic bonds occur between elements with low electron-negativities, so that the electrons are only loosely attracted to the ionic nuclei. A metal is thought of as a set of positively charged ions embedded in an electron sea.
- Van der Waals bonds are due to the different internal electronic polarities between adjacent atoms or molecules leading to weak (secondary) electrostatic dipole bonding forces.

Materials Spatial Atomic Structure. The amorphous or crystalline arrangement of atoms (or molecules) in crystalline structures is characterized by unit cells which are the fundamental building blocks or modules repeated many times in space within a crystal.

Grains. Crystallites made up of identical unit cells repeated in space, separated by grain boundaries.

Phases. Homogeneous aggregations of matter with respect to chemical composition and uniform crystal

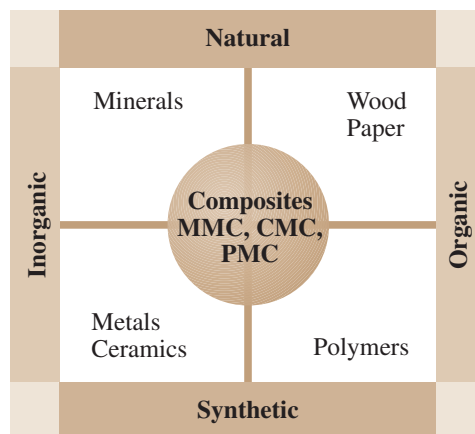

Fig. 3.2 Classification of materials

structure: grains composed of the same unit cells are the same phase.

Lattice Defects. Deviations of an ideal crystal structure:

- Point defects or missing atoms: vacancies
- Line defects or rows of missing atoms: dislocations
- Area defects: grain boundaries
- Volume defects: cavities

Microstructure. The microscopic collection of grains, phases, lattice defects and grain boundaries.

Together with bulk material characteristics, surface and interface phenomena have to be considered.

3.1.2 Types of Materials

It has been estimated that there are between 40 000 and 80 000 materials which are used or can be used in today's technology [3.3]. Figure 3.3 lists the main conventional families of materials together with examples of classes, members, and attributes. For the examples of attributes, sufficient characterization methods are named.

From a technological point of view, the materials categorized in Fig. 3.3 as families have different characteristics relevant for engineering applications [3.5]:

Metallic Materials; Alloys. In metals, the grains as the building blocks are held together by the electron gas. The free valence electrons of the electron gas account for the high electrical and thermal conductivity and the optical gloss of metals. The metallic bonding – seen as an interaction between the sum total of atomic nuclei and the electron gas – is not significantly influenced by a displacement of atoms. This is the reason

for the good ductility and formability of metals. Metals and metallic alloys are the most important group of the so-called structural materials (see below) whose special features for engineering applications are their mechanical properties, e.g. strength and toughness.

Semiconductors. Semiconductors have an intermediate position between metals and inorganic non-metallic materials. Their most important representatives are the elements silicon and germanium, possessing covalent bonding and diamond structure and the similarly structured III–V-compounds, like gallium arsenide (GaAs). Being electric non-conductors at absolute zero, semiconductors can be made conductive through thermal energy input or atomic doping which leads to the creation of free electrons contributing to electrical conductivity. Semiconductors are important *functional materials* (see below) for electronic components and applications.

Inorganic Non-Metallic Materials, Ceramics. Atoms in these materials are held together by covalent and ionic bonding. As covalent and ionic bonding energies are much higher than metallic bonds, inorganic non-metallic materials, like ceramics have high hardness and high melting temperatures. These materials are basically brittle and not ductile: In contrast to the metallic bond model, a displacement of atomistic dimensions theoretically already breaks localised covalent bonds or transforms anion–cation attractions into anion–anion or cation–cation repulsions. Because of missing free valence electrons, inorganic non-metallic materials are poor conductors for electricity and heat, this qualifies them as good insulators in engineering applications.

Subject	Family	Class	Member	Attributes
Materials	Natural	Steels	CuBeCo	Composition: Chemical <i>analysis</i> Density: <i>Measurement</i> Grain size: <i>Computational modelling</i> Wear resistance: <i>3-body-systems-testing</i> Reliability: <i>Probabilistic simulation</i>
	Ceramics	Cast iron	CuCd	
	Polymers	Al-alloys	CuCr	
	Metals	Cu-alloys	CuPb	
	Semiconductors	Ni-alloys	Bronze	
	Composites	Ti-alloys	CuTe	
	Biomaterials	Zn-alloys	CuZr	

Fig. 3.3 Materials types with examples of materials attributes and characterization methods (after [3.3])

Fig. 3.4 Scale of materials: systems and structures

Organic Materials; Polymers, Blends. Organic materials whose technologically most important representatives are the polymers, consist of macromolecules containing carbon covalently bonded with itself and with elements of low atomic number (e.g. H, N, O, S). Intimate mechanical mixtures of several polymers are called blends. In thermoplastic materials, the molecular chains have long linear structures and are held together through (weak) intermolecular (van der Waals) bonds, leading to low melting temperatures. In thermosetting materials the chains are connected in a network structure and do not melt. Amorphous polymer structures (e.g. polystyrene) are transparent, whereas the crystalline polymers are translucent to opaque. The low density of polymers gives them a good strength-to-weight ratio and makes them competitive with metals in structural engineering applications.

Composites. Generally speaking, composites are hybrid creations made of two or more materials that maintain their identities when combined. The materials are cho-

sen so that the properties of one constituent enhance the deficient properties of the other. Usually, a given property of a composite lies between the values for each constituent, but not always. Sometimes, the property of a composite is clearly superior to those of either of the constituents. The potential for such a synergy is one reason for the interest in composites for high-performance applications. However, because manufacturing of composites involves many steps and is labour intensive, composites may be too expensive to compete with metals and polymers, even if their properties are superior. In high-tech applications of advanced composites it should also be borne in mind that they are usually difficult to recycle.

Natural Materials. Natural materials used in engineering applications are classified into natural materials of mineral origin, e.g. marble, granite, sandstone, mica, sapphire, ruby, diamond, and those of organic origin, e.g. timber, India rubber, natural fibres, like cotton and wool. The properties of natural materials of mineral

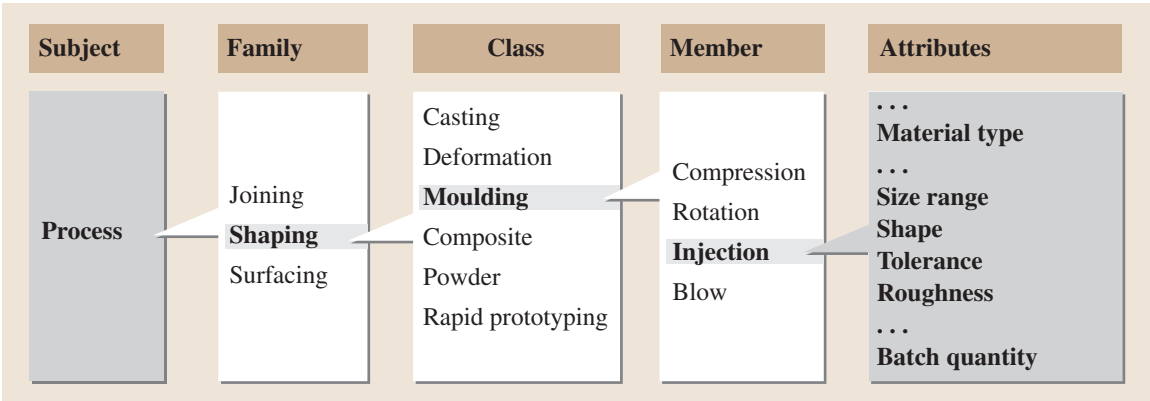

Fig. 3.5 Hierarchy of processing of materials

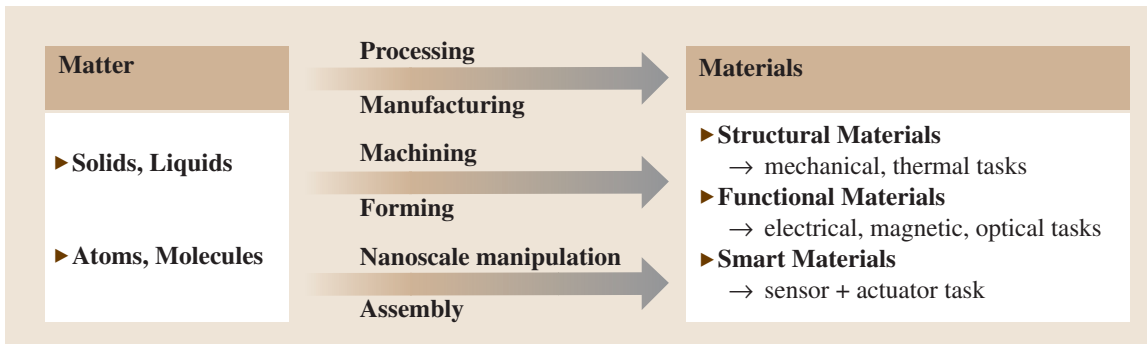

Fig. 3.6 Materials and their characteristics result from the processing of matter

origin, such as for example high hardness and good chemical durability, are determined by strong covalent and ionic bonds between their atomic or molecular constituents and stable crystal structures. Natural materials of organic origin often possess complex structures with direction-dependent properties. Advantageous application aspects of natural materials are recycling and sustainability.

Biomaterials. Biomaterials can be broadly defined as the class of materials suitable for biomedical applications. They may be synthetically derived from non-biological or even inorganic materials or they may originate in living tissues. The products that incorporate biomaterials are extremely varied and include artificial organs; biochemical sensors; disposable materials and commodities; drug-delivery systems; dental, plastic surgery, ear and ophthalmological devices; orthopedic replacements; wound management aids; and packaging materials for biomedical and hygienic uses.

For the application of biomaterials the understanding of the interactions between synthetic substrates and biological tissues are of crucial importance to meet the needs of clinical requirements. However, medical and clinical aspects of biomaterials are not treated in this Handbook.

3.1.3 Scale of Materials

The geometric length scale of materials has more than twelve orders of magnitude. The scale ranges from the nanometer dimensions of quantum-well structures – with novel application potentials for advanced communications technologies – to the kilometer-long structures of bridges for public transport, pipelines and oil-drilling platforms for the energy supply of society. Accordingly,

materials measurement methods have to characterize materials with respect to the

1. Nanoscale, sizes of about 1 to 100 nanometers [3.6],
2. Microscale, relevant for micro-devices and micro-systems having sizes of typically 1 to 1000 micrometers [3.7],
3. Macroscale materials have the dimensions of all customary products, devices and plants, ranging from the millimeter to the kilometer scale [3.8].

Figure 3.4 gives an overview on materials scales with some key words.

3.1.4 Processing of Materials

For their use, materials have to be engineered by processing and manufacture in order to fulfil their purpose as the physical basis of products designed for the needs of the economy and society. There are the following main technologies to transform matter into engineered materials [3.9]:

- *Machining*, i.e. shaping, cutting, drilling, etc. of solids,
- *Net forming* of suitable matter, e.g. liquids, moulds,
- *Nanotechnology assembly* of atoms or molecules.

In addition to these methods, there are also further technologies, like surfacing and joining, which are applied to process, shape and assemble materials and products. The design of materials may also be supported by computational methods [3.10]. It has been estimated that there are at least 1000 different ways to produce materials [3.3]. Figure 3.5 lists some of the families of processing materials together with examples of classes, members, and attributes.

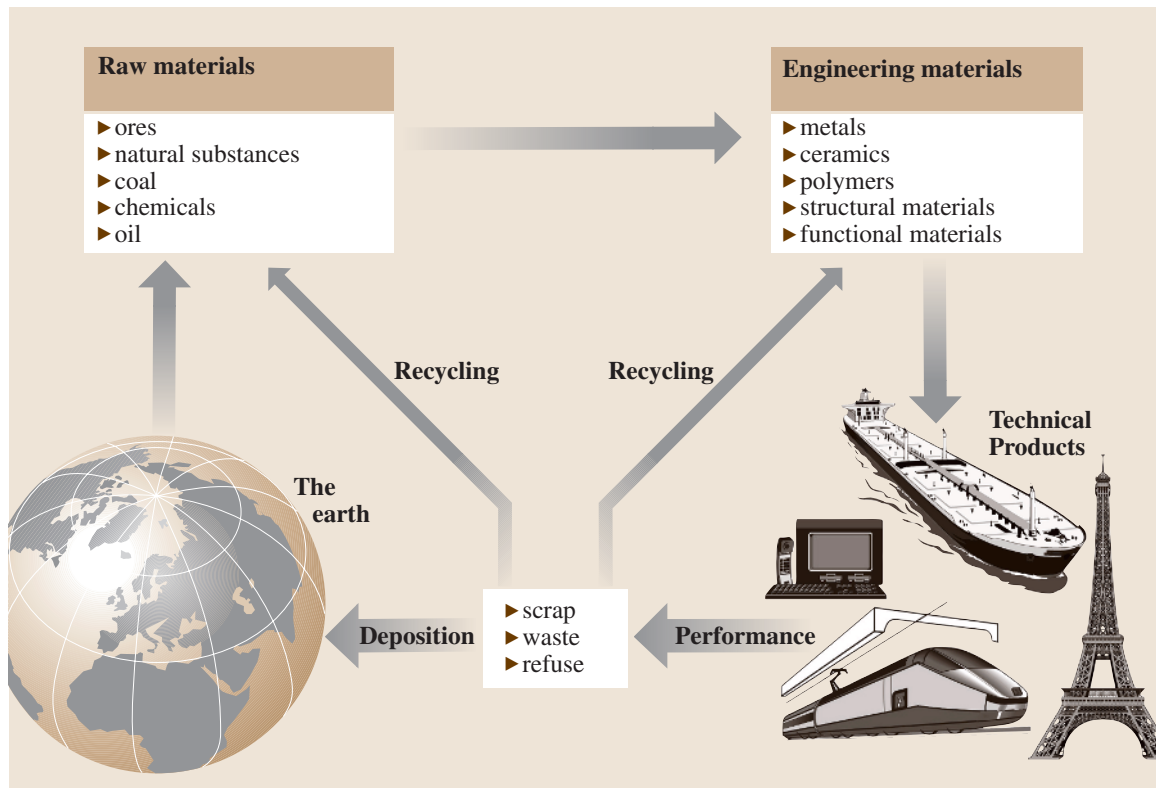

Fig. 3.7 The materials cycle

3.1.5 Properties of Materials

According to their properties, materials can be broadly classified into the following groups [3.11]:

- *Structural materials*: engineered materials with specific mechanical or thermal properties
- *Functional materials*: engineered materials with specific electrical, magnetic or optical properties
- *Smart materials*: engineered materials with intrinsic or embedded “sensors” and “actuators” which are able to react in response to external loading, aiming at optimising the materials’ behaviour according to given requirements for the materials performance [3.12].

It must be emphasized that the characteristics of engineered structural, functional, and smart materials depend essentially on their processing and manufacture, as illustrated in a highly simplified manner in Fig. 3.6.

3.1.6 Application of Materials

For the application of materials, their quality, safety and reliability as constituents of products and engineered components and systems are of special importance. This adds performance attributes to the characteristics to be determined by materials measurement and testing. In this context the materials cycle must be considered.

Figure 3.7 illustrates that all materials (accompanied by the necessary flow of energy and information) move in cycles through the techno-economic system: from raw materials to engineering materials and technical products, and finally, after the termination of their task and performance, to deposition or recycling. From the materials cycle, which applies to all branches of technology, it is obvious that materials and their properties – to be determined through measurement and testing – are of crucial importance for the performance of technical products. This is illustrated in Table 3.1 for some examples of products and technical systems from the energy sector [3.13].

Table 3.1 Application examples of materials in energy systems and relevant materials properties [3.13]

Application	Materials properties				
	Mechanical	Thermal	Electrical	Magnetic	Optical
Heat engine	High-temperature strength				
Electricity generator	High-temperature strength				
Nuclear pressure vessel	Resistance to crack growth				
Solar energy		Heat absorption	Photoelectricity		Reflectance
Superconductor	Ductility; strength		High current capacity	Magnetic quenching	
Conservation	Light weight; strength	Thermal insulation; high-temperature resistance	Semiconductivity	Magnetic efficiency	Low transmission loss

3.2 Classification of Materials Characterization Methods

From a realization concerning the application of all material, a classification of materials characterization methods can be outlined in a simplified manner:

Whenever a material is being created, developed, or produced the properties or phenomena the material exhibits are of central concern. Experience shows that the properties and performance associated with a material are intimately related to its composition and structure at all levels, including which atoms are present and how the atoms are arranged in the material, and that this structure is the result of synthesis, processing and manufacture. The final material must perform a given task and must do so in an economical and socially acceptable manner. These main elements:

- composition and structure,
- properties,
- performance

and the interrelationship among them define the main categories of materials characterization methods to be applied to these elements, see Fig. 3.8.

Figure 3.8 illustrates that the materials characterization methods comprise analysis, measurement, testing, modelling, and simulation. These methods

are described in detail in the following parts of this book:

- Methods to analyze the composition and structure of materials with respect to chemical composition, nanoscopic architecture and microstructure, surfaces and interfaces are compiled in Part B .
- Methods to measure the mechanical, thermal, electrical, magnetic and optical material properties are described in Part C .
- Methods of testing material performance through the determination of mechanisms which are detrimental to materials integrity, like corrosion, wear, biodegradation, materials-environment interactions, are outlined in Part D , which also contains the description of methods for performance control and condition monitoring.
- Methods of modelling and simulation by mathematical and computational approaches – ranging from Molecular Dynamics Modelling to Monte Carlo simulation – are described in Part E .

Supporting the presentation of the materials characterization methods, in the Appendix relevant International Standards of Materials Measurement Methods are compiled.

Chemical Composition

4. Chemical Composition

Measurements of the chemical compositions of materials and the levels of certain substances in them are vital when assessing and improving public health, safety and the environment, are necessary to ensure trade equity, and are required when monitoring and improving industrial products and services. Chemical measurements play a crucial role in most areas of the economy, including healthcare, food and nutrition, agriculture, environmental technologies, chemicals and materials, instrumentation, electronics, forensics, energy, and transportation.

This chapter presents a broad overview of the analytical techniques that can be used to perform the “higher order chemical characterization of materials”. Techniques covered include mass spectrometry, molecular spectrometry, atomic spectrometry, nuclear analytical methods, chromatographic methods and classical chemical methods.

For each technique, information is provided on the principle(s) of operation, the scope of the technique, the nature of the sample that

can be used, qualitative analysis, traceable quantitative analysis, and key references. Examples of representative data are provided for each technique, where possible.

4.1 Bulk Chemical Characterization

4.1.1 Mass Spectrometry

[4.1–8]

Inductively Coupled Plasma Mass Spectrometry (ICP–MS)

Principles of the Technique. The inductively coupled plasma (ICP) associated with this technique is an atmospheric-pressure argon plasma that is produced in a quartz torch connected to a radiofrequency (RF) generator. Operating RF powers are typically between 1000 W and 1500 W. The aqueous liquid sample solution is injected as an aerosol into the axial channel of the ICP, where temperatures on the order of 7000 K prevail. Here the sample is decomposed into its constituent elements, which are ionized. The ions are differentially

pumped into a mass spectrometer (MS) through a sampling cone and skimmer. The relative ion count rates are used to gauge the relative concentrations of the elements in the sample. The most common instruments use quadrupole mass spectrometers with unit mass resolution capabilities. Higher resolution magnetic sector mass spectrometers are also available.

Scope. ICP–MS is used primarily for quantitative elemental analysis, in other words to determine the concentrations of specific elements in a sample. It is also used to measure elemental isotope ratios. It is roughly 1000 times more sensitive than ICP–atomic emission spectrometry (AES), making it very suitable for trace metal analysis at ng/g and even pg/g solution concentrations. It is widely used in the semiconductor industry to

test high-purity production chemicals. It is also heavily used for the environmental monitoring of water and soil samples. **ICP-MS** is used in geological studies, including isotope ratio studies.

Nature of the Sample. In the most common situations, samples are introduced into the **ICP** as solutions. If the sample being analyzed is a solid, it must first be dissolved. This typically involves dissolving a 0.1 g sample in 100 mL of acidified aqueous solution. Dissolving most samples will require hot concentrated mineral acids.

An alternative sample introduction system uses laser ablation of solid samples to generate an aerosol of sample particles, which can be injected directly into the **ICP**.

Qualitative Analysis. Specific elements are identified based on the known mass/charge ratios and isotopic patterns of the elements.

Traceable Quantitative Analysis. For systems using solution sample introduction, the **ICP-MS** instrumentation must be calibrated using solutions containing known concentrations of the analyte elements. Such calibration solutions are available from many commercial suppliers. These solutions are often traceable to one of a set of **NIST** single-element solution Standard Reference Materials. The analysis of complex samples can be susceptible to matrix effects (the combined effect that all of the species present in the sample have on the mass spectrometric signal of the analyte). This will lead to measurement bias if the calibration solutions are not matched to the matrix of the sample being analyzed. The method of standard additions is an effective strategy for dealing with matrix effects. Use of an internal standard will also reduce susceptibility to matrix interferences.

For high-accuracy work, quantitation can also be accomplished through isotope dilution. In this procedure the isotope ratio of a pair of analyte isotopes is perturbed by spiking the sample with a known amount of a solution that is enriched in the concentration of an isotope of the element that is naturally not very abundant. The degree of perturbation of the isotope ratio depends on the concentration of the analyte element present in the sample before being spiked, and the concentration can be calculated by measuring the perturbed isotope ratio.

Isobaric interferences occur when two or more ionic species with nominally the same mass-to-charge ratio are present in the **ICP**. The argon plasma is the source of the most severe of these interferences. For example,

^{40}Ar interferes with ^{40}Ca , and $^{40}\text{Ar}^{16}\text{O}$ interferes with ^{56}Fe in quadrupole systems. The latter example can be resolved with high-resolution systems.

Calibration of systems using sample introduction based on laser ablation is more difficult. The laser ablation process is very matrix-dependent, and calibration requires the use of solid standards that match the characteristics of the sample quite closely.

Certified reference materials are available in a wide variety of sample matrix types from **NIST** and other sources. These **CRMs** should be used to validate **ICP-MS** methods.

Glow Discharge Mass Spectrometry (GD-MS)

Principles of the Technique. A glow discharge is a reduced-pressure, inert gas plasma maintained between two electrodes. Argon is typically used at absolute pressures of a few hundred Pascals or less, and the solid sample serves as the cathode in the circuit. When the discharge is ignited, Ar^+ ions formed in the plasma are accelerated toward the sample surface by means of electrical fields. A substantial fraction of these Ar^+ ions strike the surface of the sample with enough kinetic energy to eject sample atoms from the surface. In this way, the solid sample is directly atomized. Once in the plasma, sputtered atoms may be ionized through collisions with metastable Ar atoms (Penning ionization) or energetic electrons (electron impact ionization). The ions generated are extracted from the plasma and directed into a mass analyzer with one or more detectors. The ions are separated and detected according to the mass-to-charge (m/z) ratios, resulting in a glow discharge mass spectrum.

GD-MS instruments usually employ quadrupole or double-focusing magnetic sector mass analyzers, although other types have also been reported [such as time-of-flight (**TOF**), ion cyclotron resonance (**ICR**), and ion traps]. To date, there has only been one commercial **GD-MS** instrument that can truly be said to have been successful in the marketplace. This is the VG-9000 double-focusing glow discharge mass spectrometer (Thermo Elemental, Cambridge, United Kingdom), costing more than \$500 000 (To describe experimental procedures adequately, it is occasionally necessary to identify commercial products by manufacturer's name or labels. In no instance does such identification imply endorsement by the National Institute of Standards and Technology, nor does it imply that the particular products or equipment are necessarily the best available for that purpose). The number of VG-9000 instruments in use around the world is probably some-

where between 40 to 60. Some other double-focusing instruments, as well as quadrupole instruments, often custom-built by the user, are also employed.

Scope. Glow discharge devices used in GD-MS may be powered by either a direct-current (DC) or radiofrequency (RF) power supply. In DC-GD-MS, the sample must be electrically conductive, since current must pass through it. Therefore, DC-GD-MS is applicable to conductive bulk samples. In principle, the technique is also applicable to samples consisting of conductive layered materials (such as thin films on surfaces). In such a case, registration of ion intensities as surface layers are “sputtered” away results in a “depth profile” of the sample. However, very little work in this area has been reported so far. RF-GD-MS overcomes the restriction to conductive sample types, because in this configuration it is not necessary for net current to flow through the sample. As a result, RF-GD-MS can be applied to electrically insulating bulk solids and coated surfaces with insulating substrates and/or layers.

The greatest strengths of GD-MS, whether DC or RF, are the high sensitivities and low limits of detection available (sub- to low ng/g range directly in the solid state). Owing to these characteristics, the technique has been most widely applied for purity assessments of highly-pure, solid materials, such as those used in the semiconductor industry. The ability to detect H, O and N is also advantageous for this application. Isobaric interferences are not generally problematic in GD-MS, unless low-resolution mass analyzers (such as quadrupoles, which have only unit resolution) are used.

Disadvantages of GD-MS include the fact that matrix effects, while relatively mild compared to many other direct solid techniques, are nonetheless present. Matrix effects manifest themselves mainly as overall sputtering rates that vary from matrix to matrix. Fortunately, even though this is true, once sputtering has reached “steady state” for a given sample, the relative fluxes of sputtered atoms accurately reflects the stoichiometry of that sample. Another disadvantage of GD-MS is that it is inherently a “relative” technique, requiring reference materials for calibration. Unfortunately, reference materials with certified values in the mass fraction range of greatest interest (<1 mg/g) are rare. As a result, GD-MS calibration can only be accomplished to the degree allowed by available reference materials.

Nature of the Sample. As noted above, samples amenable to GD-MS analysis include bulk solids and

layered surfaces. Bulk solids are often machined into pins for analysis, although flat samples can also be employed.

Qualitative Analysis. Calibration of a GD-MS instrument consists of measuring relative sensitivity factors (RSFs) for the analytes. RSFs are generated by measuring the signal levels for suitable reference materials. When suitable reference materials are lacking, GD-MS cannot be calibrated, resulting in qualitative analysis. Nonetheless, given the very low limits of detection, the technique finds much use in this mode.

Traceable Quantitative Analysis. Quantitative GD-MS analysis (with accuracies in the range of $\pm 30\%$ relative, for example) is performed by employing RSFs generated from matrix-matched reference materials. If RSFs must be developed from non-matrix-matched reference materials, then GD-MS becomes a semiquantitative technique (giving accuracies within a factor of 2 for example). In either case, the calibrants constitute the traceability link to the SI.

4.1.2 Molecular Spectrometry

[4.9–34]

Traceability in UV/Visible Molecular Absorption Spectrometry

Principles of the Technique. Molecular absorption spectrometry in the ultraviolet and visible spectral region, often simply known as “UV/vis,” is one of the oldest and most mature instrumental methods of chemical analysis, with the development of photoelectric detection spectrophotometers dating from the 1920s. Numerous books and review articles have been written on the instrumentation and applications of this mature technology. The present treatment will thus only touch on the bare essentials of the technology as they relate to the subject of assuring traceable measurements at levels of measurement uncertainty that are appropriate to the application, or “fit for purpose.”

The basic measurement of molecular absorption spectrometry is the *absorbance* (A) of a sample, defined as

$$A(\lambda) = \log[I_0(\lambda)/I(\lambda)], \quad (4.1)$$

where the numerator of the logarithmic argument is the intensity of light incident on the sample centered at a given wavelength (λ), and the denominator is the reduced intensity of the same distribution as it exits the far

side of the absorbing sample. In chemical applications, the sample would normally be a solution containing one or more species that absorb UV/visible radiation, and the intensity measurements may be made in such a way as to compensate for reflective losses at the faces of the cell containing the solution.

Scope. A plot of A as a function of λ for a known concentration of a neat compound in a transparent solvent, the *absorbance spectrum*, is characteristic of the compound (and sometimes the solvent), and may be employed for qualitative and quantitative analysis. Compounds are frequently characterized by the wavelength and *absorptivity* (absorbance per unit concentration and path length) of the major absorbance bands in the spectrum. Mixtures of absorbing compounds are subject to spectral interference errors during quantitation, since the absorbance bands tend to be relatively broad. Separations and other chemical methods used to avoid these errors are beyond the scope of this article.

Nature of the Sample. The main sample requirement for UV/vis analyses is at least partial transparency to optical radiation in the range between 200 nm and 700 nm. Homogeneous, clear solutions are the most usual sample formats for UV/vis analyses, but there is no requirement that such solutions be liquid, as glasses, polymer mixtures and thin film materials on transparent substrates are also commonly measured. Samples containing dispersed particulates are troublesome for UV/vis measurements due to photometric errors generated by reflectance and scattering of the incident light by the particles.

Qualitative Analysis. UV/vis can be used qualitatively to determine the presence or absence of components in a sample; however, the broad absorbance bands of most samples often limit the utility of this approach. The UV/vis spectrum of a material combined with its luminescence and reflectance spectra determine the color appearance of the material. This aspect of optical spectroscopy, often referred to as color science, has tremendous commercial utility and implications and has evolved into a nearly separate field from optical spectrometry, which is primarily devoted to the quantitation of materials based on their optical spectra.

Traceable Quantitative Analysis. Most absorbance standards and many UV/visible “methods” specify wavelength accuracy on the order of ± 1 nm. Rare earth elements in solution or in glass provide sharp absorbance bands appropriate to wavelength standardization, and

these are available in a sample geometry that is compatible with the most common chemical sample holder. Traceability of these standards to the meter may derive from the intrinsic properties of the absorbing species in the stated matrix, documented along with all the required uncertainty analysis, or by individual or batch calibration or certification of the artifact by a standards-producing organization.

Because the absorbance scale is based on the ratio of two intensities (see (4.1)), accuracy requires that the combination of the wavelength-selection device and the photoelectric detector yield a signal, S , that is directly proportional to the light intensity, I . Instead, allowing for a background, B , and an intensity-dependent proportionality between signal and intensity, $k(I)$, we may have

$$S_0/S = [k(I_0)I_0 + B]/[k(I)I + B]. \quad (4.2)$$

Equation (4.2) may be seen to reduce to the desired ratio I_0/I in the special case for which there is no dark current or stray radiant energy (SRE) ($B = 0$) and for which the proportionality between the light intensity and the detector signal is constant [$k(I) = k(I_0) = \text{constant}$]. Most research-grade spectrophotometers are designed to render these bias sources negligible over the useful analytical range $0 \leq A \leq 3$, and are frequently employed as *transfer spectrophotometers* to provide absorbance calibrations or absorbance-certified reference materials with traceability to a *reference spectrophotometer* maintained by a National Metrology Institute (NMI) such as the National Institute of Standards and Technology (NIST) in the USA. Utility instruments used for routine measurement may also exhibit negligible bias, but calibrated or certified artifact standards are typically run periodically to verify the accuracy of the instrument and to provide a record for quality management or regulatory purposes.

An extensive treatment of the history and development of reference materials for spectrophotometry, as well as current recommendations, has been given in the 50th anniversary publication of the UV Spectrometry Group (UVSG) of the United Kingdom. While NMIs may be credited with designing and distributing spectrophotometric certified reference materials (CRMs) for many years, current trends in fit-for-purpose quality management and multinational commerce favor a more distributed model. The infrastructure for leveraging the production of CRMs into the private sector is supported by the concept of *traceability* as defined by the International Organization for Standardization (ISO) and endorsed by NIST and other NMIs. Producers of CRMs may assert traceability by rigorous documentation of

adherence to the requirement of “an unbroken chain of comparisons, all having stated uncertainties” relating the certified values to “stated references.”

ISO Guide 34 provides a detailed framework for the production of CRMs. The accreditation of a laboratory to this guide for the production of specified CRMs is recognized by ISO as a necessary and sufficient condition for the assertion of traceability of the certified values for those materials. Similarly, ISO Guide 17025 confers the mantle of traceability on absorbance and wavelength calibration measurements on customer-furnished artifact samples.

Fluorescence/Phosphorescence Spectroscopy

Principles of the Technique. Fluorescence/phosphorescence spectroscopy is the study of UV, visible and near infrared (NIR) light that is emitted by a chemical species after it has absorbed light. This absorption of light puts the species into an electronically excited state. The emission wavelengths are usually longer or less energetic than the excitation wavelength. A fluorescence spectrometer or fluorometer is the instrument that is used to measure the intensity of emitted light, or emission, as a function of wavelength. Fluorescence and phosphorescence are the two types of emission activated by light absorption. Fluorescence has a short lifetime (typically 1 ns to 10 ns) and usually arises from an “allowed” transition from an excited singlet state to the ground electronic state. Phosphorescence has a long lifetime (typically 1 ms to 1 s) and usually arises from a “forbidden” transition from an excited triplet state to the ground electronic state. Emission with lifetimes that fall in the range from hundreds of nanoseconds to hundreds of microseconds is not uncommon and may possess characteristics of both fluorescence and phosphorescence. Fluorescence is almost always more intense than phosphorescence, under similar conditions. For the sake of simplicity and space, fluorescence detection will be discussed exclusively in what follows, but much of this discussion also applies to phosphorescence.

Scope and Qualitative Analysis. Fluorescence spectroscopy is a “background-free” technique, meaning that the measured signal should be equal to zero (the lower bound for the signal) if the sample does not fluoresce. The upper bound for the signal is not well-defined, making it very difficult to express fluorescence intensity on a scale that is independent of instrument geometry and excitation intensity (fluorescence intensity is dependent upon the excitation intensity, the absorption coefficient, concentration, quantum yield, and geom-

etry of the sample, the instrument geometry, and the response of the detection system). This is quite different from absorption spectrophotometry, for instance, where the transmittance is measured as the ratio of the light intensity transmitted by the sample versus the light intensity incident upon the sample, the latter intensity being the upper limit. Because of this difficulty in defining the fluorescence intensity scale, few have attempted to compare fluorescence intensities measured by different instruments or even by the same instrument over long periods of time. For most of its history, fluorescence spectroscopy has mainly been used to determine whether or not a particular species is present in an unknown sample. When this technique has been used to quantitate amounts of analyte, it has been done using a calibration curve of fluorescence intensity versus concentration, which is only useful for measuring the particular analyte on the particular instrument on which the curve was obtained. Only in recent years has the need to compare fluorescence intensities and spectral contours taken at different times or on different instruments become crucial in order to ensure compliance with quality and regulatory standards in many key areas where fluorescence detection is used.

Fluorescent species have been detected at low concentrations since the first commercial fluorometers were produced in the 1950s. The high sensitivity of fluorescence detection enables nanomolar concentrations of fluorophores to be detected routinely and single molecules to be detected with more difficulty. In the past, fluorometry was primarily viewed as a research technique due to the fact that few naturally occurring compounds fluoresce. This view has changed dramatically over the past 10 to 15 years due to the synthesis of a long list of fluorescent probes, which have been tailored to bond to an equally large and varied number of analytes. This development has caused fluorescence to become a highly selective detection technique, thereby expanding its scope of use into a broad range of commercial applications. The powerful combination of sensitivity and selectivity of fluorescence-based measurements has fueled the dramatic growth in biotechnology and drug discovery in recent years. Fluorescence detection was used to map the human genome, and is being used to map proteins and the genes of viruses and living organisms. It is also being used by pharmaceutical companies to single out promising drug “leads” in combinatorial chemistry libraries of compounds using microwell plates and microarrays, and in clinical diagnostics to count relative populations of diseased or drug-responsive cells using flow cytom-

etry. In addition, fluorescence detection has important applications in environmental monitoring, where it is used to detect contaminants such as polycyclic aromatic hydrocarbons (PAHs).

Nature of the Sample. The conventional fluorometer is a benchtop instrument with a light source (such as a Xe lamp) and wavelength selector for excitation before the sample, a sample compartment with a mount to hold the sample in the path of the excitation light, and a wavelength selector and detector for emission after the sample. The wavelength selector is usually a monochromator with a range from 200 nm to 800 nm. Fluorescence from liquid samples is measured at a 90° angle relative to the excitation beam using a rectangular cuvette that holds 3 mL to 4 mL. Fluorescence from solid samples is typically collected from the same side of the sample as the excitation beam at an angle of 90° or less with respect to the excitation beam. Portable fluorometers are becoming more popular due to their low cost and ease of use in the field. They commonly use a grating to disperse fluorescence onto a linear, charge-coupled device (CCD) array detector, and a fiber optic is often used to both deliver excitation light to and collect fluorescence from the sample. Portable fluorometers have a broad emission range from 200 nm to 1100 nm, but use a lamp, light-emitting diode (LED) or diode laser without a wavelength selection device for excitation. They are less sensitive and have lower spectral resolutions than benchtop instruments. High-throughput fluorometers – microwell and microarray readers – are designed to measure a large number of samples in a short period of time. Typical sample densities are 1536 wells on a 12.8 cm (L) × 8.5 cm (W) microwell plate and 40 000 spots on a 7.5 cm (L) × 2.5 cm (W) microarray chip. A lamp with a bandpass filter and a monochromatic laser are used for excitation with microwell plate and microarray readers, respectively. Filters with a bandpass of 25 nm or more are used for wavelength selection of emission.

Traceable Quantitative Analysis. Quantitative determinations of fluorescent or fluorescently labeled species are performed most often by first making a plot of fluorescence intensity versus concentration using standard solutions of the species of interest. This plot is typically linear at low concentrations, so it can be fitted to a straight line function. The fitted function can then be used to determine the concentration of an unknown solution by measuring its fluorescence intensity, but a calibration curve of this type is only useful for the instrument on which it was obtained with a fixed

set of instrument parameters and for that one particular species used to obtain the curve. In addition, organic dyes, used to make standard solutions, are difficult to acquire with known purity, and their fluorescence intensity is often environment-dependent, making them less than ideal standards for quantifying fluorescent probe concentrations. As fluorescence-based assays become more and more quantitative, particularly in regulated areas such as clinical diagnostics and pharmaceutical quality assurance, it is essential for fluorescence intensities to be comparable between different instruments and laboratories. This requires fluorometers to be rigorously calibrated.

Fluorometers with a wavelength selection device, such as a monochromator, should first be calibrated for wavelength and bandwidth accuracy for emission and excitation. Then, the fluorescence intensity should be calibrated as a function of emission and/or excitation wavelength, depending on whether the intensity is being measured as a function of one or both wavelength axes. Wavelength and bandwidth accuracy are most commonly calibrated using atomic lamps at the sample and/or source positions. The Raman line of water with a Stokes shift of 3382 cm^{-1} can also be used to calibrate one wavelength axis if the other has already been calibrated.

The fluorescence intensity as a function of wavelength, or the spectral emissivity, can be calibrated relatively (calibrated for spectral shape) or absolutely (calibrated for both shape and absolute intensity). Relative intensity can be calibrated as a function of emission or excitation wavelength using a calibrated light source or a calibrated detector at the sample position, respectively. An absolute calibration is usually done in one of two ways: either by using a calibrated detector at the sample position followed by a calibrated reflector at the sample position, or by using a calibrated light source at the sample position followed by a calibrated reflector at the sample position. The absolute calibration yields a correction factor for intensity as a function of wavelength that enables the bispectral luminescence radiance factor (BLRF) of a fluorescent sample to be determined from its measured fluorescence spectrum. The BLRF is defined as the ratio of the radiance of the fluorescence of a sample versus the excitation irradiance incident on the sample, and is a function of both the excitation and emission wavelengths. A fluorescence spectrum or intensity that is expressed in BLRFs is termed “absolute” because it is not instrument-dependent, only sample-dependent. Material standards supplied with certified values for relative intensity, or better still BLRFs, would

greatly simplify the calibration process, enabling non-experts to calibrate their fluorometers with greater ease and at less expense. Several national metrology institutes are developing certified reference materials of this type, but at present, SRM 936a quinine sulfate dihydrate, a relative intensity standard that effectively covers the emission region from 390 nm to 590 nm, is the only such standard that is commercially available.

Raman Spectroscopy

Principles of the Technique. The Raman effect occurs when a sample is irradiated with intense monochromatic light, usually from a laser. The resulting inelastically scattered light is shifted in frequency due to interactions with the vibrational modes of the chemical sample. Although similar in principle to infrared spectroscopy, quantum mechanical selection rules choose only those vibrational modes that cause the polarizability of the chemical bond to become Raman active. The effectiveness of the bond toward scattering is directly dependent upon the polarizability; polarizability decreases as the electron density increases or the length of the bond decreases. As a result, symmetric vibrational bond stretches are typically Raman active.

The sample to be measured is illuminated with a laser and the resulting scattered light measured with a spectrometer. Raman spectrometers can be either grating or Fourier transform instruments. Because the scattering is very inefficient, typically less than one photon in 10^6 , very efficient filters are required to separate the laser scatter from the Raman spectrum. The invention of holographic notch filters allowed rejection ratios as great as 10^{12} and enabled the use of optically efficient spectrometers coupled with high quantum efficiency detectors. The net result is that Raman spectroscopy, once a strictly academic technique requiring room-filling instrumentation, is now a real-time, suitcase-portable analytical technique.

Scope and Nature of the Sample. Raman spectroscopy is applicable to gases, liquid, and solid samples, and instruments accommodating microsamples as well as bulk chemical samples have been developed. Because the lasers typically used are visible and diode-based, fiber optic sampling is becoming more common and this is facilitating its use in routine qualitative spectroscopy in nontraditional locations. An example is its use on loading docks at pharmaceutical companies to assure the identity of incoming materials. Raman spectroscopy is predominantly a qualitative technique. That is, many applications capitalize on the unique spectrum that each

compound or class of compounds exhibits. It is suitable for the identification of both organic and inorganic materials.

Raman spectroscopy's strengths are that it is non-destructive and requires very minimal, if any, sample preparation. It is also rapid, as the spectra of neat compounds can be acquired in seconds. Water has very weak Raman scatter. Aqueous samples are measurable using Raman in contrast to IR spectroscopy, where water is a major interference. An additional advantage of the technique (over IR) is that very low wavenumber vibrational modes are easily measured. Typical commercial analytical systems allow measurement to 150 cm^{-1} , and some as low as 4 cm^{-1} . IR, in contrast, is limited to at best 500 cm^{-1} . The low-frequency region provides detailed information about crystal structure and is becoming commonly used in the pharmaceutical industry for polymorph characterization.

Raman spectroscopy's weakness is that it is an emission measurement (single beam), and as a result the spectra are highly instrument-dependent. The resulting spectrum is a convolution of the instrument response (due to laser color, optical geometry, fiber optic sampling, and other factors), the scattering characteristics of the sample, and the "true" Raman spectrum of the compound. Because of the complexities of this convolution, all libraries of Raman spectra today are instrument-dependent. Unfortunately, interpreting Raman spectra from first principles is often difficult for the nonspecialist. In addition, Raman spectroscopy is not a trace quantitative analytical technique. For even strongly scattering samples, such as benzene, quantitation of less than 1% by mass of an analyte is difficult. This is due to the noise characteristics of the measurement and also interference. If a sample or its matrix should fluoresce, this "noise" is several orders of magnitude greater than the Raman signal and may make the measurement impossible. This can be alleviated, in part, by switching to longer wavelength lasers, but at the expense of sensitivity. It should be noted though that microscope-based Raman techniques allow the identification of very small quantities of neat materials. Nanogram quantities of organics can be routinely measured, and submonolayer coverage of chemical vapor deposited (CVD) diamond on silicon is a routine measurement for semiconductor manufacturers.

Qualitative Analysis. Raman spectroscopy is primarily a qualitative technique, useful for identifying compounds by their unique spectral features. Unlike infrared spectroscopy, not many Raman libraries exist due to the

instrument-dependent response mentioned previously. Those that have been developed are typically useable at a single excitation wavelength, which to date are predominately Fourier transform (FT) Raman systems operating at 1064 nm. NIST is producing a set of artifact standards that will correct the relative intensity axis of Raman spectrometers operating with a variety of commercially important laser excitation wavelengths. This will enable the production of instrument-corrected libraries, allowing their use on differing systems.

Traceable Quantitative Analysis. Quantitative analysis by Raman spectroscopy is a growing practice, but still rare compared to its use for qualitative analysis. Similar to absorbance-based techniques, the Raman emission scattering from a vibrational mode is proportional to the concentration of the analyte. Standard addition and internal standard techniques have been used for quantitative analysis. Recently, however, the use of multivariate statistical techniques is becoming more common for quantitative work with Raman. This method uses a series of spectra of known analyte concentrations to “train” a calibration model. The spectrum of an unknown sample is then compared to the training set utilizing a variety of regression-based statistical techniques. Because the full spectrum of the analyte may be used, high precision – and in some cases lower limits of quantitation – may be obtained with these methods than with similar univariate (Beer’s law) type calibrations.

Example Spectrum. A Raman spectrum of cyclohexane is shown in Fig. 4.1. The x -axis is in Raman shift units, expressed as the difference between the absolute

wavenumber frequency of the band and the excitation laser. This practice is observed to make the spectra appear similar to infrared spectra. The upper spectrum was acquired using 785 nm laser excitation and is uncorrected for instrument response. The lower spectrum is corrected for instrument response. As can be seen, the C–H stretching region (3300 cm^{-1} to 2600 cm^{-1}) is greatly affected by the system response.

Infrared Spectroscopy

Principles of the Technique. The infrared (IR) region of the spectrum spans from approximately 750 nm to $300\text{ }\mu\text{m}$, or in wavenumbers roughly from $13\,000\text{ cm}^{-1}$ to 33 cm^{-1} . Radiation is absorbed in this spectral region when its frequency matches a vibrational mode of the chemical sample. Quantum mechanical selection rules dictate that only those modes of the molecule that undergo a change in dipole moment will absorb in the infrared. Vibrational modes of homonuclear and/or linear molecules such as Cl_2 or N_2 do not show a net change in charge distribution and thus are not IR-absorbing. Molecules that contain heteroatomic substituents or have nonsymmetric vibrational modes are IR active due to the net charge density change. Carbonyl groups are an example.

In IR spectroscopy the sample to be measured is illuminated with a broadband IR source. The resulting IR spectrum is measured with an IR spectrometer. These spectrometers may be either grating-based or Fourier transform (FT) instruments, although in the last ten years FT instruments have all but replaced the dispersive systems due to their many advantages (speed, sensitivity, signal-to-noise ratio, and cost). As the IR range spans a very large wavelength/wavenumber range, material constraints of the optics comprising the spectrometer, such as the beam splitter, detector sensitivity, and so on, limit the range of typical IR spectrometers from 6000 cm^{-1} to 660 cm^{-1} . This is not viewed as a major limitation, as this range covers the entire fundamental vibrational mode space for most organic molecules.

Scope and Nature of the Sample. Infrared spectroscopy is applicable to gases, liquids and solid samples. Instruments accommodating microsamples as well as bulk chemical samples have been developed. With the advent of 2-D focal plane detectors, chemical mapping is becoming more widespread. Compositional mapping has applications in analytical chemistry and in health-related areas such as pathology and forensics.

The technique’s strengths are many. It is highly sensitive due to the nature of the absorbance, and micro-

Fig. 4.1 Raman spectroscopy. *Upper:* Raman spectrum of cyclohexane uncorrected for instrument response; *Lower:* Raman spectrum of cyclohexane corrected for instrument response

gram quantities of neat material are readily measured with excellent sensitivity. The instrumentation is relatively inexpensive and easily used by the nonspecialist. Because the technique is absorbance-based (based on a transmittance ratio), all spectra look alike on all spectrometers, unlike emission techniques such as Raman spectroscopy. As a result, a large number of spectral libraries exist. Specialized IR libraries include polymers, pharmaceuticals, forensic materials, drugs, explosives, pesticides, chemical warfare agents – the list is essentially endless. In fact, several commercial libraries comprise more than 220,000 spectra. Arguably, IR is the second most useful identification technique behind mass spectrometry, with much less sample preparation required. It is, in principle, nondestructive to the sample, and has been paired with other analytical techniques to provide additional information. Examples include gas chromatography–infrared (GC-IR) and thermal gravimetric analysis–infrared (TGA-IR).

The weakness of IR spectroscopy is in fact due to the high absorbance of the vibrational modes of chemical bonds. Neat compounds will typically completely absorb portions of the IR spectrum unless the optical pathlength through the sample is kept below 100 μm . This requires the use of expensive and difficult-to-maintain optical cells, the materials of which are limited to inorganic salts (such as KBr or NaCl) or expensive semiconductor-type materials. Glass or quartz – commonly used for UV/vis, Raman or fluorescence spectroscopy – are not appropriate as they completely absorb all IR radiation. In addition, water cannot be used as a solvent for similar reasons. Water vapor can be a significant interference, which requires a dry nitrogen purge of the spectrometer. All the above require significant time for sample preparation, and significant skill may be required of the operator.

Qualitative Analysis. IR is most commonly used to identify chemical samples, as the IR spectrum of a compound represents one of its truly unique physical properties. No two compounds have identical IR spectra, with the exception of optical isomers. As mentioned, sample dilution/preparation can be difficult for traditional transmission measurements. However, an array of new sampling techniques enable acquisition of the IR spectra of intact samples. Attenuated total reflectance utilizes the principle of frustrated total internal reflectance to control the depth of penetration into sample. One micrometer sample pathlengths are easily achieved and highly scattering/absorbing samples such as cloth, oil or even foods such as peanut butter are readily measured.

Fig. 4.2 Infrared spectroscopy: IR spectrum of benzene

New polytetrafluoroethylene (PTFE, Teflon) polymer cards allow liquid samples to be smeared onto disposable cards for transmission measurements, eliminating the need for expensive and delicate salt windows.

Traceable Quantitative Analysis. Infrared spectroscopy may be used for quantitative analysis, but it is only infrequently used in this way compared to UV/Vis transmission measurements due to the difficulty in maintaining similar cell pathlengths for the sample and reference cells. The tolerance required would be on the order of 1 μm or less. When IR is used for quantitative analysis, typically the internal standard or standard addition methods are used to relate the sample concentration to the band area (or height). NIST produces one SRM appropriate to IR spectrometry. SRM 1921 is a wavelength calibration standard useful for both dispersive and FT instruments.

Example Spectrum. An example infrared spectrum of benzene is displayed in Fig. 4.2.

Quantitative Proton Nuclear Magnetic Resonance Spectroscopy – ^1H QNMR

Principles of the Technique. When a nucleus with a nonzero spin quantum number is placed in a homogeneous external magnetic field, the spin of the nuclear charge creates a magnetic dipole that aligns itself in specific orientations with the external field. The quantum spin number of the nucleus (I) determines the number of these orientations ($2I+1$), and the energy difference between them is $B_0 h \gamma / 2\pi$, where B_0 is the bulk magnetic field strength, h is Planck's constant, and γ is the magnetogyric ratio, a fundamental constant for each type of magnetically active nucleus. For protons (^1H),

Table 4.1 Properties of commonly observed NMR-active nuclei

Nucleus	Resonance at 14.09 T (MHz)	Spin number (I)	Natural abundance (%)	Relative sensitivity	Abundance × sensitivity
¹ H	599.944	1/2	99.984	1.000	99.984
¹⁹ F	564.511	1/2	100	0.834	83.4
³¹ P	242.862	1/2	100	0.0664	6.64
¹³ C	150.856	1/2	1.108	0.0159	0.018
²⁹ Si	119.192	−1/2	4.7	0.00785	0.037
² H	92.095	1	0.0156	0.00964	0.00015
¹⁵ N	60.815	−1/2	0.365	0.00104	0.00038

I equals $\frac{1}{2}$, so there are two states with a slight population excess in the lower state. Transitions between the lower energy state and higher level state can be effected by applying radiofrequency radiation (RF) at the Larmor or resonance frequency equal to $B_0\gamma/\pi$. At resonance, the nuclei undergoing the transition absorb energy from the RF that is detected and measured. The RF can be introduced either by continuous wave (CW) scanning (holding the bulk field constant and scanning the RF or vice versa) or by applying an RF pulse. At resonance, the magnetic dipoles not only transit from the low to the higher energy state, but also the phases of their spins synchronize (phase-up) to establish a net magnetization. When the resonance condition is removed, the nuclear spin system reverts to its thermodynamically normal state by first-order rate processes. The means by which the energy state population distribution is re-established is called the spin–lattice relaxation, with a rate constant of $1/T_1$, while the spin dephasing mechanism is called spin–spin relaxation, with a rate constant of $1/T_2$.

The magnetic environments of each of the same nuclei in a molecule are often slightly different depending on the molecular and electronic configurations, and this gives rise to slightly different resonance frequencies and forms the basis for a chemical shift scale that is very useful for identifying the structural environments of atoms in the molecule. Furthermore, the magnetic environment of a given nucleus can be influenced by that of other nearby nuclei, causing a further splitting of the energy levels depending on whether the adjacent dipoles are aligned or opposed. These splitting patterns (or couplings) are used to determine the number and type of the nearest neighbor nuclei in a molecule and their orientations. The resonance frequencies for different types of nuclei are often widely separated (megahertz apart), whereas the chemical shift range for a given nucleus is smaller (kilohertz), and the splitting differences are smaller still (hertz).

Modern NMR spectrometers use superconducting solenoids to provide the bulk magnetic field. While these instruments could be operated in the CW mode, it has proved much more efficient to operate them where the RF is provided through a brief (μ s) RF pulse. This excites all of the nuclei simultaneously, and the resulting signals (the free-induction decay or FID) are collected digitally in the time domain (intensity versus time) and then converted to the frequency domain (intensity versus frequency) by Fourier transformation. The signal-to-noise ratios (S/N) of such measurements are improved by collecting and time-averaging multiple FIDs prior to Fourier transformation. The S/N improves by the square root of the number of FIDs collected, provided all of the nuclei have fully relaxed between pulses.

Scope. While there is a wide range of NMR-active nuclei, only a handful are commonly used. Fortunately, isotopes of the most common atoms in organic molecules are in this category. ¹H is the most commonly observed nucleus due to its large natural abundance and high relative sensitivity. Other commonly utilized nuclei are shown in Table 4.1.

Nature of the Sample. High-resolution NMR spectra are most commonly collected from liquid samples or materials in solution. Sample sizes range from micrograms to hundreds of milligrams. NMR spectra of solids can be obtained. However, special techniques involving spinning the sample very rapidly about an axis specifically oriented to the bulk field (at the “magic angle”) are necessary to narrow the lineshapes. The NMR process is nondestructive, so samples can be recovered. To avoid interferences, solvents devoid of the nuclei being observed are often employed. For ¹H NMR, deuterated solvents are commonly used. The NMR signals from the deuterium nuclei are also utilized in a separate detection channel to provide a field-frequency lock to stabilize the

spectrometer, as it is necessary to maintain the field-frequency ratio to better than 1 part in 10^9 for modern instruments. Commonly, a small amount of a standard is added along with the solvent to provide a chemical shift reference. Tetramethylsilane (TMS) is often used for this purpose in ^1H , ^{13}C and ^{29}Si spectra.

Qualitative Analysis. The chemical shift differences between the various nuclei and the internuclear couplings in a molecule can be used to determine the atomic interconnections in a molecule. The number and chemical type of the observed nuclei can also be determined. Often, only a single structural configuration will fit the spectrum, making it easy to differentiate isomers. Molecular conformations and components of mixtures can also be determined. Even enantiomers can be determined if the molecule of interest interacts with a chiral solvent or another material to form a diastereomer. The direction and extent of chemical reactions can be monitored. Rates of configurational, conformational, or tautomeric interchange in molecules can be studied, providing they fall within the NMR timescale (reciprocal of chemical shift difference in Hz between the signals of the forms).

Traceable Quantitative Analysis. The area under the NMR peaks (the integrated resonance intensity of the NMR signal) is directly proportional to the concentration of the nuclei giving the resonance. If the experiment is done properly, the proportionality constant is the same for each resonance in the spectrum. Therefore, the ratio of peaks due to different materials in a sample gives the molar ratio of the materials once the peak integrals are corrected for the number of equivalent nuclei present for each resonance. Relative concentrations can be determined directly from the relative peak areas.

$$\frac{C_t}{C_n} = \frac{\frac{I_t}{N_t}}{\frac{I_n}{N_n}} \quad (4.3)$$

Equation (4.3) describes the determination of relative concentration by QNMR where: C_t = concentration of test material; C_n = concentration of other material; I_t = integral of test material signal; N_t = relative number of nuclei responsible for test material signal; I_n = integral of other material signal; N_n = relative number of nuclei responsible for other material signal.

If each resonance in the spectrum can be accounted for and assigned to a specific molecule, then molar purity can be determined without the need for standards, assuming, of course, that all of the impurities

are observable:

$$\text{mole\% } P_t = \frac{\frac{I_t}{N_t}}{\sum \frac{I_n}{N_n}} 100, \quad (4.4)$$

Here P_t = purity of the test material; I_t = integral of test material signal; N_t = relative number of nuclei responsible for test material signal; I_n = integral of other signals; N_n = relative number of nuclei responsible for other signals.

If the molecular mass of each material is known, then the molar purities can be converted into the more useful mass-based purities by multiplying each by its molecular mass and dividing by the sum of the respective masses. If this cannot be established for a given mixture, then an internal standard procedure can be utilized to determine absolute purities where a known amount of an internal standard material is added to a solution containing a measured amount of the test material.

$$\text{mass\% } P_t = \frac{I_t N_s M_t W_s}{I_s N_t M_s W_t} P_s 100, \quad (4.5)$$

Here: P_t = purity of the test material; I_s = integral of standard; I_t = integral of test material; N_s = relative number of nuclei responsible for standard signal; N_t = relative number of nuclei responsible for test material signal; M_s = molecular mass of standard; M_t = molecular mass of test material; W_s = mass of standard; W_t = mass of test material; P_s = purity of standard.

Several key conditions must be met for accurate QNMR determinations. Spectral signal-to-noise ratio and resolution should be optimized. To avoid effects due to relaxation of the NMR signals, the T_1 of each nucleus in the sample should be known, and either the RF pulse width or delay time between pulses should be adjusted to ensure sufficient time for full relaxation between acquisitions. Since the frequency width covered by the RF pulse is inversely related to the pulse width, care should be taken to ensure that nuclei at the extreme ends of wide spectral widths receive similar excitation intensities. The “skirts” of Lorentzian-shaped NMR signals extend to infinity, so care must be taken when comparing the integrals of peaks with very different peak widths. ^1H NMR spectra are complicated by signals due to coupling of the proton signals with the 1.1% of ^{13}C nuclei naturally present in organic materials. These signals must be treated consistently – either always integrated with the main signal or always omitted. Spectra acquired at higher fields help in this regard because chemical shifts (expressed in hertz) increase in proportion to the magnitude of the bulk field, whereas coupling constants (also in hertz) remain constant. Sidebands due to modulation

caused by spinning the sample tube are best avoided by obtaining the spectrum in nonspinning mode with careful shimming (adjustment of the magnetic field homogeneity) to maintain resolution. For best results, only the highest grade solvents should be used in QNMR, although a spectrum of the solvent only (blank spectrum) can sometimes be used to correct for some solvent impurities. Vigilance in sample preparation is needed to avoid adventitious interferences. Sample tubes should be cleaned, then rinsed with the NMR solvent, and dried at 140°C overnight prior to use. All transfer tools (pipettes, spatulas, and so on) must be scrupulously clean. At no time should the sample solution come into contact with the NMR tube cap or septum, as just a single contact can result in the extraction of sufficient plasticizers, surfactants and other contaminants from these materials to render a sample useless for QNMR. Similarly, touching a pipette or syringe needle with bare hands can result in the introduction of observable squalene and other components of body oil into the sample. It is common practice to make up the analytical solution in the NMR tube itself, as this minimizes inadvertent contamination. When this is done, and when accurate weighings are required (such as when using the internal standard method), care must be used to avoid weighing errors due to static charges on the tube. Commercially available radioactive sources can be used to minimize such static effects. Nevertheless, uncertainties in weighing are likely to dominate the error equation. The requirements and attributes of appropriate internal standard materials have been well-documented, but it should be apparent from (4.5) that the purity of the internal standard material and its uncertainty are key parameters. Finally, the NMR signals used for quantitation should be immune to chemical exchange. For ^1H NMR, this often means avoiding signals due to protons bound to oxygen and nitrogen.

With modern NMR spectrometers, optimal ^1H QNMR can be routinely carried out with detection and quantitation down to the 0.01% mass-fraction level with uncertainties (U_{95}) in the 0.5% to 1.0% range. In many cases, the detection and quantitation limits can be reduced by an order of magnitude by spending additional time on the data collection. High-field, state-of-the-art spectrometers with cryogenically cooled probes and preamplifiers can extend the useable detection and quantitation limits by another factor of four. While these limits do not begin to impinge on the ultimate sensitivities of other analytical techniques, such as mass spectrometry or fluorescence spectrometry, the use of QNMR for moderate trace-level determinations

is on the increase. The coupling of NMR with chromatographic separation techniques further increases its utility.

4.1.3 Atomic Spectrometry

[4.35–49]

Atomic Absorption Spectrometry (AAS)

Principles of the Technique. The sample being analyzed is decomposed to free atoms and ions in a high-temperature flame or furnace. These atoms absorb light emitted at atomic resonance wavelengths from a hollow cathode discharge lamp with a cathode containing the analyte element. The optical absorbance is measured, and through Beer's Law is proportional to concentration.

The most common atomizer is the premixed air–acetylene flame. Measurement of refractory elements requires the use of the hotter N_2O –acetylene flame. Better sensitivity is obtained using an electrically heated furnace referred to as an electrothermal atomizer or graphite furnace. The longer residence time of atoms within the beam of hollow cathode emission yields improved sensitivity in comparison to flame atomizers.

Scope. AAS is used for quantitative elemental analysis, in other words for the determination of total concentrations of specific elements in a sample. It is commonly used for the analysis of environmental samples, industrial materials such as metal alloys, clinical or industrial hygiene measurements, and others. In general, flame AAS can be used for solution concentrations in the 10 mg/L to 100 mg/L range, and electrothermal AAS in the 1 $\mu\text{g/L}$ to 100 $\mu\text{g/L}$ range. AAS cannot be used for the determination of nonmetallic elements.

The instrumentation is generally less expensive than other forms of elemental analysis. In the vast majority of cases, only a single element can be measured at a time. The hollow cathode lamp must be changed to one of a different element before that element can be detected. Consequently, measurement times can be impractically long if multi-element information is required. Flame instrumentation requires training to use safely, and fumes must be exhausted.

Nature of the Sample. With few exceptions, samples are introduced into the flame or electrothermal atomizer as solutions. If the sample being analyzed is a solid, it must first be dissolved. A typical dissolution will dissolve a gram of sample in 100 mL of acidified aqueous

solution. Dissolution of most samples will require hot concentrated mineral acids.

Qualitative Analysis. AAS is not typically used for qualitative analysis. The specificity (or identification) of the analyte element is provided by the atomic resonance wavelength emitted by the hollow cathode lamp.

Traceable Quantitative Analysis. AAS instrumentation must be calibrated using solutions containing known concentrations of the analyte element. Such calibration solutions are available from many commercial suppliers. These solutions are often traceable to one of a set of NIST single-element solution Standard Reference Materials. Many AAS analyses are susceptible to matrix effects (the combined effect that the constituent species present in the sample have on the atomic absorption signal of the analyte). This will lead to measurement bias if the calibration solutions are not matched to the matrix of the sample being analyzed. The method of standard additions is an effective strategy for dealing with matrix effects. Another common source of bias is broadband molecular absorption resulting from matrix elements that are not fully atomized, or scattering of the hollow cathode beam by small particles. Most instruments utilize one of several background correction procedures to deal with such interferences. Certified reference materials are available in a wide variety of sample matrix types from NIST and other sources. These CRMs should be used to validate AAS methods.

Inductively Coupled Plasma Atomic Emission Spectrometry (ICP-AES)

Principles of the Technique. The inductively coupled plasma (ICP) used in this technique is an atmospheric-pressure argon plasma that is produced in a quartz torch connected to a radiofrequency generator. Operating RF powers are typically between 1000 W and 1500 W. The aqueous liquid sample solution is injected as an aerosol into the axial channel of the ICP, where temperatures on the order of 7000 K prevail. Here the sample is decomposed to free atoms and ions, and atomic or ionic emission results as thermally populated excited states of valence electrons of the atoms or ions return to lower energy levels. A suitable optical transfer system, a monochromator or polychromator, and a detector selectively and quantitatively measure the relative emission intensities at specific analytical wavelengths. The emission intensity at an elemental emission wavelength is used as a relative measure of the concentration of that

element in the sample. The method is sometimes referred to as ICP optical emission spectrometry (ICP-OES).

Scope. ICP-AES is used for quantitative elemental analysis; in other words to determine the total concentrations of specific elements in a sample. Typical application areas include metallurgy, geological measurements, environmental monitoring, food analysis, the measurement of additives or wear metals in oil, and forensics. In general, ICP-AES is used for solution concentrations in the 1 mg/L to 100 mg/L range. Some nonmetallic elements (S, P) can be measured.

The instrumentation is generally more expensive than AAS, but unlike AAS it has the significant advantage of being able to detect multiple elements simultaneously. This results in significant time savings if multielement analysis is required. It is generally less expensive than ICP-MS.

Nature of the Sample. In the most common situations, samples are introduced into the ICP as solutions. If the sample being analyzed is a solid, it must first be dissolved. Typically, 1 g of sample is dissolved in 100 mL of acidified aqueous solution. The dissolution of samples often requires hot concentrated mineral acids.

An alternative sample introduction system uses laser ablation of solid samples to generate an aerosol of sample particles, which can be injected directly into the ICP.

Qualitative Analysis. Specific elements are identified via the known wavelengths of atomic emission lines.

Traceable Quantitative Analysis. For systems using solution sample introduction, ICP-AES instrumentation must be calibrated using solutions containing known concentrations of the analyte elements. Such calibration solutions are available from many commercial suppliers. These solutions are often traceable to one of a set of NIST single-element solution Standard Reference Materials. The analysis of complex samples can be susceptible to matrix effects (the combined effect that the constituent species present in the sample has on the atomic emission signal of the analyte). This will lead to measurement bias if the calibration solutions are not matched to the matrix of the sample being analyzed. The method of standard additions is an effective strategy for dealing with matrix effects.

Calibrating systems using laser ablation sample introduction is more difficult. The laser ablation process is very matrix-dependent, and calibration requires the

use of solid standards that match the characteristics of the sample quite closely. A measurement of the ratio of the analyte emission relative to a matrix emission line is often used in some form to improve accuracy and precision.

Spectral interference from the argon plasma emission or sample matrix components is another potential source of bias. Most systems utilize some form of spectral background correction to deal with such interferences. Certified reference materials are available in a wide variety of sample matrix types from NIST and other sources. These CRMs should be used to validate ICP-OES methods.

Spark Optical Emission Spectrometry (Spark OES)

Principles of the Technique. A high-voltage spark is generated from a cathode in an argon atmosphere to a conducting sample which acts as the anode. The sample is melted and atomized and the free atoms are excited to yield atomic emission. A suitable optical transfer system, polychromator, and detector selectively and quantitatively measure the relative emission intensity at specific analytical wavelengths. The emission intensity at an elemental emission wavelength is used as a relative measure of the concentration of that element in the sample. The method is sometimes referred to simply as optical emission spectrometry (OES) or as spark atomic emission spectrometry.

Scope. The analysis of metals is the major application area of spark OES. Tens of thousands of spark OES instruments are installed in large steel mills, aluminum smelters, and casting operations, as well as small forges and small foundries. Measurements are made for quality control, raw material testing and research. Speed of analysis, without the need for sample dissolution, is the major advantage of spark OES over ICP-OES.

Nature of the Sample. Metal samples may need to be ground flat to form a good electrode. Powders can be mixed with graphite and pressed to form a flat surface.

Qualitative Analysis. Specific elements are identified via the known wavelengths of atomic emission lines.

Traceable Quantitative Analysis. The spark sampling and excitation process is very complex and matrix-dependent. Calibration is done using large sets of Certified reference materials selected to match the type of sample to be analyzed.

As with any spectroscopic measurement, spectral interference from the sample matrix components or the spark source is a potential source of bias. Most systems utilize some form of spectral background correction to deal with such interferences.

An individual spark lasts only several microseconds, and will vaporize less than a microgram of sample. Sample inhomogeneity can impede accurate analysis of the bulk sample. Analyses are based on multiple sparks from different locations on the sample.

Glow Discharge Optical Emission Spectroscopy (GD-OES)

Principles of the Technique. A glow discharge is a reduced-pressure inert gas plasma maintained between two electrodes. Argon is typically used at absolute pressures of between a few hundred Pascals and about 2.5 kPa, and the solid sample serves as the cathode in the circuit. When the discharge is ignited, Ar^+ ions formed in the plasma are accelerated toward the sample surface by means of electric fields. At least a substantial fraction of these Ar^+ ions strike the surface of the sample with enough kinetic energy to eject sample atoms from the surface. In this way, the solid sample is directly atomized. Once in the plasma, sputtered atoms may be electronically excited through collisions with energetic electrons and other particles. Some fraction of the excited sputtered atoms will relax to lower electronic energy levels (often the ground state) by means of photon emission. The wavelengths of these photons are characteristic of the emitting species. A grating spectrometer, with either photomultiplier tubes (PMTs) mounted on a Rowland circle, or one or more charge transfer devices (CTDs), is used to measure the intensity of the plasma emission at specific wavelengths. In this way, the elemental constituents of the solid sample can be quantitatively estimated.

A significant number of GD-OES instruments have been available commercially from several manufacturers for many years. The instruments that are currently available vary in both capabilities and costs. An instrument for a specific and routine application can be obtained for as little as \$60 000, whereas a “fully loaded” research instrument may cost in excess of \$200 000. There are currently more than 1000 GD-OES instruments in use around the world.

Scope. Glow discharge devices used in GD-OES may be powered by either a DC or RF power supply. In DC-GD-OES, the sample must be electrically conductive, since current must pass through it. RF-GD-OES overcomes

this restriction, because in this configuration it is not necessary for net current to flow through the sample. As a result, RF-GD-OES can be applied to both electrically conductive and insulating samples.

GD-OES has traditionally been applied to bulk analysis of solids, and it is still routinely used for this purpose. More recently, GD-OES “depth profiling” (the determination of elemental composition as a function of depth) has begun to mature. In GD-OES depth profiling, registration of emission intensities over time as surface layers are “sputtered” away produces the “depth profile” of the sample. Algorithms exist to convert the resulting intensity versus time plot into elemental mass fraction versus depth. While much development remains to be done, GD-OES depth profiling is already being fairly widely applied for analyses of both electrically conductive and insulating layers on either electrically conductive or insulating substrates. Probably the widest application to date has been the analysis of galvanized coatings on steel. However, depth profiling of other sample types, such as thin films (<10 nm thickness) and organic coatings, is being demonstrated. While bulk analysis will likely remain an important application of GD-OES, the brighter future of the technique lies in the depth profiling arena.

Some strengths of GD-OES include a relative lack of interferences and matrix effects compared to many other direct solid techniques (such as spark OES and secondary ion mass spectrometry, or SIMS). Also, limits of detection are useful for many applications (sub- to low parts per million range directly in the solid state). The ability to detect H, O and N is also an advantage. An important disadvantage is that GD-OES is inherently a “relative” technique, requiring reference materials for calibration.

Nature of the Sample. As described above, GD-OES is applicable to bulk and depth profiling analyses of electrically conductive and insulating solid samples. The RF mode is required when insulating samples are involved. Analyzed surfaces are usually flat, although special sample holders can be used for surfaces of different shapes (such as tubing).

Qualitative Analysis. Calibration of a GD-OES instrument consists of measuring emission intensities for suitable reference materials and calculating a calibration equation. Qualitative analysis can be performed without calibration, simply by noting the elemental wavelengths at which signals exist. Owing to the prominent lack of certified mass fractions for H, O and N in reference

materials, GD-OES is often capable of only qualitative determinations of these nonmetallic elements.

Traceable Quantitative Analysis. Quantitative GD-OES analyses are accomplished through calibration with suitable reference materials. Accuracies improve with the level of matrix-matching of the calibrants to the unknowns. Mass fraction biases on the order of 1% relative are usually found for major and minor elements, while those observed at mass fractions below $100 \mu\text{g g}^{-1}$ are normally higher (for example, >15% relative). The accuracy of the depth axis obtained in GD-OES depth profiling may vary widely, depending upon the circumstances, but can be as good as $\pm 5\%$ relative. Whether bulk analysis or depth profiling is performed, traceability to the SI is accomplished through calibration with reference materials.

X-Ray Fluorescence (XRF)

Principles of the Technique. The specimen to be analyzed can be solid (powder or bulk) or liquid (aqueous or oil-based). It is placed in an instrument and irradiated by a primary X-ray source or a particle beam (electrons or protons). The primary radiation is absorbed and ejects electrons from their orbitals. Relaxation processes fill the holes and result in the emission of characteristic X ray radiation. The intensity of characteristic radiation that escapes the sample is proportional to the number of atoms of each element present in the specimen. Therefore, XRF is both qualitative, using the “fingerprint” of characteristic X rays to identify constituent elements, and quantitative, using a counting process to relate the number of X rays detected per unit time to the total concentration of the element.

X-ray fluorescence spectrometers are available in a number of designs suited for a variety of applications and operating conditions. State-of-the-art laboratory spectrometers are typically designed as wavelength-dispersive spectrometers with a high-power tube source and a high-resolution detection system comprised of collimators or slits, a set of interchangeable crystals to diffract the characteristic X rays according to Bragg’s equation, and two or more detectors mounted on a goniometer with the crystals. Lower-cost, lower-power spectrometers consist of either smaller wavelength-dispersive spectrometers with low-power tube sources or energy dispersive spectrometers using solid-state detectors and low-power tubes or radioisotope sources. Some energy-dispersive spectrometers use beams of electrons or protons as the primary radiation source. There are even handheld units designed for field use. Given the

wide variety of instruments, prices range from \$25 000 to \$300 000.

Scope. *XRF* is used for quantitative elemental analysis, typically without regard to the chemical environment of the elements in the specimen. It is a relative technique that must be calibrated using reference materials. X rays from one element are absorbed by other elements in the specimen possibly resulting in fluorescence from those other elements. Due to these matrix effects, the best performance is obtained when the calibrant(s) are similar in overall composition to the specimen. A number of sophisticated procedures are available to compensate for matrix effects including empirical and theoretical calibration models. It is possible to obtain composition results using just theory and fundamental parameters (basic physical constants describing the interactions of X rays with matter); however, the quality of such results varies widely. *XRF* measurements are also influenced by the physical nature of the specimen including particle size or grain size, mineralogy, surface morphology, susceptibility to damage by ionizing radiation, and other characteristics.

XRF is often referred as being nondestructive because it is possible to present specimens to the instrument with little or no preparation, and with little or no damage resulting from the measurement. However, X rays cause damage at a molecular level and are not truly nondestructive, especially to organic matrices. Still, in many cases (the best example being alloys), specimens may be analyzed for other properties following *XRF* analysis.

XRF is at its best for rapid, precise analyses of major and minor constituents of the specimen. Spectrometers can be used for concentrations ranging from approximately 1 mg/kg to 100% mass fraction. Analyses are accomplished in minutes and overall relative uncertainties can be limited to 1% or less. *XRF* is widely used for product quality control in a wide range of industries including those involving metals and alloys, mining and minerals, cement, petroleum, electronics and semiconductors.

Trace analysis is complicated by varying levels of spectral background that depend on spectrometer geometry, the excitation source, the atomic number of the analyte element, the average atomic number of the specimen, and other factors. Trace analysis below 1 mg/kg is possible using specially designed spectrometers, such as total reflection *XRF*, and destructive sample preparation techniques similar to other atomic emission.

Qualitative Analysis. *XRF* is uniquely suited for qualitative analysis with its (mostly) nondestructive nature and sensitivity to most of the periodic table (Be through U). Characteristic X-rays from each element consist of a family of lines providing unambiguous identification. Energy-dispersive spectrometers are especially well-suited for qualitative analysis because they display the entire spectrum at once. For the purpose of choosing the optimum measurement conditions, qualitative analysis is performed prior to implementation of quantitative analysis methods.

Traceable Quantitative Analysis. *XRF* spectrometers must be calibrated to obtain optimum accuracy. The choice of calibrants depends on the form of the specimens and the concentration range to be calibrated. Using destructive preparation techniques such as borate fusion, calibrants can be prepared from primary reference materials (elements, compounds and solutions) and the results are traceable to the SI provided the purity and stoichiometry of the reference materials are assured. The caveat is that calibrants and unknowns must be closely matched in terms of their entire composition. The same can be accomplished for liquid materials when calibrant solutions are sufficiently similar in matrix to the unknowns.

In cases where a variety of calibrants with varying degrees of comparability to the unknowns must be used, it is necessary to apply matrix corrections. The preferred approach is to use theory and fundamental parameters to estimate the corrections. Still, some number of calibrants in the form of reference materials must be used to calibrate the spectrometer. Traceability is established through the set of reference materials to the issuing body or bodies.

Alternatives to matrix correction models are internal standards, internal reference lines and standard additions. Of course, these apply only under the appropriate circumstances in which the material to be analyzed can be prepared in some manner to incorporate the spiking material.

4.1.4 Nuclear Analytical Methods

Additional discussions of X-ray Techniques are described in the Charged Particle Techniques (4.1.4) and in Microanalysis Techniques (4.2) [4.50–72].

Neutron Activation Analysis (NAA)

Neutron activation analysis (*NAA*) is an isotope-specific, multielemental, analytical method that deter-

mines the total elemental content of about 40 elements in many materials. The method is based on irradiating a sample in a field of neutrons, and measuring the radioactivity emitted by the resulting irradiation products. Typically a nuclear reactor is used as the source of neutrons, and germanium-based semiconductor detectors are used to measure the energy and intensity of the gamma radiation, which is then used to identify and quantify the analytes of interest. **NAA** is independent of the chemical state of the analytes, since all measurement interactions are based on nuclear and not chemical properties of the elements. In addition, both the incoming (excitation) radiation (neutrons) and the outgoing radiation (gamma rays) are highly penetrating. Due to the above characteristics, there are very few matrix effects and interferences for **NAA** compared to many other analytical techniques. **NAA** can be applied in nondestructive or “instrumental” (INAA) mode, or in a destructive mode involving dissolution and/or other chemical manipulation of the samples. The most common form of the latter mode is radiochemical **NAA** (RNAA), where all chemical processing is done after the irradiation step. Both INAA and RNAA are essentially free from chemical blank, since after irradiation, only the radioactive daughter products of the elements contribute to the analytical signal. In fact, for most RNAA procedures, carriers (stable forms of the elements under investigation) are added to the samples after irradiation to enhance separation and minimize losses. The amount of carrier remaining after separation can be measured to determine the chemical yield of each sample when separations are not quantitative. In other cases, a small amount of a radioactive tracer of an element under investigation can be used to determine the chemical yield.

Principles of the Technique. Most elements have one or more isotopes that will produce a radioactive daughter product upon capturing a neutron. Samples are irradiated for a known amount of time in a neutron field, removed, and then subjected to a series of gamma-ray spectrometry measurements using suitable decay intervals to emphasize or suppress radionuclides with different half-lives. Spectra of gamma-ray intensity versus energy (typically from about 70 keV to 3 MeV) are collected. For RNAA measurements, virtually any type of separation procedure can be applied after irradiation. Radionuclides are identified by both their gamma-ray energy (or energies) and approximate half-lives.

Elemental content in a sample is directly proportional to the decay corrected gamma-ray count rate if irradiation and gamma-ray spectrometry conditions are

held constant. The decay-corrected count rate (A_0) is given in (4.6)

$$A_0 = \frac{\lambda C_x e^{\lambda t_1}}{(1 - e^{-\lambda \Delta})(1 - e^{-\lambda T})}, \quad (4.6)$$

where:

- A_0 = decay-corrected count rate,
- λ = decay constant = $\ln 2/t_{1/2}$,
- Δ = live time of count,
- C_x = net counts in γ -ray peak,
- t_1 = decay time to start of count,
- T = irradiation time.

Scope. This method is useful for elements with isotopes that produce radioactive daughter products after neutron irradiation and decay by gamma-ray emission. Although approximately 75 elements meet these criteria, typically 30 to 45 elements can be quantified instrumentally in most samples. Low-intensity signals can be lost in the continuum of background noise of the gamma-ray spectra (unless radiochemical separations are employed to isolate elements of interest). Detection limits vary by approximately six orders of magnitude for INAA, and depend mainly on the nuclear properties of the elements, as well as experimental conditions such as neutron fluence rate, decay interval, and detection efficiency of the gamma-rays of interest.

Nature of the Sample. Samples of interest are encapsulated in polyethylene or quartz prior to irradiation. Typical sample sizes range from a few milligrams to about a gram, although some reactor facilities can irradiate kilogram-size samples. Because of the highly penetrating nature of both neutrons and gamma-rays, the effects of sample sizes of up to a gram are minimal unless the sample is very dense (metals) or contains large amounts of elements that are highly neutron-absorbing (B, Li, Cd, and some rare earths). Smaller sample sizes are needed for dense or highly neutron-absorbing samples. The presence of large amounts of elements that activate extremely well, such as Au, Sm, Eu, Gd, In, Sc, Mn or Co, will worsen the detection limits for other elements in the samples.

Qualitative Analysis. Radionuclides are identified by gamma-ray energies and half-lives. ^{51}Ti and ^{51}Cr have identical gamma-ray energies (320.1 keV) since they decay to the same, stable daughter product (^{51}V). However, their half-lives differ greatly: 5.76 min for ^{51}Ti and 27.7 d for ^{51}Cr . Gamma rays with an en-

ergy of 320.1 keV observed shortly after irradiation are almost entirely from Ti, while those observed even one day after irradiation are entirely from ^{51}Cr . It is possible to determine Ti in a sample with a high Cr content by first counting immediately after irradiation, counting again under the same conditions one day after irradiation, and then subtracting the ^{51}Cr contribution to the ^{51}Ti peak. In addition, many radionuclides have more than one gamma-ray, and the presence of all the intense gamma-rays can be used as confirmation.

Traceable Quantitative Analysis. Quantification for NAA can be achieved by three basic methods: (1) use of fundamental parameters; (2) by comparing to a known amount of the element under investigation, or (3) some combination of the two previous methods (the k_0 method is the best-known variant of this). The second method, often called the comparator method, contains the most direct traceability links and will be discussed further. Typically, standards containing known amounts of the elements under investigation are irradiated and counted under the same conditions as the sample(s) of interest. Decay-corrected count rates (A_0) are calculated via (4.6), and then the masses of each element in the sample(s) are calculated through (4.7). The R -values account for any experimental differences between standards and sample(s), and are normally very close to unity

$$m_{\text{unk}} = m_{\text{std}} \frac{(A_{0,\text{unk}})}{(A_{0,\text{std}})} R_{\theta} R_{\phi} R_{\sigma} R_{\varepsilon}, \quad (4.7)$$

where: m_{unk} = mass of an element in the unknown sample, m_{std} = mass of an element in the comparator standard, R_{θ} = ratio of isotopic abundances for unknown and standard, R_{ϕ} = ratio of neutron fluences (including fluence drop-off, self-shielding and scattering), R_{σ} = ratio of effective cross-sections if neutron spectrum shape differs from unk. to std., R_{ε} = ratio of counting efficiencies (differences due to geometry and γ -ray self-shielding).

Prompt Gamma Activation Analysis (PGAA)

Principles of the Technique. The binding energy released when a neutron is captured by an atomic nucleus is generally emitted in the form of instantaneous gamma-rays. Measuring the characteristic energies of these gamma rays permits qualitative identification of the elements in the sample, and quantitative analysis is accomplished by measuring their intensity. The source of neutrons may be a research reactor, an accelerator-

Table 4.2 Prompt gamma activation analysis: approximate detection limits. Data from [4.61]

> 1 μg	B, Cd, Sm, Eu, Gd, Hg
1 μg to 10 μg	H, Cl, Ti, V, Co, Ag, Pt
10 μg to 100 μg	Na, Al, Si, S, K, Ca, Cr, Mn, Fe, Cu, Zn, As, Br, Sr, Mo, I, W, Au
100 μg to 1000 μg	N, Mg, P, Sn, Sb
1 mg to 10 mg	C, F, Pb, Bi

based neutron generator, or an isotopic source. The most sensitive and accurate analyses use reactor neutron beams with high-resolution Ge gamma-ray spectrometers. A sample is simply placed in the neutron beam, and the gamma-ray spectrum is measured during an irradiation lasting from minutes to hours. The method is nondestructive; residual radioactivity is usually negligible. Because PGAA employs nuclear (rather than chemical) reactions, the chemical form of the analyte is unimportant. No dissolution or other sample pretreatment is required.

Scope. The sensitivity of the analysis depends on experimental conditions and on the composition of the sample matrix. For a neutron beam with a flux of $10^8 \text{ cm}^{-2}\text{s}^{-1}$ and an irradiation time of several hours, approximate detection limits are given in Table 4.2.

Nature of the Sample. Typical samples are in the range of 100 mg to 1000 mg, preferably pressed into a pellet. Samples can be smaller if the elements of interest have high sensitivities, and must be smaller if the matrix is a strong neutron absorber. Large samples may be most accurately analyzed through element ratios.

Qualitative Analysis. The energies of the peaks in the gamma-ray spectrum are characteristic of the elements. Because the spectra of most elements contain numerous peaks, elemental identification is generally positive.

Quantitative Analysis. Standards of known quantities of pure elements or simple compounds are irradiated to determine sensitivity factors. Multiple gamma rays are used for quantitation to verify the absence of interferences.

Example Spectrum. The plot shown in Fig. 4.3 is a PGAA spectrum of a fertilizer reference material. In this material, the elements H, B, C, N, P, S, Cl, K, Ca, Ti, V, Mn, Fe, Cd, Sm and Gd are quantitatively measurable.

Neutron Depth Profiling

Neutron depth profiling (NDP) is a method of near-surface analysis for isotopes that undergo neutron-induced positive Q -value (exothermic) charged particle reactions, for example (n,α) , (n,p) . NDP combines nuclear physics with atomic physics to provide information about near-surface concentrations of certain light elements. The technique was originally applied in 1972 by Ziegler et al. [4.62] and independently by Biersack and Fink [4.63]. Fink [4.64] has produced an excellent report giving many explicit details of the method. The method is based on measuring the energy loss of the charged particles as they exit the specimen. Depending on the material under study, depths of up to $10\mu\text{m}$ can be profiled, and depth resolutions of the order of 10nm can be obtained. The most studied analytes have been boron, lithium, and nitrogen in a variety of matrices, but several other analytes can also be measured. Because the incoming energy of the neutron is negligible and the interaction rate is small, NDP is considered a nondestructive technique. This allows the same volume of sample to receive further treatment for repeated analysis, or to be subsequently analyzed using a different technique that might alter or destroy the sample.

Principles of the Technique. Lithium, boron, nitrogen, and a number of other elements have an isotope that undergoes an exoergic charged particle reaction upon capturing a neutron. The charged particles are protons or alpha particles and an associated recoil nucleus. The energies of the particles are determined by the conservation of mass-energy and are predetermined for each reaction (for thermal neutrons, the added energy brought in by the neutron is negligible). As the charged particle exits the material, its interaction with the matrix causes it to lose energy, and this energy loss can be measured and used to determine the depth of the originating reaction. Because only a few neutrons undergo interactions as they penetrate the sample, the neutron fluence rate is essentially the same at all depths. The depth corresponding to the measured energy loss is determined by using the characteristic stopping power of the material. The chemical or electrical state of the target atoms has an inconsequential effect on the measured profile in the NDP technique. Only the concentration of the major elements in the material is needed to establish the depth scale through the relationship to stopping power.

Fig. 4.3 Prompt gamma activation analysis

Mathematically, the relationship between the depth and residual energy can be expressed as

$$x = \int_{E(x)}^{E_0} dE/S(E), \quad (4.8)$$

where x is the path length traveled by the particle through the matrix, E_0 is the initial energy of the particle, $E(x)$ is the energy of the detected particle, and $S(E)$ is the stopping power of the matrix. Examples of the relationship between x and $E(x)$ are displayed in Fig. 4.4 for $^{10}\text{B}(n,\alpha)$ in silicon and $^{14}\text{N}(n,p)$ in ScN. For the boron reaction, $^{10}\text{B}(n,\alpha)^7\text{Li}$, there are two outgoing alpha particles with energies of 1.472 MeV (93% branch) and 1.776 MeV (7%), and two corresponding recoil ^7Li nuclei with energies of 0.840 MeV and 1.014 MeV. For the

Fig. 4.4 Neutron depth profiling: stopping power for alphas in silicon and protons in ScN

nitrogen reaction, $^{14}\text{N}(\text{n,p})^{14}\text{C}$, there is a 584 keV proton and a 42 keV ^{14}C recoil. A silicon surface barrier detector detects particles escaping from the surface of the sample. The charge deposited in the detector is directly proportional to the energy of the incoming particle.

Scope. A principal limitation of the technique is that it can only be applied to a few light elements. The most commonly analyzed are boron, lithium and nitrogen. However, as a result, very few interfering reactions are encountered. Furthermore, since the critical parameters in the technique are nuclear in origin, there is no dependence upon the chemical or optical characteristics of the sample. Consequently, measurements are possible at the outer few atomic layers of a sample or through a rapidly changing composition such as at the interface between insulating and conducting layers, and across chemically distinct interfaces. In contrast, measurement artifacts occur with surface techniques such as secondary ion mass spectrometry and Auger electron spectrometry when the sample surface becomes charged and the ion yields vary unpredictably.

Nature of the Sample. Samples of interest are usually thin films, multilayers or exposed surfaces. Because of the short range of the charged particles, only depths to about 10 μm can be analyzed. The samples are placed in a thermal neutron beam and the dimensions of the beam determine the maximum area of the sample that can be analyzed in a single measurement. Some facilities have the ability to scan large-area samples. The analyzed surface must be flat and smooth to avoid ambiguities caused by surface roughness. All samples are analyzed in vacuum, so the samples must be nonvolatile and robust enough to survive the evacuation process. Some samples may become activated and require some decay time before being available for further experimentation. The latter condition is the only barrier to the entire process being completely nondestructive.

Qualitative Analysis. Most of the interest in the technique relates to determining the shape of the distribution of the analyte and how it responds to changes in its environment (annealing, voltage gradients and so on). Determining the shape of the distribution involves determining the energy of the particles escaping from the surface and comparing with the full energy of the reaction. The detector can be calibrated for the full energy by measuring a very thin surface deposit of the analyte in question. The detector is typically a surface-barrier detector or another high-resolution charged particle de-

tector. The difference between the initial energy of the particle and its measured energy is equal to the energy loss, and with (4.8) it yields the depth of origin. The depth resolution varies from a few nanometers to a few hundred nanometers. Under optimum conditions the depth resolution for boron in silicon is approximately 8 nm.

Stopping powers for individual elements are given in compilations like that of Ziegler [4.65]. Because the analytical results are obtained in units of areal density (atoms per square centimeter), a linear depth scale can be assigned only if the volume density of the material remains constant and is known. Consequently, the conversion of an energy loss scale to a linear depth axis is only as accurate as the knowledge of the volume density. By supplying a few physical parameters, customized computer programs are used to convert the charged particle spectrum to a depth profile in units of concentration and depth. A Monte Carlo program, SRIM [4.66], can also be used to provide stopping power and range information. Even if the density is not well-known, mass fraction concentration profiles can be accurately determined even through layered materials of different density. In many cases, it is the mass fraction composition that is the information desired from the analysis.

Traceable Quantitative Analysis. To compare concentration profiles among samples, both the charged particle spectrum and the neutron fluence that passes through each sample are monitored and recorded. The area analyzed on a sample is defined by placing an aperture securely against the sample surface. This aperture need only be thick enough to prevent the charged particle from reaching the detector and can therefore be very thin. Neutron collimation is used to reduce unwanted background, but it does not need to be precise. The absolute area defined by the aperture need not be accurately known as long as the counting geometry is constant between samples. The neutron fluence recorded with each analysis is used to normalize data from different samples. In practice, a run-to-run monitor that has a response proportional to the total neutron fluence rate is sufficient to normalize data taken at differing neutron intensities and time intervals. To obtain a traceable quantitative analysis of the sample, a spectrum should be obtained using a sample of known isotopic concentration, such as the NIST SRM 2137 boron implanted in silicon standard for calibrating concentration in a depth profile. When determining an NDP profile it should be remembered that only the isotopic concentration is actually determined and that the elemental profile is inferred.

Photon Activation Analysis (PAA)

Principles of the Technique. PAA is a variant of activation analysis where photons are used as activating particles. The nuclear reactions depend on the atomic number of the target and on the energy of the photons used for irradiation. The source of photons for PAA is nearly always the bremsstrahlung radiation produced with electron accelerators. The photon energies are commonly 15 MeV to 20 MeV, predominantly inducing the (γ, n) reaction. Other reactions that can be used include (γ, p) , $(\gamma, 2n)$, and (γ, α) . PAA is very similar to neutron activation analysis (NAA) in that the photons can completely penetrate most samples. Thus procedures and calculations are similar to those used in NAA. The method has constraints due to the stability and homogeneity of the photon beam, with inherent limitations to the comparator method. Recent developments in bremsstrahlung target technology have achieved improvements in the photon source that greatly benefit the precision and accuracy of the method [4.59]. A detailed discussion of PAA has been given by Segebade et al. [4.67].

Scope. The method is complementary to INAA, and the determination of light elements C, N, O and F are good examples of PAA where detection limits of $<0.5 \mu\text{g}$ are possible. A few heavy metal elements can be determined in biological and environmental materials with similar sensitivity, such as Ni, As, and Pb; the latter cannot be determined by thermal NAA. One reaction with lower energy photons is the ${}^9\text{Be}(\gamma, n){}^{10}\text{Be} \rightarrow 2 {}^4\text{He} + 2n$ reaction because of the low neutron binding energy of the Be. The reaction can be induced by the 2.1 MeV gamma rays from ${}^{124}\text{Sb}$ and measured through the detection of the neutrons. (The same reaction is also used as a neutron source).

Nature of the Sample. Samples are commonly in solid form, requiring little or no preparation for analysis. Metals, industrial materials, environmental materials and biological samples can be characterized in their original form.

Qualitative Analysis. The (γ, n) reaction leaves the product nucleus proton-rich, consequently the analytical nuclide is frequently a positron emitter. This requires discrimination by half-life or radiochemical separation for element-specific characterization. Heavier elements can form product nuclides which emit their own characteristic gamma rays, rather than just positron annihilation radiation.

Traceable Quantitative Analysis. The comparator method of activation analysis relates directly the measured gamma rays of a sample to the measured gamma rays of a standard with a known element content [see (4.7) in the section on Neutron Activation Analysis]. Spectral interferences, fluence differences in sample and standard, and potential isotopic differences must be carefully considered.

Charged Particle (Beam) Techniques

Principles of the Technique. In charged particle activation analysis (CPAA), the activating particles, such as protons, deuterons, tritons, ${}^3\text{He}$, α - and higher atomic number charged particles are generated by accelerators. The type of nuclear reaction induced in the sample nuclei depends on the identity and energy of the incoming charged particle. Protons are selected in many instances because they can be easily accelerated and have low Coulomb barriers. The (p, n) and (p, γ) reactions result most often with protons up to about 10 MeV in energy. Higher energy protons may also induce (p, α) , (p, d) or $(p, 2n)$ reactions. Larger incident particles require higher energies to overcome the Coulomb barrier. They then deposit higher energies in the target nucleus during reaction, which leads to a greater variety of pathways for the de-excitation of the activated nucleus. Therefore, a great variety of reactions and measurement options are available to the analyst in CPAA. CPAA has been discussed in more detail by Strijckmans [4.68].

Particle-induced X-ray emission (PIXE) is a combined process, in which continuum and characteristic X-rays are generated through the recombination of electrons and electron vacancies produced in ion-atom collision events when a beam of charged particles is slowed down in an object. Usually protons of energies between 0.1 MeV to 3 MeV are utilized; the energies typically depend on the accelerator type and are selected to minimize nuclear reactions. The target elements emit characteristic X-ray lines corresponding to the atomic number of the element. A detailed introduction to the technique and its interdisciplinary applications is given by Johansson et al. [4.69].

Scope. CPAA can be regarded as a good complement to neutron activation analysis (NAA), since elements that are measured well are quite different from those ordinarily determined by NAA. The low Coulomb barriers and low neutron capture cross-sections of light elements make CPAA a good choice for the nuclear analysis of B, C, N, O, and so on. PIXE is generally applicable to elements with atomic numbers $11 \leq Z \leq 92$. Because

charged particles may not penetrate the entire sample as neutrons do, CPAA or PIXE is often used for determinations in thin samples or as a surface technique. The ability to focus charged particle beams is widely used in applications for spatial analysis. Elaborate ion-optical systems of particle accelerators composed of focusing and transversal beam scanning elements offer an analytical tool for lateral two-dimensional mapping of elements in micro-PIXE.

Nature of the Sample. Samples are commonly in solid form, requiring no or little preparation for analysis. Metals, industrial materials, environmental materials and biological samples can be characterized in their original solid form. However, many facilities require that the sample is irradiated in a vacuum chamber connected to the accelerator beam line. Samples with volatile constituents and liquid samples require that the beam is extracted from the beam line through a thin window. Activation and X-ray production in the window and surrounding air significantly increases the background in prompt gamma ray and X-ray spectra. An additional restriction may be imposed on sample materials by the sensitivity of the sample to local heating in the particle beam.

Qualitative Analysis. The selection of nuclear reaction parameters in CPAA permits the formation of rather specific product nuclides which emit their own characteristic gamma rays for unique identification. PIXE offers direct identification of elements via their characteristic K and L series X rays.

Traceable Quantitative Analysis. For CPAA, the interaction of the charged particle with the sample requires a modification of the activation equation, introduced in Sect. 4.2.4. The particles passing through a sample lose energy, so the cross-section for the nuclear reaction changes with depth. The expression for the produced activity in NAA has to be modified to account for this effect

$$A(t) = n I \int_0^R \sigma(x) dx . \quad (4.9)$$

Here I is the beam intensity (replacing the neutron flux Φ), n is the density of target nuclides, and R is the penetration range determined by the stopping power of the medium according to Sect. 4.2.4.

As with NAA, the fundamental equation is not used directly in practice, but a relative standardization (com-

parator) method is used. A working equation for the comparator method is

$$m_x = m_s \frac{A_x I_s R_s}{A_s I_x R_x} . \quad (4.10)$$

Here we have omitted the saturation, decay, and counting factors, which should be applied the same as in the case of NAA [see (4.7) in the section on NAA].

Like NAA, PIXE can be described by sets of equations relating to all of the physical parameters applicable in the excitation process. However, accurate calibration of a PIXE system is extremely difficult. The comparator method suffers from the fact that only one sample, either the unknown or the standard, can be irradiated at a given time. Thin target yields for thin homogeneous samples with negligible energy loss of the bombarding particle and no absorption of X rays in the sample can be calculated and normalized for standards and unknowns. For a thick homogeneous sample, thick target yields can be calculated if the composition is known. The comparator method is further affected by the problem of insufficient matrix match between unknown and standard sample here. Often internal standards, such as homogeneously mixed in yttrium, provide an experimental calibration method with a potential limit to uncertainties of 3% to 5%.

Activation Analysis with Accelerator-Produced Neutrons

Principles of the Technique. This nuclear analytical method is based on small, low-voltage (≈ 105 kV to 200 kV) accelerators producing 3 MeV and 14 MeV neutrons via the $^2\text{H}(d,n)^3\text{He}$ and $^3\text{H}(d,n)^4\text{He}$ reactions, respectively. Principles of operation and output characteristics of these neutron generators have been described in the past [4.70] and were recently updated in a technical document [4.55]. The NAA procedures follow the same principles as those with thermal neutrons. The high-energy neutrons can be used to interact directly with target nuclides in fast neutron activation analysis (FNAA), or they are moderated to thermal energies before interacting with a sample like in conventional NAA. Hence, the principal neutron energies of interest obtained from neutron generators are ≈ 14 MeV, ≈ 2.8 MeV, and ≈ 0.025 eV (thermal). The different nuclear reactions of the generator neutrons are listed here in the approximate order of increasing threshold energy: (n,γ) , $(n,n'\gamma)$, (n,p) , (n,α) , and $(n,2n)$. The (n,γ) reaction is exoergic and the cross-section in most cases decreases with increasing neutron energy. Nevertheless, some nuclides have high resonance absorption at certain neutron

energies and **FNAA** is used in their determination. The $(n,n'\gamma)$ reactions are slightly endoergic; most can be induced by the 3 MeV neutrons. Only a limited number of nuclides, however, have longer lived isomeric states that can be measured after irradiation. The (n,p) , (n,α) , and $(n,2n)$ reactions are predominantly endoergic and generally occur with the 14 MeV neutrons only. With this wide array of selectable parameters, highly specialized applications have been developed.

Scope. The **FNAA** methods based on small neutron generators play an important role in the development of new technologies in process and quality control systems, exploration of natural resources, detection of illicit traffic materials, transmutation of nuclear waste, fusion reactor neutronics, and radiation effects on biological and industrial materials. A considerable number of systems have been specifically tailored to the important application of oxygen determination via the $^{16}\text{O}(n,p)^{16}\text{N}$ ($T_{1/2} = 7.2$ s) reaction. This outstanding analytical application for the direct, nondestructive determination of oxygen is discussed here in more detail. The procedure has been documented in an evaluated standard test method (**ASTM**).

Nature of the Sample. Samples are in solid or liquid form, requiring little or no preparation for analysis. Metals, industrial materials, environmental materials and biological and other organic samples can be characterized in their original forms. For highly sensitive oxygen determinations, samples are commonly prepared under inert gas protection and sealed in low-level oxygen irradiation containers. Comparator standards are commonly prepared from stoichiometric oxygen-containing chemicals measured directly or diluted with relatively oxygen-free filler materials.

Qualitative Analysis. In general applications of **FNAA**, the activation products are identified by their unique nuclear decay characteristics. The oxygen analysis commonly utilizes the summation of all gamma rays above ≈ 4.7 MeV; the specificity of the accumulated counts is ascertained by decay curve analysis.

Traceable Quantitative Analysis. **FNAA** follows the general principles of **NAA** for quantitative analysis. The specific nature of the neutron flux distributions and intensities during an activation cycle with a generator and the produced nuclides, which are frequently short-lived, however, require specific measures to control sources of uncertainty.

Fig. 4.5 Activation analysis with accelerator-produced neutrons: multiscaling spectrum of neutron beam monitor and oxygen gamma-ray counts in the **FNAA** of coal

The 14 MeV **FNAA** method has been used to determine the uptake of oxygen in SRM 1632c trace elements in coal (Bituminous) [4.71]. In this application it was expected to quantify a relative change of 5% in the oxygen content ($\approx 12\%$ mass fraction) in the SRM. Automated irradiation and counting cycles alternate samples and standards and achieve high precision through multiple (ten) passes for each sample and standard. Figure 4.5 illustrates the signals recorded in the analyzer for each pass. The duration of the irradiation and its intensity is recorded from a neutron monitor, while the oxygen gamma rays are obtained from a matched pair of NaI(Tl) photon detectors after travel of the sample from the irradiation to the counting position. An on-line laboratory computer controls the process and quantitatively evaluates the data [4.72].

4.1.5 Chromatographic Methods

[4.73–83]

Gas Chromatography (GC)

Principles of the Technique. Gas chromatography (**GC**) can be used to separate volatile organic compounds. A gas chromatograph consists of a flowing mobile phase (typically helium or hydrogen), an injection port, a separation column containing the stationary phase, and a detector. The analytes of interest are partitioned between the mobile (inert gas) phase, and the stationary phase. In capillary gas chromatography, the stationary phase is coated on the inner walls of an open tubular column typically comprised of fused silica. The avail-

able stationary phases include methylpolysiloxanes with varying substituents, polyethylene glycols with different modifications, chiral columns for separations, as well as other specialized stationary phases. The polarity of the stationary phase can be varied to effect the separation.

The suite of gas chromatographic detectors includes the flame ionization detector (FID), the thermal conductivity detector (TCD or hot wire detector), the electron capture detector (ECD), the photoionization detector (PID), the flame photometric detector (FPD), the atomic emission detector (AED), and the mass spectrometer (MS). Except for the AED and MS, these detectors produce an electrical signal that varies with the amount of analyte exiting the chromatographic column. In addition to producing the electrical signal, the AED yields an emission spectrum of selected elements in the analytes. The MS, unlike other GC detectors, responds to mass, a physical property common to all organic compounds.

Scope. Capillary chromatography has been used for the separation of complex mixtures, components that are closely related chemically and physically, and mixtures that consist of a wide variety of compounds. Because the separation is based on partitioning between a gas phase and stationary phase, the analytes of interest must volatilize at temperatures obtainable by GC injection port temperatures (typically 50 °C to 300 °C) and be stable in the gas phase.

Samples may be introduced using split, splitless or on-column injectors. During a split injection, a portion of the carrier gas is constantly released through a splitter vent located at the base of the injection port, so that the same proportion of the sample injected will be carried out of the splitter vent upon injection. For applications where sensitivity or degradation in the injection port is not an issue, split injections are performed. During a splitless injection, the splitter vent is closed for a specified period of time following injection and then opened. For applications where sensitivity is an issue but degradation in the injection port is not an issue, and there are a lot of coextractables in the sample, splitless injection is used. Inlet liners are used for both split and splitless injections. For on-column injection, the column butts into the injection port so that the syringe needle used for injections goes into the head of the column. In this case, all of the sample is deposited onto the head of the column typically at an injection temperature below the boiling point of the solvent being used. For applications where sensitivity and degradation in the injection port are both issues and there is a limited amount of coextractables in the sample, on-column injection is used.

Nature of the Sample. The samples are introduced into the gas chromatograph as either gas or liquid solutions. If the sample being analyzed is a solid, it must first be dissolved into a suitable solvent, or the analytes of interest in the matrix must be extracted into a suitable solvent. In the case of complex matrices, the analytes of interest may be isolated from some of the coextracted material using various steps, including but not limited to size exclusion chromatography, liquid chromatography and solid-phase extraction.

Qualitative Analysis. Gas chromatography provides several types of qualitative information simultaneously. The appearance of the chromatogram is an indication of the complexity of the sample. The retention times of the analytes allow classification of various components roughly according to volatility. The rate at which a component travels through the GC system (retention time) depends on factors in addition to volatility, however. These include the polarity of the compounds, the polarity of the stationary phase, the column temperature, and the flow rate of the gas (mobile phase) through the column. GC-AED and GC/MS provide additional qualitative information.

Traceable Quantitative Analysis. Regardless of the detector being used, GC instrumentation must be calibrated using solutions containing known concentrations of the analyte of interest along with internal standards (surrogates) that have been added at a known concentration. The internal standards (surrogates) chosen should be chemically similar to the analytes of interest, and for many of the GC/MS applications are isotopically labeled analogs of one or more of the analytes of interest. Approximately the same quantity of the internal standard should be added to all calibration solutions and “unknown” samples within an analysis set. Calibration may be performed by constructing a calibration curve encompassing the measurement range of the samples or by calculating a response factor from measurements of calibration solutions that are very similar in concentration to or closely bracket the sample concentration for the analyte of interest. For more detail on quantitative analysis as it relates to chromatography, see the section in this chapter on liquid chromatography.

Certified reference materials are available in a wide variety of sample matrix types from NIST and other sources. These CRMs should be used to validate the entire GC method, including extraction, analyte isolation and quantification.

Liquid Chromatography (LC)

Liquid chromatography (LC) is a method for separating and detecting organic and inorganic compounds in solution. The technique is broadly applicable to polar, nonpolar, aromatic, aliphatic and ionic compounds with few restrictions. Instrumentation typically consists of a solvent delivery device (a pump), a sample introduction device (an injector or autosampler), a chromatographic column, and a detector. The flexibility of the technique results from the availability of chromatographic columns suited to specific separation problems, and detectors with sensitive and selective responses. The goal of any liquid chromatographic method is the separation of compounds of interest from interferences, in either the chromatographic and/or detection domains, in order to achieve an instrumental response proportional to the analyte level.

Principles of the Technique. Retention in liquid chromatography is a consequence of different associations of solute molecules in dissimilar phases. In the simplest sense, all chromatographic systems consist of two phases: a fixed “stationary phase” and a moving “mobile phase.” The diffusion of solute molecules between these phases usually occurs on a time scale much more rapid than that associated with fluid flow of the mobile phase. Differential association of solute molecules with the stationary phase retards these species to different extents, resulting in separation. Retention processes depend on a complex set of interactions between solute molecules, stationary phase ligands and mobile phase molecules; the characteristics of the column (such as the physical and chemical properties of the substrate, the surface modification procedures used to prepare the stationary phase, the polarity, and so on) also provide a major influence on retention behavior. Two modes of operation can be distinguished: reversed-phase liquid chromatography (RPLC) and normal-phase LC. For normal-phase LC, the mobile phase is less polar than the stationary phase; the opposite situation exists with RPLC. Column choice is critical when developing an LC method. Most separations are performed in the reversed-phase mode with C₁₈ (octadecylsilane, ODS) columns. An instrumental response proportional to the analyte level typically results from spectrometric detection, although other forms of detection exist. Common detectors include ultraviolet/visible absorbance (UV/vis), fluorescence (FL), electrochemical (EC), refractive index (RI), evaporative light scattering (ELSD), and mass spectrometric (MS) detection.

Scope. Liquid chromatography is applicable to compounds that are soluble (or can be made soluble by derivatization) in a suitable solvent and can be eluted from a chromatographic column. Accurate quantification requires the resolution of constituents of interest from interferences. Liquid chromatography is often considered a low-resolution technique, since only about 50 to 100 compounds can be separated in a single analysis; however, selective detection can be implemented to improve the overall resolution of the system. Recent emphasis is on the use of mass spectrometry for selective LC detection. In general, liquid chromatographic techniques are most suited to thermally labile or nonvolatile solutes that are incompatible with gas phase separation techniques (such as gas chromatography).

Nature of the Sample. Liquid chromatography is relevant to a wide range of sample types, but in all cases samples must be extracted or dissolved in solution to permit introduction into the liquid chromatograph. To reduce sample complexity, enrichment (clean-up) of the samples is sometimes carried out by liquid-liquid extraction, solid-phase extraction, or LC fractionation. Sample extracts should be miscible with the mobile phase, and typically small injection volumes (1 μ L to 20 μ L) are employed. Solvent exchange can be carried out when sample extracts are incompatible with the mobile phase composition.

Qualitative Analysis. Liquid chromatography is sometimes used for tentative identification of sample composition through comparison of retention times with authentic standards. Identifications must be verified by complementary techniques; however, disagreement in retention times is usually sufficient to prove the absence of a suspected compound.

Traceable Quantitative Analysis. Liquid chromatography is a relative technique that requires calibration. The processes of calibration and quantification are similar to those used in other instrumental techniques for organic analysis (such as gas chromatography, mass spectrometry, capillary electrophoresis, and related hyphenated techniques). The quantitative determination of organic compounds is usually based on the comparison of instrumental responses for unknowns with calibrants. Calibrants are prepared (usually on a mass fraction basis) using reference standards of known (high) purity. This comparison is made by using any of several mathematical models. Linear relationships between response and analyte level are often assumed; however, this is not

a requirement for quantification, and nonlinear models may also be used.

Several approaches to quantification are potentially applicable: the external standard approach, the internal standard approach, and the standard addition approach. The external standard approach is based on a comparison of absolute responses for analytes in the calibrants and unknowns. The internal standard approach is based on a comparison of relative responses of the analytes to the responses of one or more compounds (the internal standard(s)) added to each of the samples and calibrants. The standard addition approach is based on one or more additions of a calibrant to the sample, and may also utilize an internal standard.

The external standard approach is often used when an internal standard is not available or cannot be used, or when the masses of standard and unknown samples can easily be controlled or accounted for. The external standard approach demands care since losses from sample handling or sample introduction will directly influence the final results. All volumes (or masses) must be accurately known, and sample transfers must be quantitative.

The internal standard approach utilizes one or more constituents (the internal standard(s), not present in the unknown samples) which are added to both calibrants and unknowns. Calculations are based on relative responses of the analytes to these internal standards. The use of internal standards lessens the need for quantitative transfers and reduces biases from sample processing losses. Internal standards should (ideally) have properties similar to the analytes of interest; however, even internal standards with unrelated properties may provide benefits as “volume correctors”. An isotopic form of the analyte of interest is used for isotope dilution methods. A mass difference of at least 2 and substitution at nonlabile atoms is typically required for mass spectrometric methods. Separation of isotopically labeled species (required for non-mass selective detection) is sometimes possible for deuterated species when the number of deuterium atoms is 8–10 or greater. Separation of the internal standard is required when detection is nonselective, as with ultraviolet absorbance detection. For techniques that utilize selective detection (such as mass spectrometry), separation of the internal standard is not required, and often it is desired that the internal standard and analyte coelute for improved precision (as in isotope dilution approaches).

The standard addition approach is based on the addition of a known quantity(s) of a calibrant to the unknown (with or without addition of an internal standard). At

least two sample levels must be prepared for each unknown; one sample can be the unspiked unknown. Since separate calibrations are carried out for each unknown sample, this approach is labor-intensive.

Internal and external standard approaches to quantification can utilize averaged response factors, a zero intercept linear regression model, a calculated intercept linear regression model, or another nonlinear model. The responses can be unweighted or weighted. The model utilized should be evaluated as appropriate for the measurement problem.

The number and level of calibrants used depends on the measurement problem. When the level(s) of the unknown can be estimated, calibrants should be prepared to approximate this level(s). Preparation of calibrants in this way minimizes the issue of response linearity. When less is known about the unknowns, or when unknowns are expected to span a concentration range, calibrants should be prepared to span this range. It is undesirable to extrapolate to concentrations outside of the calibration interval. When possible, prepare calibrants by independent gravimetric processes and avoid serial dilutions or use of stock solutions.

When internal standards are used as part of the method, levels should be selected to approximate the levels of components being measured. The response for the internal standard should be the same or similar for calibrants and unknowns, and the ratio of internal standard and analyte(s) should be similar. When possible, the absolute response for analytes and internal standards should be significantly greater than the noise level. If the analyte level(s) are low in the unknown samples, the internal standard should be added at higher levels (measurement precision should be enhanced if the internal standard is significantly greater than the noise level).

Capillary Electrophoresis

Principles of the Technique. Capillary electrophoresis (CE) refers to a family of techniques that are based upon the movement of charged species in the presence of an electric field. A simplified diagram of a CE instrument is shown in Fig. 4.6. When a voltage is applied to the system, positively charged species move toward the negatively charged electrode (cathode), while negatively charged species migrate toward the positively charged electrode (anode). Neutral species are not attracted to either electrode.

Separations are typically performed in fused silica capillaries with an internal diameter of 25 μm to 100 μm and a length of 25 cm to 100 cm. The capillary is filled with a buffer, and the applied voltage generally ranges

from 10 kV to 30 kV. A number of different detection strategies are available, including UV absorbance, laser-induced fluorescence, and mass spectrometry.

Scope. CE is applicable to a wide range of pharmaceutical, bioanalytical, environmental and forensic analyses. Various modes of CE are employed depending upon the type of analyte and the mechanism of separation. Capillary zone electrophoresis (CZE) is the most widely used mode of CE and relies upon differences in size and charge between analytes at a given pH to achieve separations. Some of the demonstrated applications of CZE include the analysis of drugs and their metabolites, peptide mapping, and the determination of vitamins in nutritional supplements. Neutral compounds are typically resolved using micelles, through a technique known as micellar electrokinetic capillary chromatography (MECC or MEKC). Both CZE and MEKC have also been utilized for enantioselective separations. Capillary gel electrophoresis (CGE) has been used extensively for the separation of proteins and nucleic acids. The gel network acts as a sieve to separate components based on size. Capillary isoelectric focusing (CIEF) separates analytes on the basis of their isoelectric points and incorporates a pH gradient. This technique is commonly used for the separation of proteins. Capillary isotachopheresis (CITP) utilizes a combination of two buffer systems and is sometimes used as a preconcentration method for other CE techniques.

CE has been viewed as an alternative to liquid chromatography (LC), although CE is not yet as well-established as LC. CE typically provides a higher efficiency than LC and has lower sample consumption.

Fig. 4.6 Capillary electrophoresis: diagram of CE instrumentation

In addition, the various modes of CE offer flexibility in method development. Because CE utilizes a different separation mechanism to LC, it can be viewed as an orthogonal technique that provides complementary information to LC analyses. Currently, the primary limitations of CE involve sensitivity and reproducibility issues, but improvements continue to be made in these areas.

Nature of the Sample. Samples for CE cover a wide range and include matrices such as biological fluids, protein digests and pharmaceutical compounds. Depending on the sample matrix, the sample may be injected directly or may be diluted in water or the run buffer. Certain sample preparation techniques can be utilized to optimize sensitivity. Derivatization of the analytes is often required for laser-induced fluorescence detection.

Qualitative Analysis. CE is particularly applicable to qualitative analyses of peptides and proteins. The high efficiency of CE yields separations of even closely related species, and the “fingerprints” resulting from the analysis of two different samples can be compared to reveal subtle differences.

Traceable Quantitative Analysis. Quantification in CE is generally performed by preparing calibration solutions of the analyte(s) of interest at known concentrations and comparing the peak areas obtained for known and unknown solutions. Quantification approaches used in CE are generally similar to those used in LC. One unique aspect of CE is the fact that the peak area is related to the migration velocity of the solute. Corrected peak areas, obtained by dividing the peak area by the migration time of the analyte, improve quantitative accuracy in CE.

Liquid Chromatography/Mass Spectrometry (LC/MS) and LC/MS/MS

The combination of liquid chromatography (LC) with mass spectrometry (MS) is a powerful tool for the determination of organic and organometallic species in complex matrices. While LC is sometimes combined with ICP-MS for elemental analysis, this section will focus on combining LC with MS using either electrospray ionization (ESI)¹ or atmospheric pressure chemical ionization (APCI), the most widely used approaches for the determination of organic species. Generally, reversed-phase LC using volatile solvents and additives is combined with a mass spectrometer equipped with either an ESI or an APCI source. ESI is the favored ap-

proach for ionic and polar species, while **APCI** may be preferred for less polar species. If the mass spectrometer has the ability to perform tandem mass spectrometry (**MS/MS**) using collision-induced dissociation, analysis of daughter ions adds additional specificity to the process.

Principles of the Technique. The principles of liquid chromatography are covered in the liquid chromatography section. For **LC/MS**, the effluent from the **LC** column flows into the source of the mass spectrometer. For **ESI** the effluent is sprayed out of a highly charged orifice, creating charged clusters that lose solvent molecules as they move from the orifice, resulting in charged analyte molecules. For **APCI**, a corona discharge is used to ionize solvent molecules that act as chemical ionization reagents to pass charges to the analyte molecules. Desolvated ions pass into the **MS** vacuum system through a pinhole. The ions may be separated by various devices including quadrupole, ion trap, magnetic sector, time-of-flight, or ion cyclotron resonance devices. The principles of operation of these devices are beyond the scope of this discussion. Ions are generally detected using electron or ion multipliers.

Scope. **LC/MS** and **LC/MS/MS** have been used to determine organic species ranging from highly polar peptides and oligonucleotides to low-polarity species such as nitrated polycyclic aromatic hydrocarbons in virtually any matrix imaginable. For many polar substances such as drug metabolites or hormones, **LC/MS** has largely supplanted **GC/MS** as the approach of choice for two reasons. Sample preparation is much simpler with **LC/MS** in that the analyte is generally not derivatized and analyte isolation from the matrix is often faster. Nevertheless, with most complex matrices, some sample processing is generally necessary before the sample is introduced into the **LC/MS**. Secondly, sensitivity is often greater, resulting in better quantification of very low concentrations. Because both **ESI** and **APCI** are soft ionization techniques, there is little fragmentation observed in contrast to what is seen for many analytes in **GC/MS**. This can be either advantageous or a negative feature. The ion intensity is concentrated in far fewer ions, thus improving sensitivity. However, if there are interferences at the ions being monitored, there are not usually any alternatives ions that can be used for measurement, such as there often are with **GC/MS**. However, if **MS/MS** is available, there is usually a parent–daughter combination that is free from significant interference. For both **LC/MS** and **LC/MS/MS**, use of an isotope-labeled form

of the analyte as the internal standard is the preferred approach for quantification. However, satisfactory results are sometimes possible with a close analog of the analyte, provided that they can be separated.

Qualitative Analysis. **LC/MS** can be a useful tool for qualitative analysis. With **ESI**, this approach is widely used for characterizing proteins. **LC/MS/MS** is also used for protein studies and can be used to determine the amino acid sequence. It is also very useful for drug metabolite studies.

Traceable Quantitative Analysis. Excellent quantitative results can be obtained with these techniques. With an isotope-labeled internal standard, measurement precision is typically 0.5% to 5%. Accuracy is dependent upon several factors. The measurements must be calibrated with known mixtures of a pure form of the analyte and the internal standard. Knowledge about the purity of the reference compounds is essential. Other important aspects that must be considered are: liberation of the analyte from the matrix, equilibration with the internal standard, and specificity of the analytical measurements.

4.1.6 Classical Chemical Methods

[4.84–96]

Classical chemical analysis comprises gravimetry, titrimetry and coulometry. These techniques are generally applied to assays: analyses in which a major component of the sample is being determined. Classical methods are frequently used in assays of primary standard reagents that are used as calibrants in instrumental techniques. Classical techniques are not generally suited to trace analyses. However, the methods are capable of the highest precision and lowest relative uncertainties of any techniques of chemical analysis. Classical analyses require minimal equipment and capital outlay, but are usually more labor-intensive than instrumental analyses for the corresponding species. Other than rapid tests, such as spot tests, classical techniques are rarely used for qualitative identification.

Kolthoff et al. [4.94] provide a thorough yet concise summary of the classical techniques described in this section.

Gravimetry

Principles of the Technique. Gravimetry is the determination of an analyte (element or species) by measuring the mass of a definite, well-characterized product of a stoichiometric chemical reaction (or reactions) involv-

ing that analyte. The product is usually an insoluble solid, though it may be an evolved gas. The solid is generally precipitated from solution and isolated by filtration. Preliminary chemical separation from the sample matrix by ion-exchange chromatography or other methods is often used.

Gravimetric determinations require corrections for any trace residual analyte remaining behind in the sample matrix and any trace impurities in the insoluble product. Instrumental methods, which typically have relatively large uncertainties, can be used to determine these corrections and improve the overall accuracy and measurement reproducibility of the gravimetric analysis, since these corrections represent only a small part of the final value (and its uncertainty).

Scope. Gravimetric determination is normally restricted to analytes that can be quantitatively separated to form a definite product. In such cases, relative expanded uncertainties are in the range of 0.05% to 0.3%. The applicability of gravimetry can be broadened (at the cost of increased method uncertainty) to cases where the product is a compound with greater solubility and/or more impurities by judicious use of instrumental techniques to determine and correct for residual analyte in the solution and/or impurities in the precipitate. Gravimetry can be labor-intensive and is usually applied to an analytical set of 12 or fewer samples, including blanks.

The advantage of coupling gravimetry with instrumental determination of a residual analyte and contaminants can be demonstrated by the gravimetric determination of sulfate in a solution of K_2SO_4 . In an application of this determination [4.87], sulfate was precipitated from a K_2SO_4 solution and weighed as $BaSO_4$. The uncorrected gravimetric result for sulfate was 1001.8 mg/kg with a standard deviation of the mean of 0.32 mg/kg. When instrumentally determined corrections were applied to each individual sample, the corrected mean result was 1003.8 mg/kg sulfate with a standard deviation of the mean of 0.18 mg/kg. The uncorrected gravimetric determination had a significantly negative bias (0.2%, relative) and a measurement reproducibility that was nearly twice that of the corrected result.

The insoluble product of the gravimetric determination can be separated from the sample matrix in several ways. After any required dissolution of the sample matrix, the analyte of interest can be separated from solution by precipitation, ion-exchange or electrodeposition. Other separation techniques (such as distillation or gas evolution [4.84]) can also be used. The specificity

of the separation procedure for the analyte of interest and the availability of suitable complementary instrumental techniques will determine the applicability of a given gravimetric determination.

Separation by precipitation from solution can be accomplished by evaporation of the solution, addition of a precipitating reagent, or by changing the solution pH. After its formation, the precipitate may be filtered, rinsed and/or heated and weighed. The resulting precipitate must be relatively free from coprecipitated impurities. An example is the determination of silicon in soil [4.85]. Silicon is separated from a dissolved soil sample by dehydration with HCl and is filtered from the solution. The SiO_2 precipitate is heated and weighed. HF is added to volatilize the SiO_2 and the mass of the remaining impurities is determined. The SiO_2 is determined by difference. Corrections for Si in the filtered solution can be determined by instrumental techniques.

With ion-exchange separation of the analyte, the precipitation and filtration step may not be required. After collection of the eluate fraction containing the analyte, if no further precipitation reactions are required, the solution can be evaporated to dryness with or without adding other reagents. Ion-exchange and gravimetric determination is demonstrated by the determination of Na in human serum [4.88]. The Na fraction in a dissolved serum sample is eluted from an ion-exchange column. After H_2SO_4 is added, the Na fraction is evaporated to dryness, heated, and weighed as Na_2SO_4 . Instrumentally determined corrections are made both for Na in the fractions collected before and after the “Na fraction” and also for impurities in the precipitate.

Electrodeposition can be used to separate a metal from solution. The determination of Cu in an alloy can be used as an illustration [4.84]. Copper in a solution of the dissolved metal is plated onto a Pt gauze electrode by electrolytic deposition. The Cu-plated electrode is weighed and the plated Cu is stripped in an acid solution. The cleaned electrode is reweighed so that the Cu is determined by difference. Corrections are made via instrumental determination of residual Cu in the original solution that did not plate onto the electrode and metal impurities stripped from the Cu-plated electrode.

Nature of the Sample. Samples analyzed by gravimetry must be in solution prior to any required separation. Generally, an amount of analyte that will result in a final product weighing at least 100 mg (to minimize the uncertainty of the mass determination) to no more than 500 mg (to minimize occlusion of impurities) is preferred. Potentially significant interfering substances should be

present at insignificant levels. Examples of significant interfering substances would be more than trace B in a sample for a determination of Si (B will volatilize with HF and bias results high) or significant amounts of a substance that is not easily separated from the analyte of interest (for example, Na may not be easily separated by ion exchange from a Li matrix). The suitability of the gravimetric quantification can be evaluated by analyzing a certified reference material (CRM) with a similar matrix using the identical procedure.

Qualitative Analysis. Many of the classical qualitative tests for elements or anions use the same precipitate-forming reactions applied in gravimetry. Gravimetry can also be used to determine the total mass of salt dissolved in a solution (for example, by evaporation with weighing).

Traceable Quantitative Analysis. The mass fraction of the analyte in a gravimetric determination is measured by weighing a sample and the separated compound of known stoichiometry from that sample on a balance that is traceable to the kilogram. Appropriate ratios of atomic weights (gravimetric factors) are applied to convert the compound mass to the mass of the analyte or species of interest. Gravimetry is an absolute method that does not require reference standards. Thus it is considered a direct primary reference measurement procedure [4.93]. Gravimetry can be performed in such a way that its operation is completely understood, and all significant sources of error in the measurement process can be evaluated and expressed in SI units together with a complete uncertainty budget. Any instrumentally determined corrections for residual analyte in the solution or for impurities in the precipitate must rely on standards that are traceable to the SI for calibration. To the extent that the gravimetric measurement is dependent on instrumentally-determined corrections, its absolute nature is debatable.

Titrimetry

Principles of the Technique. The fundamental basis of titrimetry is the stoichiometry of the chemical reaction that forms the basis for the given titration. The analyte reacts with the titrant according to the stoichiometric ratio defined by the corresponding chemical equation. The equivalence point corresponds to the point at which the ratio of titrant added to the analyte originally present (each expressed as an amount of substance) equals the stoichiometric ratio of the titrant to the analyte defined by the chemical equation.

The endpoint (the practical determination of the equivalence point) is obtained using visual indicators or instrumental techniques. Visual indicators react with the added titrant at the endpoint, yielding a product of a different color. Hence, a bias (indicator error) exists with the use of indicators, since the reaction of the indicator also consumes titrant. This bias is evaluated (along with interferent impurities in the sample solvent) in a blank titration. Potentiometric detection generally locates the endpoint as the point at which the second derivative of the potential versus the added titrant function equals zero. Other techniques (amperometry, nephelometry, spectrophotometry, and so on) are also used.

The titrant is typically added as a solution of the given reagent. Solutions are inherently homogeneous and can be conveniently added in aliquots that are not restricted by particle size. The amount of titrant added is obtained from the amount-of-substance concentration (hereafter denoted “concentration”) of the titrant in this solution and its volume (amount-of-substance content and mass, respectively, for gravimetric titrations). The concentration of the solution is obtained by direct knowledge of the assay of the reagent used to prepare the solution, or, more frequently, by standardization. In titrimetry, standardization is the assignment of a value (concentration or amount-of-substance content) to the titrant solution via titration(s) against a traceable standard.

Scope. Titrimetry is restricted to analytes that react with a titrant according to a strict stoichiometric relationship. A systematic bias in the result arises from any deviation from the theoretical stoichiometry or from the presence of any other species that reacts with the titrant. The selectivity of titrimetric analyses is generally not as great as that of element-specific instrumental techniques. However, titrimetric techniques can often distinguish among different oxidation states of a given element, affording information on speciation that is not accessible by element-specific instrumental techniques. Titrimetric methods generally have lower throughput than instrumental methods.

The most commonly encountered types of titrations are acid–base (acidimetric), oxidation–reduction, precipitation, and compleximetric titrations. The theory and practice of each are presented in [4.94]. A detailed monograph [4.95] provides exhaustive information, including properties of unusual titrants.

Titrimetric methods generally have lower throughput than instrumental methods.

Nature of the Sample. Samples analyzed by titrimetry must be in solution or dissolve totally during the course of the given titration. Certain analyses require pretreatment of the sample prior to the titrimetric determination itself. Nonquantitative recovery associated with such pretreatment must be taken into account when evaluating the uncertainty of the method. Examples include the determination of protein using the Kjeldahl titration and oxidation–reduction titrimetry preceded by reduction in a Jones reductor. If possible, a certified reference material (CRM) with a similar matrix should be carried through the entire procedure, including the sample pretreatment, to evaluate its quantitiveness.

Qualitative Analysis. Titrimetry is not generally used for qualitative analysis. It is occasionally used for semiquantitative estimations (for example, home water hardness tests).

Traceable Quantitative Analysis. Titrimetry is considered a primary ratio measurement [4.93], since the measurement itself yields a ratio (of concentrations or amount-of-substance contents). The result is obtained from this ratio by reference to a standard of the same kind. However, titrimetry is different from instrumental ratio primary reference measurements (as in isotope dilution mass spectrometry), in that the standard can be a different element or compound from the analyte. This ability to “link” different chemical standards has been proposed as a basis for interrelating many widely-used primary standard reagents [4.89].

The traceability of titrimetric analyses is based on the traceability to the SI of the standard used to standardize or prepare the titrant. CRMs used as standards in titrimetry are certified by an absolute technique, most often coulometry (see the following section).

Literature references frequently note that certain titrants can be prepared directly from a given reagent without standardization. Such statements are based on historic experience with the given reagent. Traceability for such a titrant rests solely on the manufacturer’s assay claim for the given batch of reagent, unless the titrant solution is directly prepared from the corresponding CRM or prepared from the commercial reagent and subsequently standardized versus a suitable CRM. Titrants noted in the literature as requiring standardization (such as sodium hydroxide) have lower and/or variable assays. Within- and between-lot variations of the assays of such reagents are too great for use as titrants without standardization.

The stability and homogeneity of the titrant affect the uncertainty of any titrimetric method in which it is used. The concentration of any titrant solution can change through evaporation of the solvent. A mass log of the solution in its container (recorded before and after each period of storage, typically days or longer) is useful for estimating this effect. In addition, the titrant solution can react during storage, either with components of the atmosphere (for example, O₂ with reducing titrants or CO₂ with hydroxide solutions) or with the storage container (for instance, hydroxide solutions with soda-lime glass or oxidizing titrants with some plastics). Each such reaction must be estimated quantitatively to obtain a valid uncertainty estimate for the given titrimetric analysis.

In titrations requiring ultimate accuracy, the bulk (typically 95% to 99%) of the titrant required to reach the endpoint is often added as a concentrated solution or as the solid titrant (see the Gravimetric Titrations section). The remaining 1% to 5% of the titrant is then added as a dilute solution. This approach permits optimal determination of the endpoint, which is further sharpened by virtue of the decreased total volume of solution. Using this approach, a precision on the order of 0.005% can be readily achieved.

Gravimetric Titrations. In traditional gravimetric titrations (formerly called “weight titrations”), the titrant solution is prepared on an amount-of-substance content (“moles per kilogram”) basis. The solution is added as a known mass. The amount of titrant added is calculated from its mass and amount-of-substance content.

Gravimetric titrimetry conveys the advantages of mass measurements to titrimetry. Masses are readily measured to an accuracy of 0.001%. Mass measurements are independent of temperature (neglecting the small change in the correction for air buoyancy resulting from the change in air density). The expansion coefficient of the solution (about 0.01% per °C for aqueous solutions) does not affect mass measurements.

A useful variation of the dual-concentration approach described above is to add the bulk of the titrant gravimetrically as the solid (provided the solid titrant has demonstrated homogeneity, as in a CRM) or as its concentrated solution. This bulk addition is followed by volumetric additions of the remainder of the titrant (for example, 5% of the total) as a dilute solution for the endpoint determination. The main advantage of this approach is that the endpoint determination can be performed using a commercial titrator. The advantages of gravimetric titrimetry and the dual-concentration ap-

proach described above are each preserved. Any effect of variation in the concentration of the dilute titrant is reduced by the reciprocal of the fraction represented by its addition (for example, a 20-fold reduction for 5%).

Coulometry

Principles of the Technique. Coulometry is based on Faraday's Laws of Electrolysis, which relate the charge passed through an electrode to the amount of analyte that has reacted. The amount-of-substance content of the analyte, v_{analyte} , is calculated directly from the current, I , passing through the electrode; the time, t ; the stoichiometric ratio of electrons to analyte, n ; the Faraday constant, F ; and the mass of sample, m_{sample} . The limits of integration, t_0 and t_f , depend on the type of coulometric analysis (see below).

$$v_{\text{analyte}} = \frac{\int_{t_0}^{t_f} I dt}{n F m_{\text{sample}}} . \quad (4.11)$$

Since I and t can be measured more accurately than any chemical quantity, coulometry is capable of the smallest uncertainty and highest precision of all chemical analyses.

Coulometric analyses are performed in an electrochemical (coulometric) cell. The coulometric cell has two main compartments. The sample is introduced into the sample compartment, which contains the working (coulometric) electrode. The other main compartment contains the counter-electrode. These main compartments are connected via one or more intermediate compartment(s) in series, providing an electrolytic link between the main compartments. The contents of the intermediate compartments may be rinsed or flushed back into the sample compartment to return any sample or titrant that has left the sample compartment during the titration.

Coulometry has two main variants, controlled-current and controlled-potential coulometry. Controlled-current coulometry is essentially titrimetry with electrochemical generation of the titrant. Increments of charge are added at one or more values of constant current. In practice, a small amount of the analyte is added to the cell initially. This analyte is titrated prior to introducing the actual sample. The endpoint of this pretitration yields the time t_0 in (4.11). The quantity t_f corresponds to the endpoint of the subsequent titration of the analyzed sample. The majority of the sample (typically 99.9%) is titrated at a high, accurately controlled constant current I_{main} (typically 0.1 A to 0.2 A) for a time t_{main} .

Lower values of constant current (1 mA to 10 mA) are used in the pretitration and in the endpoint determination of the sample titration. This practice corresponds to the dual-concentration approach used in high-accuracy titrimetry.

Controlled-potential coulometry is based on exhaustive electrolysis of the analyte. A potentiostat maintains the potential of the working electrode in the sample compartment at a constant potential with respect to a reference electrode. Electrolysis is initiated at $t = t_0$. The analyte reacts directly at the electrode at a mass-transport-limited rate. The electrode current, I , decays exponentially as the analysis proceeds, approaching zero as t approaches infinity. In practice, the electrolysis is discontinued at $t = t_f$, when the current decays to an insignificant value. A blank analysis is performed without added analyte to correct for any reduction of impurities in the electrolyte.

A survey of coulometric methods and practice through 1986 has been published [4.86].

Scope. Controlled-current coulometry is an absolute technique capable of extreme precision and low uncertainty. Analyses reproducible to better than 0.002% (relative standard deviation) with relative expanded uncertainties of less than 0.01% are readily achieved. Standardization of the titrant is not required. Most of the acidimetric, oxidation–reduction, precipitation, and compleximetric titrations used in titrimetry can be performed using controlled-current coulometry. Compared to titrimetry, controlled-current coulometry has the advantage that the titrant is generated and used virtually immediately. This feature avoids the changes in concentration during storage and use of the titrant that can occur in conventional titrimetry.

Controlled-potential coulometry is also an absolute technique. However, in most cases the correction for the background current limits the uncertainty to roughly 0.1%. Controlled-potential coulometry can afford greater selectivity, through appropriate selection of the electrode potential, than either controlled-current coulometry or titrimetry. The analyte must react directly at the electrode, in contrast to controlled-current coulometry or titrimetry, which can determine nonelectroactive species that react with the given titrant.

Compared to titrimetry, both coulometric techniques have lower throughput. A single high-precision controlled-current coulometric titration requires at least an hour to complete, using typical currents and sample masses. The exhaustive electrolysis required in

controlled-potential coulometry requires a period of up to 24 h for a single analysis.

Coulometric techniques are well-suited to automation. Automated versions of controlled-current coulometry [4.90,91] are used to certify the CRMs used as primary standards in titrimetry.

Nature of the Sample. Sample restrictions for coulometry are similar to those of titrimetry noted above. Additionally, electroactive components other than the analyte can interfere with coulometric analyses, even though the corresponding titrimetric analysis may be feasible.

Qualitative Analysis. Coulometric techniques are not used for qualitative analysis.

Traceable Quantitative Analysis. Traceability for coulometric analyses rests on the traceability of the measured physical quantities, I and t , and on the universal constant, F . In addition, the net coulometric reaction relating electrons to analyte must proceed with 100% current efficiency, so that each mole of electrons that passes through the electrode must react, directly or indirectly, with exactly $1/n$ moles [according to (4.11)] of the added analyte. Interferents or side-reactions that consume electrons yield a systematic bias in the coulometric result. Such interferents must be excluded or taken into account in the uncertainty analysis. The criterion of 100% current efficiency is evaluated by performing trial titrations with different current densities. In controlled-current titrations using an added titrant-forming reagent, its concentration can also be varied to evaluate the generation reaction [4.92].

Coulometry yields results directly as ν_{analyte} , as shown in (4.11). Results recalculated from ν_{analyte} to a mass fraction basis (“% assay”) must take into account the uncertainty in the IUPAC atomic weights [4.96] in the uncertainty analysis. In high-precision, controlled-current coulometry, this contribution to the combined uncertainty can be significant.

Assay and Purity Determinations of Analytical Reagents

The purity of an analytical reagent can be determined by two different approaches: direct assay of the matrix species, and purity determination by subtraction of trace impurities. In the first approach, a classical assay technique directly determines the mass fraction of the matrix species. In the second approach, the sum of the mass fractions of all components of the sample is taken

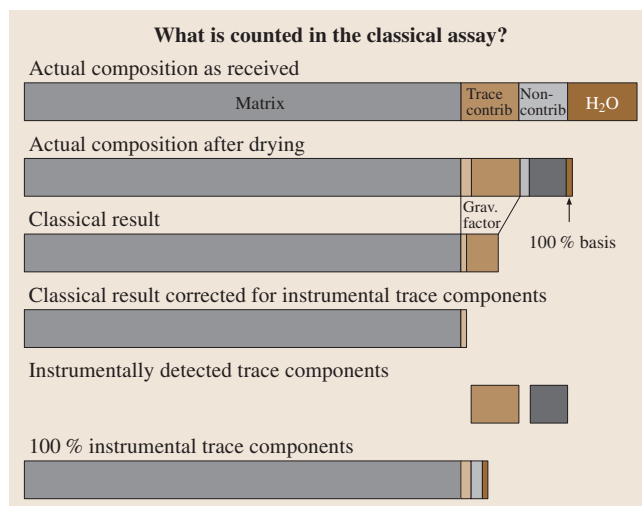

Fig. 4.7 Assay and purity determinations of analytical reagents

as exactly unity (100%). Trace-level impurities in the reagent are determined using one or more of the instrumental techniques described in this chapter. The sum of the mass fractions of all detected impurities is subtracted from 100% to yield the quoted purity (species that are not detected are taken as present at a mass fraction equal to half the detection limit for the given species, with a relative uncertainty of $\pm 100\%$; the corresponding value and uncertainty are included in the calculation of the purity and its uncertainty). No assay is performed per se.

In principle, both approaches yield the same result. However, difficulties arise in practice owing to the shortcomings of each. In the classical assay, trace impurities can contribute to the given assay, yielding a result greater than the true value. For example, trace Br^- is typically titrated along with the matrix Cl^- in classical titrimetric and coulometric assay procedures. Such trace interferents contribute to the apparent assay to an extent given by the actual mass fraction multiplied by the ratio of the equivalent weight [4.94,95] of the matrix species to that of the actual interferent, analogous to the gravimetric factor in gravimetry. The equivalent weight is given by the molar mass of the given species (calculated from IUPAC atomic weights [4.96]) divided by an integer n . For coulometry, n is that given in (4.11). For other methods, n is defined by the reaction that occurs in the titration or precipitation process.

In the “100% minus impurities” approach, the result only includes those species that are actually sought. For example, commercial high-purity reagents often state

a high purity, such as 99.999%, based on a semiquantitative survey of trace metal impurities. Other species, notably occluded water in high-purity crystalline salts, or dissolved gases in high-purity metals, are not sought, but they may be present at high levels, such as 0.1%. The purity with respect to the stated impurities is valid. However, if the level of unaccounted-for impurities is significant in comparison to the requirements for the calibrant, the stated purity is not valid for use of the reagent as a calibrant.

Figure 4.7 illustrates schematically the contrasting advantages and disadvantages of both approaches toward the purity of a hypothetical crystalline compound. The total length of each bar corresponds to the purity as obtained by the stated method(s). The matrix compound is shown at the left in gray. Impurities (including water) are denoted by segments of other shades at the right end of each bar. The upper bar shows the true composition as received. The impurities are divided into two classes: those that contribute to the classical assay, and those that do not. The second bar shows the true composition after drying. Each class of impurities is subdivided into a component that is detected instrumentally and one that is not. The two components that are detected instrumentally are shown separately in the second line from the bottom.

The third bar shows the classical assay without any corrections for contributing impurities. The lower bar

represents the purity obtained from the “100% minus impurities” approach. Each value has a positive bias with respect to the true assay, the length of the matrix segment. The gravimetric factor represents the ratio of equivalent weights noted above.

The fourth bar shows the result of the classical assay corrected for instrumentally-determined impurities that also contribute to the classical assay. This bar is closest in length to the true assay, represented by the length of the matrix segment. A small bias remains for impurities that both evade instrumental detection and contribute to the classical assay.

An additional problem with classical assays of ionic compounds is that a single technique generally determines only a component of the matrix compound (such as Cl^- in the assay of KCl by titration with Ag^+). The reported mass fraction of the assay compound is calculated assuming the theoretical stoichiometry. The identity of the counterion (such as K^+ in an argentimetric KCl assay) is assumed.

A more rigorous approach toward a “true” assay of an ionic compound by classical techniques is to perform independent determinations of the matrix components. As an example, K^+ in KCl could be assayed by gravimetry, with Cl^- assayed by titrimetry or coulometry. A rigorous version of each of these assays would include corrections for contributing trace interferences to the respective assays.

4.2 Microanalytical Chemical Characterization

Establishing the spatial relationships of the chemical constituents of materials requires special methods that build on many of the bulk methods treated in the preceding portion of this chapter. There may be interest in locating the placement of a trace chemical constituent within an engineered structure, or in establishing the extent of chemical alteration of a part taken out of service, or in locating an impurity that is impacting on the performance of a material. When the question of the relative spatial locations of different chemical constituents is at the core of the measurement challenge, methods of chemical characterization that preserve the structures of interest during analysis are critical. Not all bulk analytical methods are suited for surface and/or microanalytical applications, but many are. In the remainder of this chapter, some of the more broadly applicable methods are touched upon, indicating their utility for establishing chemical composition as a function of spatial location, in addition to their use for quantitative analysis.

4.2.1 Analytical Electron Microscopy (AEM)

[4.97–100]

When a transmission electron microscope (TEM) is equipped with a spectrometer for chemical analysis, it is usually referred to as an *analytical electron microscope*. The two most common chemical analysis techniques employed by far are energy-dispersive X-ray spectrometry (EDS) and electron energy-loss spectroscopy (EELS). In modern TEMs a field emission electron source is used to generate a nearly monochromatic beam of electrons. The electrons are then accelerated to a user-defined energy, typically in the range of 100 keV to 400 keV, and focused onto the sample using a series of magnetic lenses that play an analogous role to the condenser lens in a compound light microscope. After interacting with the sample, the transmitted electrons are formed into a real image using a magnetic objective lens. This real image is then further magnified by

a series of magnetic intermediate and projector lenses and recorded using a charged coupled device (CCD) camera.

Principles of the Technique. Images with a spatial resolution near 0.2 nm are routinely produced using this technique. In an alternative mode of operation, the condenser lenses can be used to focus the electron beam into a very small spot (less than 1 nm in diameter) that is rastered over the sample using electrostatic deflection coils. By recording the transmitted intensity at each pixel in the raster, a *scanning transmission electron microscope* (STEM) image can be produced. After a STEM image has been recorded, it can be used to locate features of interest on the sample and the scan coils can then be used to reposition the electron beam with high precision onto each feature for chemical analysis. As the beam electrons are transmitted through the sample, some of them are scattered inelastically and produce atomic excitations. Using an EELS spectrometer, a spectrum of the number of inelastic scatters as a function of energy loss can be produced. Simultaneously, an XEDS spectrometer can be used to measure the energy spectrum of X rays emitted from the sample as the atoms de-excite. Both of these spectroscopies can provide detailed quantitative information about the chemical structure of the sample with very high spatial resolution.

In many ways EELS and XEDS are complementary techniques, and the limitations of one spectroscopy are often offset by the strengths of the other. Because elements with low atomic number do not fluoresce efficiently, XEDS begins to have difficulty with elements lighter than sodium and is difficult or impossible to use for elements below carbon. In contrast, EELS is very efficient at detecting light elements. Because EELS has much better energy resolution than XEDS (approximately 1 eV for EELS and 130 eV for XEDS), it is also capable of extracting limited information about the bonding and valence state of the atoms in the analysis region. The two main drawbacks to EELS are that the samples need to be very thin compared to XEDS samples, and that it places greater demands on the analyst, both experimentally during spectrum acquisition and theoretically during interpretation of the results. Because XEDS works well on relatively thick samples and is easier to execute, it enjoys widespread use, while EELS is often considered a more specialized technique.

Nature of the Sample. Perhaps the single most important drawback to AEM is that all samples must be thinned to electron transparency. The maximum accept-

able thickness varies with the composition of the sample and the nature of the analysis sought, but in most cases the samples must be less than about 500 nm thick. For quantitative EELS, the samples must be much thinner: a few tens of nanometers thick at most. Another important limitation is that the samples be compatible with the high vacuum environment required by the electron optics. Fortunately, a wide array of sample preparation techniques have been developed over the years to convert macroscopic pieces of (sometimes wet) material into very thin slices suitable for AEM: dimpling, acid jet polishing, bulk ion milling, mechanical polishing, focused ion beam (FIB) processing, and diamond knife sectioning using an ultramicrotome. Preparation of high-quality AEM samples that are representative of the parent material without introducing serious artifacts remains one of the most important tasks facing the AEM analyst.

Qualitative Analysis. The AEM is a powerful tool for the qualitative chemical analysis of nanoscale samples. The XEDS spectrometer can be used to detect most elements present in the sample at concentrations of 1 mg/g (0.1% mass fraction) or higher (see Fig. 4.8). EELS can be used in many cases down to a detection limit of 100 $\mu\text{g/g}$, depending on the combination of elements present. While these numbers are not impressive in terms of minimum mass fraction (MMF) sensitivity, it should be noted that this performance is available with spatial resolutions measured in nanometers and for total sample masses measured in attograms. In favorable cases, single-atom sensitivity has been demonstrated in the AEM for several elements, thus establishing it as a leader in minimum detectable mass (MDM) sensitivity.

Traceable Quantitative Analysis. Through the use of standards and the measurement of empirical detector sensitivity factors (Cliff–Lorimer k -factors), XEDS measurements in the AEM can be made quantitative. The precision of the measurement is often limited by the total signal available (related to the sample thickness and elemental abundances), while the accuracy is affected by poorly-known sample geometry and absorption effects. Traceability of the results is limited by the extreme rarity of certified reference materials with sufficient spatial homogeneity suitable for the measurement of k -factors. EELS measurements can be quantified by a first-principles approach that does not require standards, but this method is limited in practice by our inability to compute accurate scattering cross-sections and our incomplete understanding of solid-state beam-sample interactions.

4.2.2 Electron Probe X-Ray Microanalysis

[4.101–103]

Most solid matter is characterized on the microscopic scale by a chemically differentiated microstructure with feature dimensions in the micrometer to nanometer range. Many physical, biological and technological processes are controlled on a macroscopic scale by chemical processes that occur on the microscopic scale. The electron probe X-ray microanalyzer (EPMA) is an analytical tool based upon the scanning electron microscope (SEM) that uses a finely focused electron beam to excite the specimen to emit characteristic X rays.

Fig. 4.9 Energy-dispersive spectrometry (EDS) of an $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ single crystal with a trace aluminum constituent. Beam energy = 20 keV

The analyzed region has lateral and depth dimensions ranging from 50 nm to 5 μm , depending upon specimen composition, the initial beam energy, the X-ray photon energy, and the exact analytical conditions.

Principles of the Technique. The EPMA/SEM is capable of quantitatively analyzing major, minor and trace elemental constituents, with the exceptions of H, He and Li, at concentrations as low as a mass fraction of approximately 10^{-5} . The technique is generally considered nondestructive and is typically applied to flat, metallographically polished specimens. The SEM permits application of the technique to special cases such as rough surfaces, particles, thin layers on substrates, and unsupported thin layers. Additionally, the SEM provides a full range of morphological imaging and structural crystallography capabilities that enable characterization of topography, surface layers, lateral compositional variations, crystal orientation, and magnetic and electrical fields over the micrometer to nanometer spatial scales. Two different types of X-ray spectrometers are in widespread use, the energy-dispersive spectrometer (EDS) and the wavelength-dispersive (or crystal diffraction) spectrometer (WDS). The characteristics of these spectrometers are such that they are highly complementary: the weaknesses of one are substantially offset by the strengths of the other. Thus, they are often employed together on the same electron beam instrument. The recent emergence of the silicon drift detector (SDD) has extended the EDS output count rate into the range 100 kHz to 500 kHz. Figure 4.9 shows a typical EDS spectrum from a multicomponent specimen, $\text{YBa}_2\text{Cu}_3\text{O}_7$, demonstrating the wide energy coverage. Figure 4.10 shows a comparison of the EDS and WDS spectra for a portion of the dysprosium L-series. The considerable improvement in the spectral resolution of WDS compared to EDS is readily apparent. Table 4.3 compares a number of the spectral parameters of EDS and WDS.

Qualitative Analysis. Qualitative analysis, the identification of the elements responsible for the characteristic peaks in the spectrum, is generally straightforward for major constituents (for example, those present at concentrations $> 0.1\%$ mass fraction), but can be quite challenging for minor (0.01–0.1% mass fraction) and trace constituents ($< 0.01\%$ mass fraction). This is especially true for EDS spectrometry when peaks of minor and trace constituent peaks are in the vicinity (< 100 eV away) of peaks from major constituents. Such interferences require peak deconvolution, especially when the minor or trace element is a light

Table 4.3 Comparison of the characteristics of EDS and WDS X-ray spectrometers

Feature	EDS (semiconductor)	WDS
Energy range	0.1–25 keV (Si) 0.1–100 keV (Ge)	0.1–12 keV (4 crystals)
Resolution at MnK α	130 eV (Si); 125 eV (Ge)	2–20 eV (E, crystal)
Instantaneous energy coverage	Full range	Resolution, 2–20 eV
Deadtime	50 MS	1 MS
Solid angle (steradians)	0.05–0.2	0.01
Quantum efficiency	$\approx 100\%$, 3 keV to 15 keV (Si)	< 30%, variable
Maximum count rate, EDS	≈ 3 kHz (best resolution)	100 kHz (single photon energy)
Maximum count rate, SDD	≈ 30 kHz (mapping)	
	≈ 15 kHz (best resolution) ≈ 400 kHz (mapping)	
Full spectrum collection	10 s to 200 s	600 s to 1800 s
Special strengths	Views complete spectrum for qualitative analysis at all locations	Resolves peak interferences; rapid pulses for composition mapping

element ($Z < 18$), for which only one peak may be resolvable by EDS. Automatic computer-aided EDS qualitative analyses must always be examined manually for accuracy. The superior spectral resolution of the WDS can generally separate major/minor or major/trace peaks under these conditions, and is also not susceptible to the spectral artifacts of the EDS, such as pile-up peaks and escape peaks. However, additional care must be taken with WDS to avoid incorrectly interpreting higher order reflections ($n = 2, 3, 4, \dots$ in the Bragg diffraction equation) as peaks arising from other elements.

Quantitative Analysis: Spectral Deconvolution. Quantitative analysis proceeds in three stages: (1) extraction of peak intensities; (2) standardization; and (3) calculation of matrix effects. For EDS spectrometry, the background is first removed by applying a background model or a mathematical filter. Peak deconvolution is then performed by the method of multiple linear least squares (MLLSQ). MLLSQ requires a model of the peak shape for each element determined on the user's instrument, free from interferences from other constituents. A peak region from an unknown that consists of contributions from two or more constituents is deconvolved by constructing linear combinations of the reference peak shapes for all constituents. The synthesized peaks are compared with the measured spectrum until the best match is obtained, based upon a statistical criterion such as minimization of chi-squared, determined on a channel-by-channel basis. For WDS spectrometry, the resolution is normally adequate to separate the peak interferences so that the only issue is the removal of

**Fig. 4.10** Comparison of EDS and WDS for dysprosium L-family X rays excited with a beam energy of 20 keV

background. Because the background changes linearly over the narrow energy window of a WDS peak, an accurate background correction can be made by interpolating between two background measurements on either side of the peak.

Quantitative Analysis: Standardization. The basis for accurate quantitative electron probe X-ray microanalysis is the measurement of the ratio of the intensity of the X-ray peak in the unknown to the intensity of that same peak in a standard, with all measurements made for the same beam energy, known electron dose (beam

current \times time), and spectrometer efficiency. This ratio, known as the k -value, is proportional to the ratio of mass concentrations for the element in the specimen and standard:

$$I_{A,\text{spec}}/I_{A,\text{std}} = k \approx C_{A,\text{spec}}/C_{A,\text{std}} . \quad (4.12)$$

This standardization step quantitatively eliminates the influence of detector efficiency, and reduces the impact of many physical parameters needed for matrix corrections. A great strength of EPMA is the simplicity of the required standard suite. Pure elements and simple stoichiometric compounds for those elements that are unstable in a vacuum under electron bombardment (such as pyrite, FeS_2 for sulfur) are sufficient. This is a great advantage, since making multielement mixtures that are homogeneous on the micrometer scale is generally difficult due to phase separation.

Quantitative Analysis: Matrix Correction. The relationship between k and ($C_{A,\text{spec}}/C_{A,\text{std}}$) is not an equality because of the action of matrix or interelement effects. That is, the presence of element B modifies the intensity of element A as it is generated, propagated and detected. Fortunately, the physical origin of these matrix effects is well-understood, and by a combination of basic physics as well as empirical measurements, multiplicative correction factors for atomic number effects (Z), absorption

(A) and fluorescence (F) have been developed:

$$C_{A,\text{spec}}/C_{A,\text{std}} = kZA F . \quad (4.13)$$

From the previous discussion, it is obvious that all three matrix effects – Z , A , and F – depend strongly on the composition of the measured specimen, which is the unknown for which we wish to solve. The calculation of matrix effects must therefore proceed in an iterative fashion from an initial estimate of the concentrations to the final calculated value. The measured k -values are used to provide the initial estimate of the specimen composition by setting the concentrations equal to normalized k -values:

$$C_{i,1} = k_i / \sum k_i , \quad (4.14)$$

where “ i ” denotes each measured element. The initial concentration values are then used to calculate an initial set of matrix corrections, which in turn are used to calculate predicted k -values. The predicted k -values are compared with the experimental set, and if the values agree within a defined error, the calculation is terminated. Otherwise, the cycle is repeated. Convergence is generally found within three iterations.

This matrix correction procedure has been tested repeatedly over the last 25 years by using various microhomogeneous materials of known composition as test unknowns, including alloys, minerals, stoichiometric binary compounds, and so on. A typical distribution of relative errors (defined as $[\text{measured} - \text{true}]/\text{true} \times 100\%$) for binary alloys analyzed against pure element standards is shown in Fig. 4.11.

Compositional Mapping. A powerful method of presenting X-ray microanalysis information is in the form of compositional maps or images that depict the area distribution of the elemental constituents. These maps can be recorded simultaneously with SEM images that provide morphological information [4.104–106]. The digital output from a WDS, EDS or SDD over a defined range of X-ray photon energy corresponding to the peaks of interest is recorded at each picture element (pixel) scanned by the beam. The most sophisticated level of compositional mapping involves collecting a spectrum, or at least a number of spectral intensity windows for each picture element of the scanned image. These spectral data are then processed with the background correction, peak deconvolution, standardization, and matrix correction necessary to achieve quantitative analysis. The resulting maps are actually records of the local concentrations, so

Fig. 4.11 Distribution of analytical relative errors (defined as $[100\% \times [\text{measured} - \text{true}]/\text{true}]$) for binary alloys as measured against pure element standards. Matrix correction by National Bureau of Standards ZAF; wavelength-dispersive X-ray spectrometry; measurement precision typically 0.3% relative standard deviation (After [Heinrich and Yakowitz])

that when displayed, the gray or color scale is actually related to the concentration. Figure 4.12 shows examples of compositional maps for an aluminum–nickel alloy.

4.2.3 Scanning Auger Electron Microscopy

[4.107–109]

Scanning Auger electron microscopy is an electron beam analytical technique based upon the scanning electron microscope. Auger electrons are excited in the specimen by a finely focused electron beam with a lateral spatial resolution of about 2 nm point-to-point in current state-of-the-art instruments. An electron spectrometer capable of measuring the energies of emitted Auger electrons in the range 1 eV to 3000 eV is employed for qualitative and quantitative chemical analysis. As in electron-excited X-ray spectrometry, the positions of the peaks are representative of the chemical composition of the specimen. The inelastic mean free path for Auger electrons is on the order of 0.1 nm to about 3 nm, which means that only the Auger electrons that are produced within a few nanometers of the specimen surface are responsible for the analytical signal. The current state-of-the-art instruments are capable of providing true surface characterization at about 10 nm lateral resolution.

Principles of the Technique. A primary electron beam interacting with a specimen knocks out a core electron, creating a core level vacancy. As a higher energy level electron moves down to fill the core level vacancy, energy is released in the form of an Auger electron, with the energy corresponding to the difference between the two levels. This is the basis for Auger electron spectroscopy (AES). The core-level vacancy can also be created by an X-ray photon, and this is the basis for X-ray photoelectron spectroscopy. The energy difference between the higher energy electron and the core level can also be released as a characteristic X-ray photon, and this is the basis for electron probe microanalysis.

The primary electron beam in an Auger microscope operates between 0.1 kV and 30 kV, and beam currents are on the order of nanoamps for analysis. Tungsten and lanthanum hexaboride electron guns can be used for AES, but field emission electron guns are the best choice because of the higher current density. It is desirable for AES to have more electrons in a small spot, and field emission guns deliver the smallest spot sizes normalized to beam current. Auger microscopes are also very good scanning electron microscopes, capable of producing secondary electron images (see Fig. 4.13) of the specimen as well as backscattered electron images if so equipped.

Auger electrons are produced throughout a sample volume defined by the interaction of the primary electron beam and the specimen. Auger electrons are relatively low in energy and so can only travel a small

Fig. 4.13 SE image of particle, 25 μm field of view

Fig. 4.14 Direct AES of copper with carbon and oxygen

Fig. 4.15 Derivative AES of copper with carbon and oxygen

distance in a solid. Only the Auger electrons that are created close to the surface, within a few nanometers, have sufficient mean free path to escape the specimen and be collected for analysis. Since the Auger information only comes from the first few nanometers of the specimen surface, AES is considered a surface-sensitive technique. Several review articles are available.

Nature of the Sample. The surface sensitivity of AES requires the specimen to have a clean surface free of contamination. For this reason, Auger microscopes are ultrahigh vacuum (UHV) in the specimen chamber, which is on the order of 10^{-8} Pa. Steps must be taken to clean specimens prior to introduction into the Auger microscope so that they are free of volatile organic compounds that can contaminate the chamber vacuum. The Auger specimen chamber is equipped with an argon ion gun for sputter cleaning-off the contamination or ox-

ide layer that coats specimens as a result of transporting them in air.

Investigation of a buried structure or an interface that is deeper than the Auger escape depth can be accomplished by Auger depth profiling. In Auger depth profiling, the instrument alternates between Ar ion sputtering of the surface and Auger analysis of the surface until, as material is sputtered away, the elemental composition changes with depth.

Qualitative/Quantitative Analysis. Auger electrons are recorded as a function of their energy by the electron spectrometer in the Auger microscope and provide elemental as well as bonding information. There are two types of electron spectrometer, the cylindrical mirror analyzer (CMA) and the hemispherical analyzer (HSA). The CMA is concentric with the electron beam and has a greater throughput because of its favorable solid angle. The HSA has the higher energy resolution, which is

desirable for unraveling overlapped peaks. In the direct display mode (Fig. 4.14), peaks on the sloping background of an Auger spectrum indicate the presence of elements between Li and U. Spectra can also be displayed in the derivative mode (Fig. 4.15), which removes the sloping background and random noise. Auger quantitation is complicated by many instrumental factors and is normally done with sensitivity factors normalized to an elemental silver Auger signal collected under the same instrumental conditions.

4.2.4 Environmental Scanning Electron Microscope

[4.110–117]

The environmental scanning electron microscope (ESEM) is a unique modification of the conventional scanning electron microscope (SEM). While the SEM operates with a modest vacuum ($\approx 10^{-3}$ Pa), the ESEM is able to operate with gas pressures ranging between 10 Pa to 2700 Pa in the specimen chamber due to a multistage differential pumping system separated by apertures. The relaxed vacuum environment of the ESEM chamber allows examination of wet, oily and dirty specimens that cannot be accommodated in the higher vacuum of a conventional SEM specimen chamber. Perhaps more significant, however, is the ability of the ESEM to maintain liquid water in the specimen chamber with the use of a cooling stage (Fig. 4.16). The capability to provide both morphological and compositional analysis of hydrated samples has allowed the ESEM to benefit a number of experimental fields, ranging from material science to biology. Several review articles are available.

Principles of the Technique. The ESEM utilizes a gaseous secondary electron detector (GSED) that takes advantage of the gas molecules in the specimen chamber. The primary electron beam, operating between 10 kV and 30 kV, are generated from tungsten, lanthanum hexaboride, or field emission electron guns. When a primary electron beam strikes a specimen, it generates both backscattered and secondary electrons. Backscattered electrons are energetic and are collected by a line-of-sight detector. The secondary electrons are low-energy and, as they emerge from the specimen, are accelerated towards the GSED by the electric field set up between the positive bias on the GSED and the grounded specimen stage. These secondary electrons collide with gas molecules, resulting in ionizations and more secondary electrons, which are subsequently ac-

Fig. 4.16 ESEM image of hydrated, freshwater algal surface. Scale bar = 10 μm

celerated in the field. This amplification process repeats itself multiple times, generating imaging gain in the gas. A byproduct of this process is that the gas molecules are left positively charged and act to discharge the excess electrons that accumulate on an insulating specimen from the primary electron beam. This charge neutralization obviates the need for conductive coatings or low-voltage primary beams, as are often used in conventional SEM to prevent surface charging under the electron beam.

Secondary and backscattered electrons are produced throughout the interaction volume of the specimen, the depth of which is dependent on the energy of the primary electron beam and the specimen composition. The backscattered electrons contain most of the energy of the primary electron beam and can therefore escape from a greater depth in the specimen. In contrast, secondary electrons are only able to escape from the top 10 nm of the specimen, although backscattered electrons can also create secondary electrons prior to exiting the sample and provide sample depth information to the image. In general, it is possible to routinely resolve features ranging from 10 nm to 50 nm. However, the primary electron beam can also interact with the gas molecules, resulting in beam electrons being scattered out of the focused electron beam into a wide, diffuse skirt that surrounds the primary beam impact point. Similarly, chamber gas composition can also impact the amplification process and thereby affect image quality. Several review articles [4.110–117] are available.

Fig. 4.17 EDS image of biological solids from a wastewater treatment facility. The indium peak is caused by the support stub

Qualitative/Quantitative Analysis. In addition to the image-producing backscattered and secondary electrons that are generated when a primary beam strikes a specimen, there are also electron beam interactions that result in the generation of X-rays from the interaction volume. The energy of the resulting X-rays is representative of the chemical composition within the interaction volume and can be measured with an EDS. X-ray counts are plotted as a function of their energy, and the resulting peaks can be identified by element and line with standard X-ray energy tables (Fig. 4.17). EDS in the ESEM is considered a qualitative method of compositional analysis since X-rays may originate hundreds of micrometers from the impact point of the primary electron beam as a result of electrons scattered out of the beam by gas molecules.

4.2.5 Infrared and Raman Microanalysis

[4.118–121]

Infrared and Raman microanalysis is the application of Raman and/or infrared (IR) spectroscopies to the analysis of microscopic samples or sample areas. These techniques are powerful approaches to the characterization of spatial variations in chemical composition for complex, heterogeneous materials, operating on length scales similar to those accessible to conventional optical microscopy while also yielding the high degree of chemical selectivity that underlies the utility of these vibrational spectroscopies on the macroscale. Sample analyses of this type are particularly useful in establishing correlations between macroscopic performance properties (such as mechanical and chemical stability, biocompatibility) and material microstructure, and are thus a useful ingredient in the rational design of

high-performance materials. Several review articles are available.

Principles of the Technique. A typical Raman microscope comprises a laser excitation source, a light microscope operating in reflection mode, and a spectrometer. Photons inelastically scatter from the sample at frequencies shifted from that of the excitation radiation by the energies of the fundamental vibrational modes of the material, giving rise to the chemical specificity of Raman scattering. A high-quality microscope objective is used both to focus the excitation beam to an area of interest on the sample and to collect the backscattered photons. In general, the Rayleigh (elastic) scattering of the incident photons is many orders of magnitude more efficient than Raman scattering. Consequently, the selective attenuation of the Rayleigh photons is a critical element in the detection scheme; recent advances in dielectric filter technology have simplified this problem considerably. The attainable spatial resolution is, in principle, limited only by diffraction, allowing sub-micrometer lateral resolution in favorable cases. Fine vertical resolution can also be achieved through the use of a confocal aperture, opening up the possibility of constructing 3-D chemical images through the use of Raman depth profiling. Raman images are usually acquired by raster scanning the sample with synchronized spectral acquisition. Wide-field illumination and imaging configurations have been explored, but they are generally only useful in limited circumstances due to sensitivity issues. Chemical composition maps can easily be extracted from Raman images by plotting the intensities of bands due to particular material components. Subtle spectral changes (such as band shifts) can also be exploited to generate spatial maps of other material properties, such as crystallinity and strain.

A typical IR microscope system consists of a research-grade Fourier transform (FT) IR spectrometer coupled to a microscope that operates in both reflection and transmission modes. Reflective microscope objectives are widely used due to their uniformly high reflectivity across the broad infrared spectral region of interest and their lack of chromatic aberration. The spectrum of IR light measured upon transmission through or reflection from the sample is normalized to a suitable background spectrum. The normalized spectrum displays attenuation of the IR light reaching the detector due to direct absorption at frequencies resonant with the active vibrational modes of the sample components. The frequencies at which absorption occurs are characteristic of the presence of particular functional groups

(such as C=O), resulting in the powerful chemical specificity of the measured spectra (Fig. 4.18). Microscopes employing a sample raster scanning approach to image acquisition were the first available, but have now been joined by those employing a wide-field illumination, array-based imaging detection approach. The spatial resolution attainable with this technique is typically on the order of 20 μm to 40 μm , and diffraction-limited performance is not achieved due to source brightness limitations. Several alternative sampling techniques that have found widespread utility in IR spectroscopy of macroscopic samples have been successfully adapted on the microscale, including attenuated total reflection (ATR) and grazing incidence reflectivity. Maps of chemical composition can be extracted from IR spectral images in a manner similar to the Raman case, wherein amplitudes of bands due to material components of interest are plotted as a function of position on the sample.

Raman and IR microanalysis are complementary techniques, as is the case for their macroscopic analogs, widely applicable to extended solids, particles, thin films and even these materials under liquid environments. The choice between these analysis techniques is often dictated by the relative strength of the Raman and/or IR transitions that most effectively discriminate among the sample components. Notably, the molecular properties that dictate the strength of these transitions, molecular polarizability in the case of Raman and transition dipole

moments for IR, are not generally correlated. In fact, for centrosymmetric molecules the techniques are particularly complementary as IR transitions forbidden by symmetry are by definition Raman active and vice versa. Sample considerations also play a role in this choice, as the nature of the material can preclude the use of one (or both) techniques. Raman microscopy can be used to study a broad array of materials, as the Raman photons are scattered over a wide, often isotropic, distribution of solid angles and are thus easily detected by the same microscope objective used for excitation. In contrast, transmission IR microscopy requires that the sample of interest be mounted on an IR-transparent substrate and that the sample itself be sufficiently thin to avoid saturation effects. Similarly, reflection mode IR microscopy is optimized when the analyte is mounted on a highly reflective substrate; the constraints on sample thickness apply in this configuration as well. However, Raman microscopy suffers from another significant limitation, as background fluorescence precludes the measurement of high signal-to-noise Raman spectra for many materials, particularly for higher-energy excitation wavelengths (for example, 488 nm, 532 nm). It is often the case that the shot noise present on a large fluorescence background is sufficiently larger than the Raman signal itself such that no amount of signal averaging will yield a high-quality spectrum. Notably, typical cross-sections for fluorescence are vastly larger than those of Raman scattering, so the Raman excitation wavelength need not be

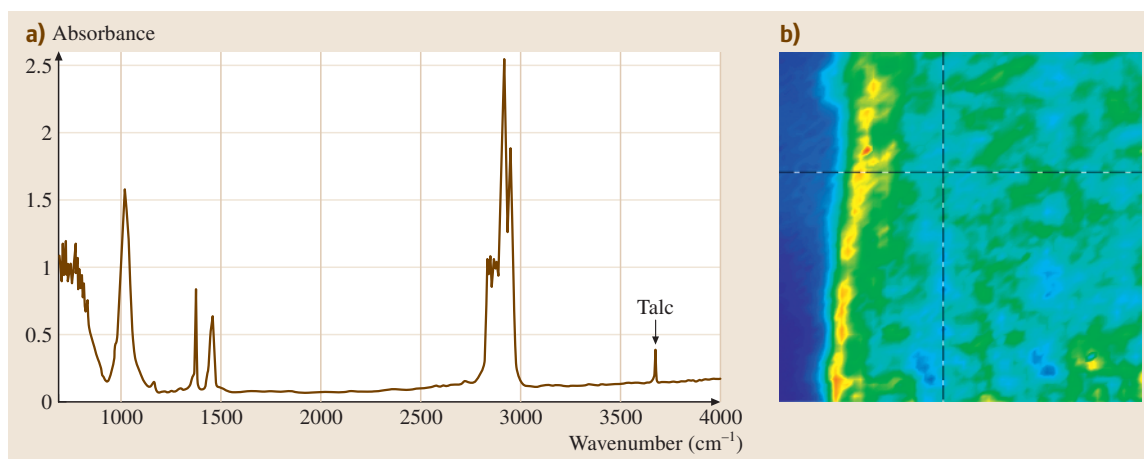

Fig. 4.18 (a) IR microspectrum of a thin film microtome section of injection-molded thermoplastic olefin. The sharp spectral feature at 3700 cm^{-1} is due to the OH stretching vibration of the talc filler (b) $325\text{ }\mu\text{m} \times 325\text{ }\mu\text{m}$ IR image of a thermoplastic olefin cross-section wherein the amplitude of the talc band is plotted on a blue (low amplitude) to red (high amplitude) color scale. The yellow–red band on the left side of the film is due to a talc-rich layer formed near the mold surface

in exact resonance with a sample electronic transition to yield an overwhelming fluorescence background. This problem can be mitigated by the use of lower energy excitation wavelengths (for example, 785 nm, 1064 nm), although the Raman scattering efficiency drops with λ^4 . The cross-sections for Raman scattering are generally much lower than those of IR absorption, and so some materials with low Raman cross-sections are not amenable to Raman microanalysis, simply due to lack of signal, particularly in the microanalysis context. Although the Raman signal does scale with incident intensity, sample damage considerations typically limit this quantity. IR microanalysis often suffers from the opposite problem, wherein even microscopic samples can absorb sufficient radiation to lead to saturation effects in the spectra.

Nature of the Sample. The sample preparation requirements for Raman microscopy are quite modest; the surfaces of most solid materials are easily examined and some depth profiling is also possible depending on the material transparency. The Raman spectra of some materials are dominated by a fluorescent background; this is the most important sample property limiting the application of Raman microscopy. Two factors are critical in sample preparation for IR microscopy: choice of mounting substrate and sample thickness. For transmission microscopy, the substrate is limited to a set of materials that are broadly transparent over the IR (such as CaF_2 or KBr). In reflection microscopy, the substrate is often a metal film that is uniformly reflective across the IR region (such as Au or Ag). The issue of sample thickness is related to the onset of saturation effects in the spectra. The cross-sections for many IR absorption transitions are sufficiently large that samples can absorb nearly all of the resonant incident radiation, leading to spectral artifacts that interfere with both qualitative and quantitative analysis. For example, polymers as thin as 30 μm can show saturation artifacts in the C–H stretching bands. Sample preparation methods such as microtomy and alternative sampling methods such as micro-ATR can be used to address this problem for some classes of samples.

Qualitative Analysis. IR and Raman microspectroscopy are both powerful tools for the qualitative analysis of microscopic samples. The appearance of particular bands in the measured vibrational spectra indicate the presence of specific functional groups, and the chemical structure of the analyte can often be obtained from an analysis of the entire spectrum. Additionally, large libraries of IR and Raman spectra of a wide variety of materials are now available, greatly facilitating the use of spectral matching algorithms in the identification of materials on the basis of the IR and/or Raman spectrum. The chemical specificity of vibrational spectroscopy is undoubtedly its most powerful characteristic, one that is particularly useful in the identification of various components of complex materials that are compositionally heterogeneous on microscopic length scales. The sensitivity of these techniques is difficult to characterize as cross-sections for these types of transitions generally vary over many orders of magnitude and thus the sensitivity for different analytes varies in a similar manner. However, analytes that occupy the minimum focal volumes attainable in these microscopies (Raman: 1 $\mu\text{m} \times 1 \mu\text{m} \times 3 \mu\text{m}$, IR: 25 $\mu\text{m} \times 25 \mu\text{m} \times 50 \mu\text{m}$) are generally detectable in both IR and Raman (particularly for strong scatterers).

Traceable Quantitative Analysis. Although traceable quantitative analysis of macroscopic samples with IR spectroscopy is well-established (particularly for gases), extension to the microanalysis of solids is quite challenging. Through the use of well-characterized standard materials, IR microscopy can be used for quantitation, although the accuracy of this approach is often limited by optical effects (such as scattering) due to the complex morphology of typical samples. Estimates of Raman scattering cross-sections can be made in favorable cases, based on the characterization of instrumental factors affecting detection efficiency. However, extension to quantitative analysis is impractical due to a lack of reference materials and difficulties associated with the ab initio calculation of Raman cross-sections for all but the simplest materials.

5. Nanoscopic Architecture and Microstructure

The methods compiled in this chapter are important in many areas of materials science and technology because various physical properties of materials (mechanical, thermal, electronic, optical, magnetic, dielectric, biological) depend on their geometric architecture, on scales ranging from the atomic or nanoscopic to the semimicroscopic. Some of the properties are governed only by an elementary atomic group in the structural hierarchy while others are brought about by cooperative functioning of multiple phases or microscopic structures in different dimensions. Corresponding to the vast variety of materials and their properties, a wide range of experimental techniques are available, so that the choice of which technique to employ on starting a study may not be clear. In this respect one should also bear in mind that some of the techniques presented in this chapter are based on physical principles, which are also relevant to the measurement methods compiled in Chaps. 4 and 6.

5.1 Fundamentals	159
5.1.1 Diffraction and Scattering Methods	159
5.1.2 Fundamentals of Crystal Diffraction	160

Following the preceding chapter on the measurement of chemical composition, this chapter focuses on the characterization of the *nanoscopic architecture and microstructure of materials*. Surface and interface characterization methods are treated in the next chapter.

To support the selection of the most appropriate method for a given problem, all readers are recommended to read Sect. 5.1 before proceeding to the relevant subsequent section. Table 5.1 may help you to select applicable methods. If you are interested in, for example, the structure of macromolecules, you go to the “Molecular architecture” column under “Subject under consideration.” You will find ◦ symbols in the rows of that column that express an applicable methodology, indicated in the first and second columns.

5.1.3 Microscopy and Topography	163
5.1.4 Spectroscopy	173
5.2 Crystalline and Amorphous Structure Analysis	180
5.2.1 Long-Range Order Analysis	180
5.2.2 Medium-Range Order Analysis	182
5.2.3 Short-Range Order Analysis	184
5.3 Lattice Defects and Impurities Analysis ...	187
5.3.1 Point Defects and Impurities	187
5.3.2 Extended Defects	199
5.4 Molecular Architecture Analysis	206
5.4.1 Structural Determination by X-Ray Diffraction	206
5.4.2 Nuclear Magnetic Resonance (NMR) Analysis	206
5.4.3 Chemophysical Analysis	214
5.5 Texture, Phase Distributions, and Finite Structures Analysis	217
5.5.1 Texture Analysis	217
5.5.2 Microanalysis of Elements and Phases	219
5.5.3 Diffraction Analysis of Fine Structures	220
5.5.4 Quantitative Stereology	221
References	225

If you find the line (method) “NMR” interesting, you may check the “Material type” and “Atom arrangement” sections on the same line to the right, to find that the method is applicable to amorphous samples as well as crystals as long as the sample is nonmetallic. Special requirements, if any, are noted in the column on the far right. The third column indicates the section(s) describing the detail of the method or literature to which the interested reader should refer. You may then proceed to each section or subsection for further details.

The organization of the chapter is as follows. After a concise review of the necessary fundamentals – diffraction and scattering methods, microscopy and topography, spectroscopy – the presentation of *Measurement Methods for Nanoscopic Architecture*

- Crystalline and amorphous structures analysis
- Lattice defects and impurities analysis
- Molecular architecture analysis

- Phase distributions, texture and finite structures analysis

For the reader's convenience, Table 5.2 lists sample requirements for the representative techniques described in this chapter.

39	Fluorescence resonance energy transfer
40	[5.6]

Table 5.2 Sample requirements in some common methods in their conventional form

Method	Minimum center density	Minimum sample amount	Maximum molecular size ^a
Element analysis			
GC-MS	10 ppb	≈ 1 ml	Boiling temperature < 400°
Radioactivation analysis	0.1 ppb	0.01 ng	—
X-ray fluorescence	10 ppm	100 mg ^b	—
Structure analysis			
Single crystal XRD	—	0.1 mm ^c	< 100 atoms ^d , > 600 atoms or 10 ⁶ in molecular weight ^e
Powder XRD	—	0.2–0.5 mm	Several 10 ³ atoms
NMR	≈ 1%	1 mM, several mg	3 × 10 ⁴ in molecular weight
Defect analysis			
ESR ^f	10 ¹² –10 ¹³ cm ^{−3g} or 10 ¹⁴ –10 ¹⁶ cm ^{−3h}	< cavity size	—
Positron annihilation	5 × 10 ¹⁵ –5 × 10 ¹⁸ cm ^{−3i}	No serious limitation	≈ 10 vacancies ^j
Raman scattering	0.01–1% (several ppb ^k)	Several μl (liquid)	—
FT-IR	0.01%	sub μg ^l	—
PL	0.1 ppm	> mg	—
Capacitance spectroscopy	10 ¹⁴ cm ^{−3}	1 mm	—

^a In crystal structure analysis, the size of atom assembly (“molecule”) occupying a lattice point

^b Reduced by orders of magnitude when a synchrotron radiation source is used

^c 0.02 mm when a synchrotron radiation source is used

Table 5.2 Sample requirements in some common methods in their conventional form, cont.

^d When direct method is used
^e When heavy atoms substitution method works
^f The sensitivity is quite dependent on what signal is detected. Here the signal is microwave absorption. Even a single spin can be detected if a special technique is used [5.7]
^g In insulators
^h In semiconductors
ⁱ For negatively charged vacancies at room temperature no serious limitation
^j Above which the vacancy clusters become indistinguishable from the surface
^k When resonant Raman scattering is employed
^l When combined with a chromatographic separation preprocess

5.1 Fundamentals

This section deals with the fundamental (minimum) knowledge that the reader should have in advance. This section is also intended to guide the reader to be able to select properly the appropriate techniques for their purpose by overviewing the range of energy, the length scale, the spatial resolution and the time scale that are covered by the entire range of these respective techniques. Since it appears that diffraction methods are not well covered in other parts of this handbook, the basic physics of diffraction and the principles of microscopic techniques (mainly TEM) based on beam diffraction will be described in some depth. We leave most of the basics of spectroscopic techniques to Chap. 4.

5.1.1 Diffraction and Scattering Methods

The scattering of particles by an interacting target is a common phenomenon usually interpretable in terms of classical mechanics with a minor correction. Generally, the waves (electromagnetic, de Broglie, vibrational, etc.) are scattered with an efficiency that can vary widely depending on the nature and the size of the scatterers and the wavelength. The diffraction of waves is a term used to describe the constructive interference of waves coherently scattered by multiple scatterers. Scattering and diffraction are, thus, inseparable concepts that are sometimes treated together in textbooks. Absorption is an apparently different aspect of waves in which some wave energy is consumed by excitation of a quasiparticle of different nature. In some cases, however, absorption is an aspect of wave scattering in which the excited state is derived from the interference of the scattered waves. The wavelength dependence of absorption is the central subject of various schemes of spectroscopy, which are addressed mainly in Sect. 5.1.3.

The scatterers of electromagnetic waves from the visible light to the X-ray regime are electrons, and those in the infrared regime are phonons or molecular vibrations. Although the penetration of electromagnetic waves through solids can vary significantly from material to material due to the wavelength dependence of the absorption coefficient, hard X-rays have a relatively high penetrability through solids as long as the constituent elements are light. In contrast, since electrons have a negative electric charge, they interact so strongly with matter that they practically cannot penetrate solids unless the energy is higher than \sim MeV. On the contrary, neutrons have no electric charge and so can penetrate deeply into solids. Neutrons have a spin magnetic moment and therefore interact with electrons, which also have a magnetic moment. This fact provides unique experimental approaches for studies of magnetism in solids. Furthermore, neutrons also interact with nuclei with scattering cross sections that are quite different from those of X-rays and electrons; for example, the detection of protons that are difficult to detect with X-rays and electrons but that are detectable by neutrons due to the large scattering cross section.

The physical parameter of fundamental importance in scattering and diffraction of waves or quantum beams is the wavelength or wave number. Figure 5.1 shows the wavelength of various beams plotted as a function of the quantum energy of the beam, the energy quantum $h\nu$ of a photon and the kinetic energy of an electron and of a neutron. Since, as explained later, diffraction occurs most significantly when the wavelength is close to the separation of the scatterers, particle beams with a wavelength of the order of 0.1 nm are most suitable for diffraction studies of atomic arrangement. Among electromagnetic waves, X-rays of 10 keV are in this range,

Fig. 5.1 Wavelength versus energy relations in various quantum beams

whereas electrons of 100 eV also have such a wavelength. The fast neutrons emitted from nuclear reactors or accelerator targets have energies of the order of MeV but can be slowed down to energies below 1 keV after passing through a moderator consisting of materials such as water and graphite. Among the slow neutrons, those whose energy is near room temperature (0.025 eV) and those below room temperature are called thermal neutrons and cold neutrons, respectively. These are the neutrons used for diffraction studies. Neutron diffraction can be an alternative to X-ray diffraction when X-rays do not detect low- Z elements well, to distinguish near- Z elements or to penetrate thick samples.

5.1.2 Fundamentals of Crystal Diffraction

Since a comprehensive description of the fundamentals of crystal diffraction is found in many good textbooks [5.8–12], only the essence is summarized here so that the reader may understand the principles of the experimental techniques described in later sections.

In cases in which the interaction of waves with matter is weak (typically in X-ray and neutron diffraction), it is a good approximation to use the kinematical theory which assumes that the wave can be scattered only once in the matter. However, when the matter is crystalline and the crystal is thick and nearly perfect, diffraction may have to be treated by the dynamical theory that rigorously takes into account multiple diffractions in the

crystal. The same situation also arises in the diffraction of charged particles such as electrons that interact very strongly with solids. Nevertheless, although the quantitative interpretation of some phenomena requires the dynamical theory, many of the phenomena encountered in experiments can be understood in the framework of the kinematical theory. For the dynamical theory, the minimum knowledge is given in Sects. 5.1.2 and 5.3.2 where it is required.

In real space, a strong diffraction of a wave of wavelength λ is induced by a set of net planes (Note that atoms on each net plane do not have to be regularly arrayed) regularly separated by a distance a (Fig. 5.2) when the wave is incident on the net planes at an angle θ satisfying the Bragg condition

$$2a \sin \theta = n\lambda \quad (n : \text{integer}). \quad (5.1)$$

In the reciprocal space, the Ewald sphere is the most commonly used graphical construction of wave diffraction, whether for X-ray or de Broglie waves. Precisely, the sphere of radius $1/\lambda$ is three-dimensional but usually represented in two dimensions by a circle touching the origin of the reciprocal lattice, as shown in Fig. 5.3. The Bragg condition is satisfied when the sphere passes through a reciprocal lattice point other than the origin.

Fig. 5.2 Diffraction by a set of net planes periodically separated by a distance a . Constructive interference takes place under the Bragg condition. Note that atoms on each net plane are not necessarily periodic for specular reflection to occur

Fig. 5.3 Graphical reconstruction of wave diffraction by Ewald sphere in the reciprocal lattice. $\mathbf{K} = \mathbf{g}$ corresponds to the Bragg condition

The wave vector of the incident wave \mathbf{k}_0 and that of the diffracted wave \mathbf{k} are indicated by the arrows drawn from the center of the sphere to the origin and to the reciprocal lattice point, respectively. Thus, the Bragg condition (5.1) is equivalent to

$$\mathbf{K} = \mathbf{g}, \quad (5.2)$$

where $\mathbf{K} \equiv \mathbf{k} - \mathbf{k}_0$ is called the scattering wave vector, and \mathbf{g} ($|\mathbf{g}| = n/a$) is the reciprocal lattice vector normal to the net planes. (Throughout this chapter, we follow the convention that the factor 2π is not included in the definition of reciprocal vectors \mathbf{g} and wave vectors \mathbf{k} .)

In X-ray diffraction, the entities that scatter X-rays in matter are electrons. Electrons forced to oscillate by the alternating electric field of the electromagnetic wave emit an electromagnetic wave of the same photon energy (elastic scattering or Thomson scattering) or of a slightly reduced energy (inelastic scattering or Compton scattering), the latter constituting the background for the coherent interference of the former, elastically scattered, waves. Generally, waves incident with intensity I_e and wave vector \mathbf{k}_0 are scattered by a collection of electrons or an electron cloud of density $\rho(\mathbf{r})$ to interfere to yield a far-field electromagnetic wave with a wave vector \mathbf{k} and intensity

$$I(\mathbf{K}) = I_e \left| \int \rho(\mathbf{r}) \exp(2\pi i \mathbf{K} \cdot \mathbf{r}) d\mathbf{v} \right|^2. \quad (5.3)$$

If the scatterers are electrons only in a single atom, the scattering intensity is given by

$$I_a(\mathbf{K}) = I_e |f(\mathbf{K})|^2, \quad (5.4)$$

with the atomic scattering factor defined by

$$f(\mathbf{K}) \equiv \int \rho_a(\mathbf{r}) \exp(2\pi i \mathbf{K} \cdot \mathbf{r}) d\mathbf{v}, \quad (5.5)$$

the magnitude of which is determined by the atomic electron density $\rho_a(\mathbf{r})$ and hence specific for the atomic element. The atomic scattering factor is a complex quantity and may also vary depending on the beam energy, bringing about the anomalous dispersion effect (Sects. 5.2.1 and 5.2.3).

In the Born approximation, or the kinematical theory, in which a *crystal* is thin enough for X-ray scattering to take place at most once in the solid, the intensity of the X-ray scattered by the assembly of atoms is simply given by

$$\begin{aligned} I(\mathbf{K}) &= I_e \left| \sum_{n,j} f_j(\mathbf{K}) \exp[2\pi i \mathbf{K} \cdot (\mathbf{R}_n + \mathbf{r}_j)] \right|^2 \\ &\equiv I_e \cdot G(\mathbf{K}) \cdot |F(\mathbf{K})|^2. \end{aligned} \quad (5.6)$$

Here, as shown in Fig. 5.4, $\mathbf{R}_n = n_1 \mathbf{a} + n_2 \mathbf{b} + n_3 \mathbf{c}$ denotes the position of the n th crystalline unit cell (the vectors \mathbf{a} , \mathbf{b} and \mathbf{c} are the unit-cell translations while n_1 , n_2 and n_3 are integers), \mathbf{r}_j is the relative position of the j th atom within the unit cell, and f_j is the atomic scattering factor of the j th atom. The factor

$$F(\mathbf{K}) \equiv \sum_j^{\text{unit cell}} f_j(\mathbf{K}) \exp(2\pi i \mathbf{K} \cdot \mathbf{r}_j) \quad (5.7)$$

Fig. 5.4 X-ray diffraction by a crystal lattice the unit cell of which is indicated with a parallelogram

is called the structure factor and characterizes the atomic arrangement in the unit cell. Another factor

$$\begin{aligned}
 G(\mathbf{K}) &\equiv \left| \sum_n \exp(2\pi i \mathbf{K} \cdot \mathbf{R}_n) \right|^2 \\
 &= \left| \sum_{n_1} \exp(2\pi i k_1 n_1 a) \sum_{n_2} \exp(2\pi i k_2 n_2 b) \right. \\
 &\quad \left. \times \sum_{n_3} \exp(2\pi i k_3 n_3 c) \right|^2
 \end{aligned} \tag{5.8}$$

is called the interference function, which is written in the second formula in terms of the components of the vector $\mathbf{K} = (k_1, k_2, k_3)$ projected onto the unit-cell translation vectors. In diffraction of a monochromatic wave from a sufficiently large single crystal (n_1, n_2 and n_3 are all large), $G(\mathbf{K})$ is nonzero ($n_1 \cdot n_2 \cdot n_3$) only when

$$k_1 a = h, \quad k_2 b = k \quad \text{and} \quad k_3 c = \ell, \tag{5.9}$$

for integers h, k and ℓ . This is again equivalent to the Bragg condition (5.2), the condition for constructive interference. In such cases, the diffraction intensity is

simply given by $|F(\mathbf{g})|^2$ times the number of unit cells in the sample. In small crystals, however, diffraction also occurs in directions other than those satisfying (5.2) with intensities that depend on the interference function, $G(\mathbf{K})$, which reflects the size and external shape of the crystal.

Thus, we have to consider two cases: the case of large crystals for which the effects of $G(\mathbf{K})$ can be neglected, and the case of small crystals for which the morphological information contained in $G(\mathbf{K})$ is our main concern.

Combining (5.5) and (5.7) we find that $F(\mathbf{K})$ is related to the electronic density $\rho(\mathbf{r})$ through a Fourier transformation. This means that for large crystals we could deduce the electronic density $\rho(\mathbf{r})$ or the atomic arrangement in the crystalline unit cell by inverse Fourier transformation of the structure factors that can be found from the experimental scattering intensity. This forms the basis of structural determination by X-ray diffraction from crystalline samples (Sects. 5.2.1 and 5.4.1).

For small crystals, we have broadening of diffraction spots as happens in the diffraction of light by an optical grating of finite size (Fig. 5.5a). This diffraction broadening could be regarded as due to the augmentation

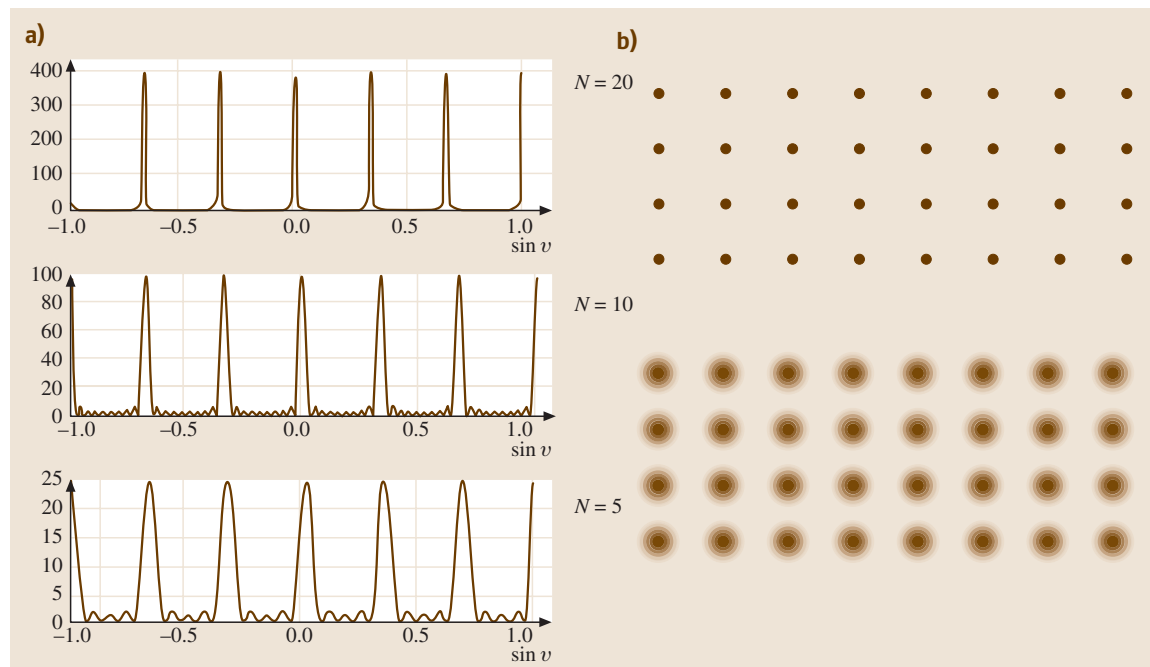

Fig. 5.5a,b As the sharpness of diffraction decreases with the decreasing size of a grating in a monochromator (a), diffraction peaks in small crystals show broadening, which is represented by the diffuseness of reciprocal lattice points (b)

Fig. 5.6a–d Broadening and sharpening of reciprocal lattice points (b),(d) due to the external shape of the crystals (a),(c)

of the reciprocal lattice points (Fig. 5.5b). Mathematically, $G(\mathbf{K})$ is again the Fourier transform of the external shape of the crystal, so thin crystals elongated in one direction, as shown in Fig. 5.6a, yield sharpening of the reciprocal lattice points along that direction but broadening perpendicular to it, as shown in Fig. 5.6b. Similarly, plate-like flat crystals (Fig. 5.6c) broaden the diffraction peaks along the surface normal, as shown in Fig. 5.6d. This fact makes it possible to analyze the medium-range order (Sect. 5.2.2), to determine experimentally the small particle size (Sect. 5.5.3), and to conduct high-resolution TEM observations (Sect. 5.1.2).

5.1.3 Microscopy and Topography

Microscopy allows one to study material structures with spatial resolution. The resolving power of microscopes depends on the “beam” that is used to construct images. Most microscopic methods may be grouped into one of two types: ordinary microscopy, which uses certain waves for sample “illumination” and a set of lenses for construction of an image; and scanning microscopy, which uses a tiny “probe” that is scanned over the sample to construct a microscopic image synchronously displayed on a two-dimensional screen. In the former type of microscopes, the dominant factor governing the

spatial resolution is the wavelength of the wave or the aberration of the objective lens (the convex lens nearest to the object being observed). Even if the lens is free of aberration, its focus is not a perfect “point” but is blurred by the effect of wave diffraction due to the finite lens diameter (Fig. 5.7). Owing to the parallel imaging capability in the former type of microscopes, one may observe in situ the dynamic change or motion of objects, which could be recorded by a video camera, although the same may also be possible in the latter type if the scanning rate is high enough to follow the events. Figure 5.8 shows the range of scales that is covered by various microscopes. The lower limit and the upper limit of the lateral scale indicate the lateral resolution and the maximum size of the specimen that can be surveyed, respectively. The lower and upper limits of the vertical scale indicate the sample thinness required for microscopic observations and the sample thickness allowed for experiments, respectively. Other features of microscopic techniques are also summarized in Table 5.3.

Optical Microscopy (OM)

We mention here only briefly three types of optical microscopy (OM): interference microscopy, which is mature but plays important roles in the assessment of mater-

Fig. 5.7a–c Point resolution in microscopes limited by wave diffraction. In lenses of finite size, even if aberration-free, the focal point is blurred due to the diffraction effect. (a) is equivalent to (b); (c) defines the point resolution

Table 5.3 Comparison of various microscopic techniques

Method	Operation mode	Object	Resolution	Sample requirement	Test environment	Merit	Demerit
Optical microscopy	Interference microscopy	Steps	<1 μm	Transparent or Reflective	Ambient, liquid	Easy operation, wide survey range, dynamic observation	Limited magnification
	LSCM	Light scatterers, fluorochromes					
	TIRFM	fluorochromes					
X-ray topography		Internal architecture	< a few μm ^a	High quality single crystal	Ambient, gaseous, vacuum	Applicable to bulky samples	Low magnification
TEM	Two-wave diffraction	Dislocations, planar defects	Several tens nm	Thickness < 1 μm ^a	Vacuum	Crystallographic analysis, dynamic observation	Narrow survey range
	Weak beam	Dislocations	0.5 nm	Thickness < 1 μm ^a	Vacuum		
	HRTEM	Extended defects, layer stacking	0.2 nm	Thickness < 100 nm ^a	Vacuum	Atomic-level resolution, dynamic observation	Critical sample preparation
STEM	HAADF	Extended defects, impurities	< 0.2 nm	Thickness < several tens nm ^a	Vacuum	Insensitivity to focusing and sample thickness	Slow image acquisition
SEM	SEM-SE	Surface morphology	< 1 nm	High SE efficiency, electrically conductive	Vacuum, gas	Easy operation, wide survey range, dynamic observation	Little information on material substance
	SEM-EBIC	Recombination centers in semiconductors	≈ 1 μm ^a	Semiconductors with electrodes	High Vacuum (HV)	High sensitivity	Needs electrical contacts
	SEM-CL	Cathodo-luminescent /nonradiative centers	≈ 1 μm ^a	Luminescent semiconductors	HV	Non-destructive spectroscopic	Limited to luminescent materials
	EPMA	Element analysis	≈ 1 μm	X-ray fluorescence	HV, Ultra-High Vacuum (UHV)	Established	Vulnerable to contamination
FIM		Surface atoms	< 0.1 nm	Electrically conductive thin needles	UHV	Atomic resolution	Difficult sample preparation
STM	Constant current	Surface LDOS, subsurface defects	< 0.1 nm	Electrically conductive clean surface	Ambient, UHV, liquid	Affinity with various micro-spectroscopic techniques	Limited imaging speed, difficulty in reproducible tip preparation
AFM	Noncontact	Surface atoms, surface morphology	≈ 0.2 nm (depends)	Roughness < 1 μm ^a	Ambient, UHV, liquid	Applicable to nonconductive samples	Limited imaging speed
SNOM	Variable	Variable	Several tens nm	Optically active	Ambient, UHV, liquid	Many potential applications	Limited imaging speed

^a variable depending on the material and experimental conditions

ial microstructures; laser scanning confocal microscopy (LSCM) of the scanning type; and total internal reflection fluorescence microscopy (TIRFM), a relatively new technique with expanding applications particularly to biological substances. For the principles of conventional OM, the interested reader should refer to [5.13].

Interference microscopy is based on the phase shifts of the illuminating light that take place when the light passes through a transparent sample with different refraction indices or when it is reflected at a surface with steps of different heights. The interference of this light with a reference light forms interference fringes or, in differential interference Nomarski microscopes (Fig. 5.9), the interference of two slightly displaced beams is converted to different colors with high spatial resolution, which allows the measurement of step heights with a precision of 20 nm.

LSCM is classified as a scanning microscope, using a laser beam as a probe. The principle is shown in

Fig. 5.9 (a) The principle of differential interference optical (Nomarski) microscopy. (b) Phase shift that occurs in reflecting waves at a step edge

Fig. 5.10, where a parallel laser beam focused at an entrance aperture is further focused by an objective lens to a small spot in the sample and the scattered light is

Fig. 5.8 Scale range covered by various types of microscopic techniques. For the meaning of the horizontal and vertical axes, see the text

Fig. 5.10 The principle of laser scanning confocal microscopy

collected by the same objective lens and focused again but now at an exit slit that is placed at the confocal position of the entrance aperture. The light passing through the confocal aperture is detected by a photosensor. The light from the sample may be luminescence from a substance at the focal spot. The important point is that light from points on the sample other than the focal spot are rejected by the confocal exit aperture, thereby greatly reducing stray background light. If we scan the sample laterally with respect to the objective lens, we obtain a two-dimensional image on the screen. It should be pointed out that, although the point resolution is limited to a subwavelength (a few hundred nanometres) due to the effect of light diffraction, tiny objects much smaller than the resolution limit may be viewed as bright spots when they scatter or emit light visible to the human eye or detectable by a photosensor. This means that signals from even a single molecule can be detected if their separation from other molecules is large enough. A disadvantage of LSCM is the long image acquisition time due to its scanning nature.

TIRFM is based on the evanescent waves generated when light is incident onto an interface between two optical media of different refractive indices. It uses an ordinary fluorescence microscope equipped with a sample illumination system, as shown in Fig. 5.11. Samples attached to the surface of a glass plate are labeled by fluorescent molecules (fluorochromes). The back of the glass surface is illuminated with light at an angle smaller than the critical angle for total internal reflection, so that only fluorochromes within the small extension distance ($<$ light wavelength) of the evanescent wave are illuminated to induce fluorescence, which is imaged by the objective lens. The sample may be immersed in a liquid whose refractive index is smaller than that of glass, so

Fig. 5.11 The principle of total internal reflection fluorescence microscopy

the magnification can be increased up to $\times 100$ by immersion, and biomolecules can be investigated *in vivo* in water solutions. TIRFM is superior to LSCM in its high speed of image acquisition.

Transmission Electron Microscopy (TEM) [5.14]

Electrons interact so strongly with solids that they cannot penetrate thick solids. Figure 5.12 shows the dependence of the electronic absorption cross section on the electron energy. Electrons lose their energy most efficiently by exciting plasmons in the low energy range (10–30 eV), but the cross section governed by electronic excitations decreases with increasing kinetic energy of electrons except at core excitation edges that are specific to the elements contained in the sample until it increases due to the start of Bremsstrahlung radiation loss. Therefore, electrons of energies higher than ≈ 100 keV can penetrate solid samples to some extent if the sample thickness is smaller than $\approx 1 \mu\text{m}$. A key issue for TEM studies is how to prepare samples thin enough for observation. The most common method is chemical thinning by using a chemical etchant after a prior mechanical thinning process, though a suitable etchant cannot always be found. The advent of the ion milling method using an accelerated Ga ion beam for sputtering, however, has relieved the common difficulty in sample preparation and so widens the range of materials that may be studied by TEM.

A great advantage of TEM over other microscopic techniques is its ability to switch operation between the imaging and diffraction modes very easily, thereby investigating *in situ* the crystallographic properties of a specific sample area just being observation in the

Fig. 5.12 Energy dependence of the absorption cross section of electrons

image. Figure 5.13 illustrates the electron optics of ordinary TEM in the two modes. Essentially, in the imaging mode, the image in the real space formed on the image plane of the objective lens is projected onto the fluorescence screen, whereas in the diffraction mode the diffraction pattern formed on the back focal plane of the intermediate electromagnetic lens. Usually, for observations of inhomogeneities in samples, to select a specific diffraction an (objective) aperture is inserted at the back focal plane where a diffraction pattern is being formed. To obtain a diffraction pattern from a specific area of the sample, an aperture for selected area diffraction (SAD) is inserted at the image plane of the objective lens. Usually the objective aperture selects only the direct beam, so the images obtained generally look bright (contrasted against a gray background due to absorption) with varying contrast due to inhomogeneities, and are therefore called bright-field (BF) images. Occasionally, a diffracted beam can be selected to brighten the images of the imperfections responsible for the diffraction against the dark background, leading to a dark-field (DF) image.

In most cases, a TEM image is an interference pattern of the electron waves diffracted by a crystalline sample. Therefore, no correct interpretation of a TEM image is possible until one carefully compares images acquired under various diffraction conditions. Although the quantitatively precise interpretation of TEM images requires the dynamical theory, in many cases encountered in conventional microscopes the images can be understood rather intuitively in the framework of the kinematical theory. Nevertheless, in some important cases, dynamical effects or multiple reflection effects must be taken into account. As illustrated in Fig. 5.14, a beam incident with a Bragg angle of θ_B onto a set of net planes is re-

Fig. 5.14a,b Periodic exchange of electron energy between direct and diffracted waves. (a) kinematical case $|\xi_g|^{-1} \ll |s|$ and (b) dynamical case $|\xi_g|^{-1} \gg |s| \approx 0$. After [5.16]

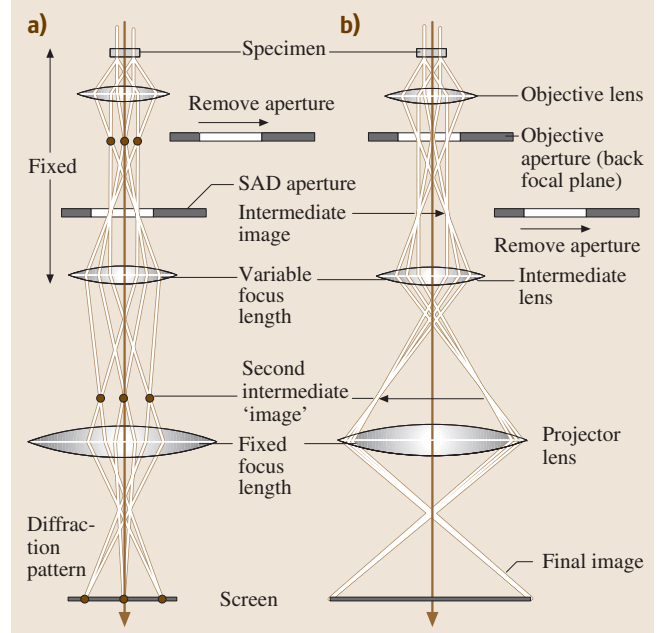

Fig. 5.13 Electron optics of transmission electron microscope in the diffraction mode A and in the imaging mode B. After [5.15, p. 144]

flected to give rise to a diffraction beam which may be reflected again by the reverse side of the same net planes returning to the primary beam direction. If the crystal is thick, this process is repeated with the electron energy being interchanged periodically between the direct beam and the diffracted beam. When only one diffraction g is excited, a detailed analysis [5.16] shows that the intensity of the direct wave and that of the diffracted wave emanating from a sample of thickness t are given by

$$I_0 = \cos^2(\pi s_{\text{eff}} t) + \left[(s_{\text{eff}} \xi_g)^2 - 1 \right] \left(\frac{\pi t}{\xi_g} \right)^2 \frac{\sin^2(\pi s_{\text{eff}} t)}{(\pi s_{\text{eff}} t)^2} \quad (5.10)$$

and

$$I_g = \left(\frac{\pi t}{\xi_g} \right)^2 \frac{\sin^2(\pi s_{\text{eff}} t)}{(\pi s_{\text{eff}} t)^2}, \quad (5.11)$$

respectively, where ξ_g , the so-called extinction distance (The terms extinction distance or extinction effects often used in textbooks originate from the fact that, due to the diffraction effect, within the distance ξ_g the primary beam intensity decays, or is extinguished, more rapidly than expected from the energy absorption effect), is defined as

$$\xi_g \equiv \frac{\pi \Omega \cos \theta_B}{\lambda F_g}, \quad (5.12)$$

where Ω is the volume of the unit cell, θ_B is the Bragg angle, λ is the electron wavelength, and F_g is the structure factor for g . The parameter s_{eff} is

$$s_{\text{eff}} \equiv \sqrt{s^2 + \xi_g^{-2}}, \quad (5.13)$$

where s denotes the deviation from the Bragg condition in reciprocal space. Figure 5.14 shows schematically how the two intensities vary with the thickness of a wedge-shaped sample. When $|\xi_g|^{-1} \ll |s|$ (Fig. 5.14a) or $t \ll \xi_g$, we could apply the kinematical theory, in which the thickness dependence is determined by s . On the other hand, when $|\xi_g|^{-1} \gg |s| \approx 0$ (Fig. 5.14b) or $t > \xi_g$, the transmission intensity must be treated rigorously by the dynamical theory, where $s_{\text{eff}} \rightarrow \xi_g^{-1}$ and the two beams exchange their intensities, alternating with a period of ξ_g , not s^{-1} . One should note that $I_0 + I_g = 1$ throughout the sample. For its resemblance to the behavior of two coupled pendulums, this effect that gives rise to thickness fringes is referred to as Pendellösung, which forms the basis of similar fringe contrasts not only in TEM but also in X-ray topography. In imperfect crystals, the argument is modified by introducing an additional phase shift due to the presence of defects. The consequence is described in Sect. 5.3.

The Pendellösung effect embodies the presence of two dispersion branches at the zone boundary corresponding to the Bragg diffraction at $\mathbf{K} = \mathbf{g}$. It may be regarded as a consequence of beating between the two Bloch waves on the two branches. They have amplitudes at different column positions as shown in Fig. 5.15: The wave (a) has its amplitude in between the atomic columns whereas the wave (b) along the columns. Since the interaction of the waves with the atoms is weak in (a) but strong in (b), the waves (a) and

Fig. 5.15a,b Bloch waves on two dispersion branches. Waves (a) and (b) are absorbed less and more, respectively

(b) are absorbed by the crystal to a lesser and greater extent, respectively. This causes the effects of anomalous absorption (Kikuchi patterns in electron diffraction, Sect. 5.5.1) or anomalous transmission (Electron channeling, Sect. 5.5.1) for electrons and the Borrmann effect for X-rays, Sect. 5.3.2) propagating in particular directions.

The Ewald sphere in the diffraction of TEM electrons of energy ≈ 100 keV is large compared with the reciprocal lattice parameter. The reciprocal lattice points are broadened perpendicular to the sample surface due to the small thickness of the sample in TEM. As a consequence, if the thickness is smaller than ≈ 100 nm, the electron diffractions practically occur in many g vectors, as shown in Fig. 5.16. This makes it possible to form an image by collecting many diffraction beams, including those of large $|g|$ values that contain information of small-scale structures in the sample. This is the basis of high-resolution transmission electron microscopy (HRTEM) which is now a standard installation in modern TEM microscopes owing to the technological progress in the improvement of spherical aberration of the objective lens. Under a special defocusing condition, called the Scherzer defocus, the HRTEM images represent approximately the arrangement of atomic rows viewed along the direction of the electron beam, as illustrated in Fig. 5.17. HRTEM images depend sensitively

Fig. 5.16 Ewald construction of electron diffraction in TEM. The reciprocal lattice points are elongated normal to the surface of thin specimens, so that many diffractions can be excited

Fig. 5.17a,b The principle of high-resolution TEM. (a) A perspective view of a schematic crystal along an axis along which the electron beam is incident to obtain a symmetric diffraction pattern, as schematically shown in (b). Diffracted beams with large wave numbers are collected to form a high-resolution TEM image that represents, under the Scherzer defocus condition, approximately the projection of the atomic columns viewed along the direct beam

on the defocus condition, the sample thickness, and the depth of the object in the films. The true atomic arrangements can be deduced only by careful comparison of experimental images taken under various defocusing conditions other than the Scherzer defocus and theoretical images simulated for model structures using the dynamical theory. The routine resolution (point resolution) of HRTEM is ≈ 0.2 nm.

X-Ray Topography (XRT)

As with transmission electron microscopy, X-ray diffraction may be used to image crystallographic inhomogeneities in crystalline samples. A significant difference from TEM, however, is the lack of good lenses for X-rays so images cannot easily be magnified as in OM and TEM. The best resolution is determined by the particle size of the emulsion in X-ray films, typically around $2\text{--}3\text{ }\mu\text{m}$, which may be reduced to $\approx 1\text{ }\mu\text{m}$ by the use of synchrotron radiation. The simplest setup for X-ray topography (XRT) is one devised by Lang shown in Fig. 5.18. A version using reflected beams for imaging (the Berg-Barrett method) is also used, particularly when the sample is not transparent to X-rays. XRT images are obtained by recording diffracted beams of a certain g vector, equivalent to dark-field images in TEM. An advantage of XRT over TEM is that it can examine rather bulky samples in a gaseous atmosphere. Owing to this fact, together with the higher accuracy in the detection of strains, XRT is suitable for studies of phenomena in which the stress state is of primary impor-

Fig. 5.18 Lang camera for transmission X-ray topography. The crystal and the X-ray film are simultaneously translated to record a topographic image consisting of sample sections

tance (e.g., fracture). A judicious choice of diffraction geometry as well as X-ray wavelength and sample thickness allows high topographic contrast. Applications of XRT are described in Sect. 5.3.2.

High-Angle Annular Dark-Field STEM (HAADF-STEM)

In scanning transmission electron microscopy (STEM), an electron beam focused to a small size is raster scanned in parallel across a sample surface and a detector collects some signal arising from the interaction of the electrons with the sample solid. The signal intensity, which may vary over the sample position depending on the crystal structure, orientation, composition, etc., is used to construct two-dimensional maps of the material properties in each pixel. The spatial resolution of STEM is limited by the size of the focused probe beam. The advantage of STEM is that it does not need imaging lenses that inevitably have some chromatic aberration and limit the resolution of TEM images, and the sample thickness may be relatively thick in comparison with TEM samples. A demerit of STEM is the lower speed of image acquisition (seconds to minutes for a single image) due to the serial recording of the signal.

In bright-field (BF) STEM, the signal collected is the directly transmitted electrons that are not diffracted by the crystallographic sample. Similarly, dark-field

(DF) STEM images can be obtained by collecting only diffracted electrons. Although the imaging principle of STEM is different from that of TEM, the two microscopic techniques could be viewed as equivalent if one regards the electron detector in STEM as the objective aperture in TEM, both of which are (not physically as for the detector in STEM) placed at the back focal plane of the objective lens.

High-angle annular dark-field STEM (HAADF-STEM) allows one to observe STEM images with higher resolution and compositional information. As shown in Fig. 5.19, HAADF-STEM images are formed by collecting high-angle scattered electrons with an annular dark-field detector placed at the back focal plane of the objective lens. The image formation mechanism is based on the fact that a fraction of electrons incident on a crystalline sample along a channeling direction are diffusely scattered by thermal vibrations of atoms at relatively high angles ($\gtrsim 70$ mrad) when the beam scans over the atomic columns. Therefore, in HAADF-STEM images, the positions of atoms are observed as bright contrasts depending strongly on the average atomic number of the atoms in the column. Owing to this feature, HAADF-STEM, otherwise called Z-contrast imaging, is a powerful technique for composition analysis especially for elements of large atomic numbers. The spatial resolution in HAADF-STEM is limited by the size of the focused probe beam as in ordinary STEM. Under good conditions, an atomic-level spatial resolution can be achieved, although such samples must be thin enough (usually

thinner than several tens of nanometres) for beam broadening to be avoided. The advantage of HAADF-STEM over HRTEM is the insensitivity to focusing conditions and sample thickness variations, both of which very substantially affect the phase sensitive contrast of HRTEM images.

Scanning Electron Microscopy (SEM). The representative microscope of the scanning type is the scanning electron microscope (SEM) [5.17], in which the scanning probe is a finely focused electron beam. Figure 5.20 shows various forms of signals generated by incidence of electrons onto solid samples. Some of the incident electrons lose most of their initial energy and are emitted from the surface with a low energy (\approx a few tens of eV). These electrons are called secondary electrons, which can escape only from very shallow depths of the solid due to their large absorption cross section (Fig. 5.12). Without losing much energy, other electrons are either reflected backward as back-scattered electrons or absorbed into the solid as a drain current. On the loss of electron energy, X-ray fluorescence or Auger electron emission occur, which are very useful for element analysis. In semiconductor samples, the electron energy may be converted to a luminescence (cathodo-luminescence, CL) or an electron-beam-induced current (EBIC) when an electric field separating electron-hole pairs is built up in the surface layer. Depending on the detected signal, SEM has several operation modes. The most common mode is secondary electron SEM (SEM-SE), in which the difference in the escape probability of secondary electrons depending on the direction relative to the surface normal produces surface roughness contrast observed from an oblique angle when the electron detector is placed as shown in Fig. 5.21.

The spatial resolution depends on what signal is used and how large the signal is. As illustrated in Fig. 5.22,

Fig. 5.19 Setup of high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM). Electrons diffusely scattered by thermal vibrations of atoms with relatively high angles are collected by an annular detector to form a scan image

Fig. 5.20 Signals generated in scanning electron microscopy

Fig. 5.21 Escape probability of secondary electrons (SE) with its maximum in the surface normal direction rendering the morphological contrasts in SEM-SE

Fig. 5.22 Factors governing the spatial resolution in SEM

incident electrons are spread by a random walk on the nanometre range that increases in depth with increasing acceleration voltage. For the primary beam size to dominate the resolution in SEM-SE, we should choose an accelerating voltage at a medium value to reduce the lateral spreading of electrons. In commercial SEM-SE operated at 5 keV, sub-nanometre resolution is achievable by the use of a field emission gun, the

high brightness of which allows extremely fine focusing of the probe beam. The resolution in SEM-SE is determined by the spread range, while the resolution in SEM-CL and SEM-EBIC is worsened by the diffusion of the carriers generated by the electrons. The samples for SEM observations must be more or less electrically conductive to avoid charging effects. If they are not metals or semiconductors, precoating the samples with Au films may work.

Scanning Probe Microscopy. Since the advent of scanning tunneling microscopy (STM) [5.18–20], the use of extremely sharp tips controlled by a piezo-actuator as shown in Fig. 5.23 opened fascinating opportunities to study materials on the nanometre scale. To date, many schemes of scanning probe (tip) microscopy (SPM) have been attempted, though most of them are still under development at present.

Scanning Tunneling Microscopy (STM). The STM is based on the fact that a quantum mechanical tunneling current flows between two electrically conductive solids closely spaced within a distance of ≈ 1 nm under an electric bias voltage, with a very sensitive dependence on the separation. Figure 5.24a–c illustrates the situation for a combination of metallic tip and a semiconductor sample. If the probe tip, usually an electrochemically etched tungsten needle, is sharp enough, the tunneling current is confined to a very narrow region (< 0.1 nm) beneath the tip. Scanning a sample surface with such a sharp tip and recording as a signal the voltage applied to the piezo-actuator that acts to keep the tip–sample distance (more precisely the tunneling current) constant, we can obtain a two-dimensional image of the surface topography, as shown in Fig. 5.25.

Fig. 5.23 Piezo-actuator (tube scanner) for tip scanning

Fig. 5.24 Vacuum tunneling between a metallic tip and a semiconducting sample, also illustrating the principle of scanning tunneling spectroscopy

Fig. 5.25 STM image of Si(111)-7×7 surface

STM images generally reflect very strongly the local density of states (LDOS) of surface electrons on which the tunneling current is also dependent. This fact provides a unique method, scanning tunneling spectroscopy (STS), for the assessment of electronic properties of the samples. Figure 5.24 illustrates the principle of STS, which is based on the fact that most of the external bias voltage is applied across the vacuum gap and that electron tunneling occurs from electronic filled states to empty states conserving energy. The tunneling current I_t varies with the bias voltage V_b as in Fig. 5.24d with its derivative with respect to V_b approximately representing the LDOS.

In principle, STM experiments could be conducted in ambient environments as long as the current is confined beneath the tip, but in most cases clean surfaces are investigated in ultra-high vacuum to achieve reproducible results. Preferably, the surface should be atomically flat with steps in atomic heights; otherwise

in rough surfaces, the tip shape is convoluted with the image giving a spurious surface morphology.

Atomic Force Microscopy (AFM). Atomic force microscopy (AFM) uses a sharp probe tip mounted on a cantilever, as shown in Fig. 5.26 [5.21, 22]. When the sample and the tip are close enough, the sample exerts a short-range force on the cantilever, an attractive force originating from the van der Waals interaction, a repulsive force due to the Pauli exclusion principle, and a variable force of chemical origin. The force may also be long-range, arising from a Coulombic interaction. The simplest AFM with the tip in mechanical contact with the sample surface detects a force-induced deviation of the cantilever by an optical or electronic method. Recently, noncontact AFM is making great progress in imaging solid surfaces at atomic resolution comparable with STM. The common technique used for the detection of atomic force is to measure the shift of the resonance frequency of the cantilever that is caused by a non-linear force operating between the sample and the tip (Fig. 5.26). In the current state-of-the-art instruments, the lateral and vertical resolutions are 10 pm and one to several pm, respectively. Figure 5.27 shows a set of noncontact AFM images of a GaAs surface. An atomic resolution is achieved when the closest distance z between the sample and the cantilever tip is shorter than ≈ 0.1 nm (b and c). The blurred contrast in (a), obtained at a slightly large closest approach, is considered to indicate the presence of charged defects beneath the sample surface.

Scanning Near-Field Optical Microscopy (SNOM). Scanning near-field optical microscopy (SNOM) [5.23] overcomes the diffraction-imposed resolution limit of OM by exploiting an evanescent field that is gener-

Fig. 5.26a–c The principle of noncontact atomic force microscopy (AFM). (a) The sample exerts a force on the probe tip on top of a cantilever whose deflection is detected, in this case, by an optical lever method. The cantilever is forced to oscillate at the resonance frequency (b) which changes with the tip–sample distance due to the nonlinear interaction between the tip and the sample (c)

ated and/or detected by a probe tip that is brought very close to the sample. Usually, the tip is made of metal-coated optical fiber with a tiny aperture at the apex. The tip–sample distance may be controlled by the same technique used in STM and AFM. There are many SNOM schemes, only two of which are illustrated in Fig. 5.28. In Fig. 5.28a, the light guided by an optical fiber illuminates the sample in a region that is highly localized by the aperture, and the light scattered or emitted by the object is collected by the probe itself or detected as a far-field light by a photosensor. In the setup in Fig. 5.28b, the sample on an optically

flat glass is illuminated with an evanescent wave of a total internal reflecting light. The probe collects secondary light, or a photodetector senses a change to the total reflected light intensity caused by the presence of the tip in close vicinity to the object. More recently, attempts at apertureless SNOM using a metallic tip illuminated with a macroscopic light to exploit the metal-tip-enhanced optical field have been reported. In any case, the spatial resolution at present is limited to tens of nanometres. SNOM is a rapidly growing technique because of the wide applicability to materials, regardless of sample properties such as electrical conductivity, and the flexible test environments. Interested readers should refer to most contemporary articles for the latest progress.

Field Ion Microscopy (FIM). The field ion microscope (FIM) [5.24] is a type of microscope based on a principle completely different from those described so far. In the basic setup, illustrated in Fig. 5.29, the sample is a metallic needle the apex of which is atomically sharpened with an end radius of 50–100 nm so that an electric field applied to the sample is concentrated on the atomic step edges. The sample faces a phosphor screen placed at a distance of ≈ 5 cm from the needle tip. To obtain images, a small amount ($\approx 10^{-3}$ Pa) of an inert gas, usually helium, is introduced into the ultra-high-vacuum chamber in which the sample and the screen are accommodated, and a positive (with respect to the screen) bias voltage is then applied to the sample. The inert gas atoms polarized by the electric field are electrostatically attracted to the tip and migrate further to the step edges where a high electric field is concentrated. When the bias voltage is high enough (a few tens of V/nm), an electron in the inert gas atom tunnels quantum mechanically to the tip resulting in the formation of a positively charged ion at the step edges. The ion formed is immediately repelled by the strong electric field present between the sample and the screen, and starts to be accelerated towards the screen along the direction of the electric field. Since the electric field emanates radially from the tip apex, the distribution of the ion impinging spots on the screen, as shown in Fig. 5.30, represents a highly magnified image of the atoms at the step edges on the sample tip. Usually, a multichannel plate is placed in front of the phosphor screen for signal enhancement. The sample may be cooled to a low temperature to suppress thermal atomic motion on the surface. FIM is useful for three-dimensional microanalysis of element distribution if combined with an atom probe method (Sect. 5.5.3).

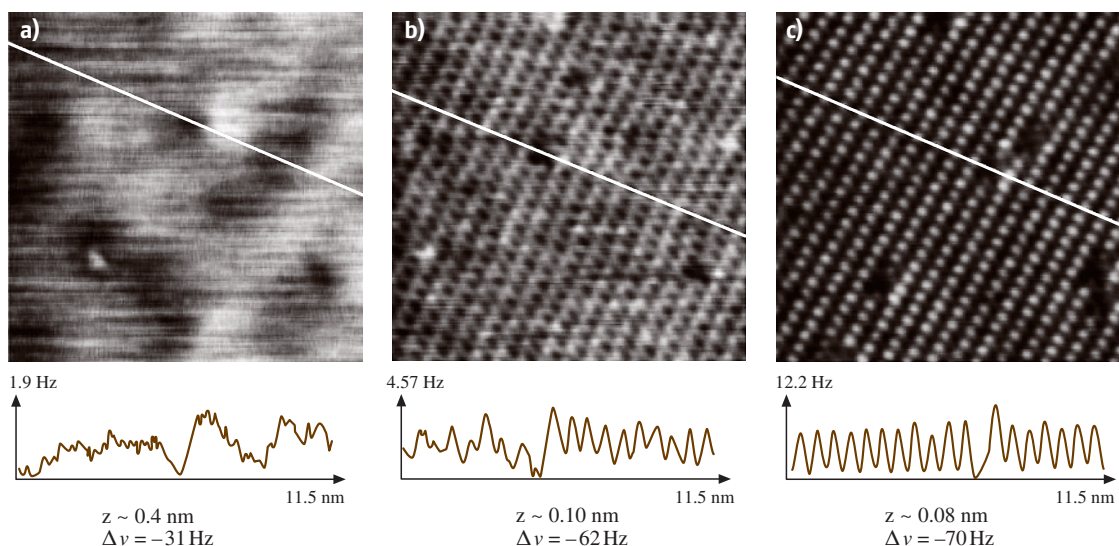

Fig. 5.27 Noncontact AFM images of a p-GaAs(110) surface. z denotes the closest distance between the sample and the tip, and $\Delta\nu$ the shift of the cantilever resonance frequency. p-GaAs(110) $N_A = 1.4 \times 10^{19} \text{ cm}^{-3}$ [5.25]

5.1.4 Spectroscopy

Optical Spectroscopy

The physical property of primary importance in optical spectroscopy is the energy of the photons. Figure 5.31 summarizes the main optical spectroscopic methods arranged according to the range of photon energies, and the corresponding wavelengths and frequencies. All

though electromagnetic waves in general range from radio frequency (RF) waves to γ -rays, we first confine ourselves in traditional optical spectroscopy, which is usually limited to a range from infrared to ultraviolet light (It should be noted that, owing to the development of more intense light sources and more sensitive light detectors, the techniques now mostly applied to this range are being extended, based on essentially the same principle, to regions down to THz waves and up to X-rays. For recent development in the range of extreme violet (30–250 eV) to soft X-rays (250 eV–several keV) see [5.26]). The interaction of light in this range of photon energies with matter has different origins depending on which quasiparticles (quanta) are excited: electronic, vibrational, or both coupled (vibronic). In the bottom of Fig. 5.31, the quanta that can be studied are shown. In this section, we touch only on matters relevant to Chap. 4.

Infrared Absorption Spectroscopy (IRAS)

Fourier transform (FT) spectroscopy has advantages over spectroscopic measurements using a dispersive monochromator (e.g., a grating monochromator), in which spectral signals are detected sequentially with a single detector, under certain conditions. For FT measurements we use, instead of a dispersive monochromator, an interferometer such as a Michelson-type device shown in Fig. 5.32. The output of the interfer-

Fig. 5.30 FIM Image of a W tip (Courtesy of Dr. K. Hono)

ometer fed with light of wavelength λ and intensity I_{λ}^0 is variable depending on Δx , the displacement of the movable mirror, through

$$I_{\lambda}(\Delta x) = I_{\lambda}^0 \sin \left(2\pi \frac{2\Delta x}{\lambda} \right) . \tag{5.14}$$

$$I_{\lambda}(t) = I_{\lambda}^0 \sin \left(\frac{4\pi v}{\lambda} t \right) = I_{\lambda}^0 \sin (\omega_{\lambda} t) . \tag{5.15}$$

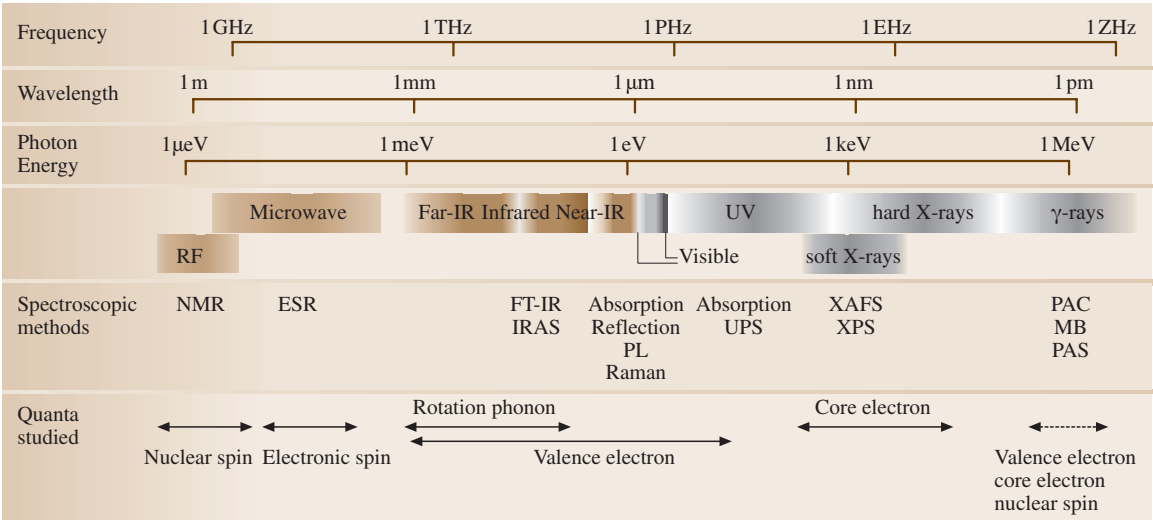

Fig. 5.31 The energy of photons used for optical spectroscopic measurements of various quanta

Fig. 5.32 Michelson-type interferometer used in Fourier transform infrared (FT-IR) spectroscopy

Equation 5.15 indicates that light of intensity I_{λ}^0 is sinusoidally modulated at a frequency given by the wavelength λ . In other words, when the light input to the interferometer contains different spectral components, the interference fringes or interferogram (Fig. 5.33a), the temporal superposition of the modulated signals, constitutes the Fourier transform of the whole spectrum. Conversely, the inverse Fourier transform of the experimentally measured interferogram provides the spectrum (Fig. 5.33b) without any spectral dispersive apparatus. The FT spectroscopy is advantageous in terms of the signal-to-noise ratio when the detector noise is large

and we need high spectral resolution. The infrared (IR) spectroscopy is a typical case to which the FT scheme is most efficiently applied.

Raman Scattering

Raman scattering is a generic term for inelastic scattering of light but in most cases it refers to inelastic scattering brought about by optical phonons (quantized vibrations) in molecules and solids. While infrared absorption originates from the polarization of the substance, Raman scattering originates from a modulation of optical polarizability of the substance by phonons. Therefore, the selection rule is different for the two phenomena. In molecules, infrared absorption occurs when the molecules have an electric dipole moment in the polarization direction of the incident light, as in the cases shown in Fig. 5.34. Raman scattering occurs when a molecular vibration in a certain mode alters the electronic distribution of the molecule (Fig. 5.34) and consequently the optical polarizability for the incident light. In solids, although the selection rules are not as intuitive as for molecules, the principles are the same. Due to this difference in the selection rules, infrared spectroscopy and Raman scattering spectroscopy are complementary in studies of atomic vibrations in matter.

In the energy diagram, the sequential two-photon process in Raman scattering is depicted in Fig. 5.35, which shows only the case of the Stokes shift, in which a phonon mode of energy $h\Omega$ is excited and as

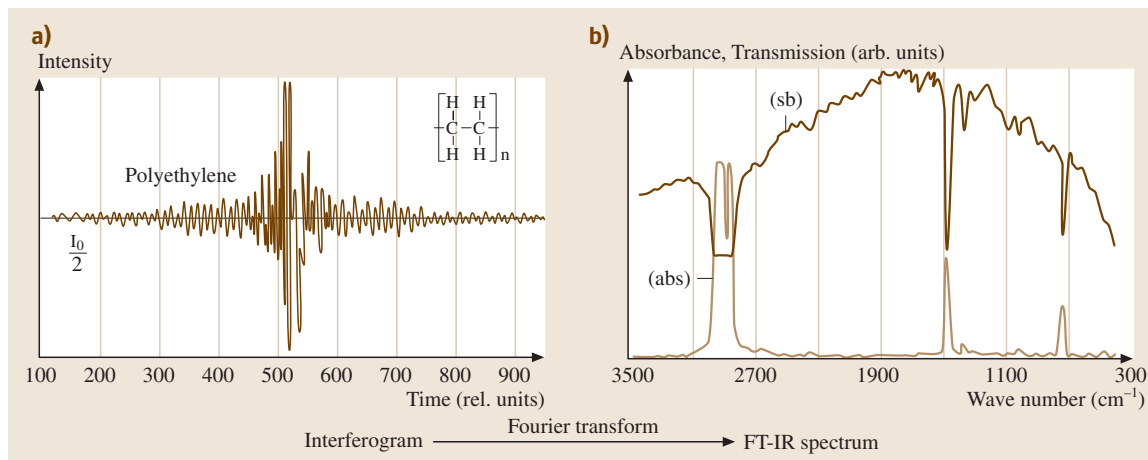

Fig. 5.33a,b An example of FT-IR absorption spectroscopy. (a) An interferogram of transmission through a polyethylene sample, (b) (sb) Fourier transform of the interferogram and (abs) the absorbance spectrum corrected for the instrumental background [5.27]

Fig. 5.35a,b Raman scattering process: (a) nonresonant, (b) resonant, shown for the Stokes shift by exciting a single phonon. $h\nu$ and $h\Omega$ are the energy of the incident photon and the phonon energy, respectively

as a result the photon energy is decreased on scattering by this amount. The broken line in Fig. 5.35a indicates an intermediate virtual electronic state via which the system evolves in the sequence of photon absorption and emission. In contrast to infrared absorption, Raman scattering is a two-photon process and the scattering signal is generally very weak. However, when the intermediate electronic state is not virtual but really present (Fig. 5.35b), Raman scattering occurs in a resonant manner with the scattering intensity being substantially enhanced (resonant Raman scattering). The minimum content of Raman-active centers required is 0.01–1% or $> 10^{19} \text{ cm}^{-3}$ in nonresonant cases. When the centers to be detected are present in the surface layer of samples, the sensitivity is further enhanced (up to 10^6 times) by employing the scheme of surface-enhanced Raman scattering [5.28,29], which exploits a dramatic increase of the optical electric field in the vicinity of metallic nanoparticles such as Ag and Au.

Magnetic Resonance Spectroscopy

Experimental methods based on magnetic resonance of nuclear or electronic spins are applied to the investigation of defects and impurities in solids, structural analysis of molecules, and in some cases, microstructure analysis.

When electrons and nuclei have an angular momentum $\hbar S$ (where \hbar is Planck's constant), a magnetic moment

$$\mu = \gamma \hbar S \quad (5.16)$$

is associated with it. S stands for $s = 1/2$ for electronic spins, for j for electronic orbital angular momenta, and for I , various multiples of $1/2$, for nuclear spins. The coefficient γ is called the magnetogyric ratio defined by

$$\gamma \equiv \frac{ge}{2mc}, \quad (5.17)$$

where g and m are the g -factor (a numeric constant in the range 1–3 depending on the origin of the angular

Fig. 5.36a–c Quantum-mechanical picture (a) and classical vector model (b),(c) of magnetic resonance illustrated for an $S = 1/2$ system. In (a), since the Zeeman-split lower spin state, α , is more occupied than the higher state, β , in thermal equilibrium, the application of a resonant electromagnetic wave causes transitions between the two states, resulting in a net energy absorption. Classically, (b) the macroscopic magnetization M is the average of the spin magnetizations precessing with random phase in thermal equilibrium. (c) On resonance the spin magnetizations are bunched and the resultant magnetization starts to flip its head down, tracing a spiral trajectory in real space

momentum) and the mass of the particle, respectively, and e is the electronic charge, and c the speed of light.

Quantum mechanically, a spin or a magnetic moment under a static magnetic field of intensity B_0 (magnetic flux density) has discrete eigenstates. For the simplest case of $S = 1/2$, the spin has two states, as shown by the energy level diagram in Fig. 5.36a, separated by an energy $\hbar\omega_L$ where

$$\omega_L = \gamma B_0 \quad (5.18)$$

is called the Larmor angular frequency. In magnetic resonance experiments, the sample is further subject to a small magnetic field perpendicular to the static field and alternating at the Larmor frequency, which resonantly induces transitions between the two states. In Fig. 5.36a, the number of filled circles indicates the population of the respective states. Since, in thermal equilibrium, the lower energy state (up-spin state) is more occupied than the higher energy state (down-spin state), the spin system absorbs a net energy from the electromagnetic oscillations.

Classically, a magnetic moment under a static magnetic field precesses around the axis of the static magnetic field (normally taken as the z -axis) at the Larmor frequency, as shown schematically in Fig. 5.36b. In thermal equilibrium, however, the precession of the spins cannot be detected because each precession is random (incoherent) and hence, in macroscopic samples containing many spins, the magnetization of the spin assembly is averaged out leaving only the z -axis component, due to the excess population of up spins. An intuitive picture of magnetic resonance is such that the spins become bunched coherently under a resonant microwave and the resultant magnetization, represented by a vector shown in Fig. 5.36c, flips its head down drawing a spiral trajectory. Although this classical vector model is rarely used in electron spin resonance (ESR) or electron paramagnetic resonance (EPR), it is repeatedly applied to interpretation of nuclear magnetic resonance (NMR). (Although ESR and EPR are often used interchangeably in textbooks, the term ESR in this chapter refers to a generic methodology including EPR.)

What makes magnetic resonance informative for structural studies of materials is the interactions of various origins operating between spins. The magnetic moments associated with spins exert an effective magnetic field on the dipole moment of other spins (classical dipole-dipole interaction). The Pauli principle gives rise to a quantum-mechanical interaction

between two electronic spins (exchange interaction). The behavior of a general system consisting of electron spins and nuclear spins interacting with each other is described by the effective spin Hamiltonian formally written as

$$H = B_0 \gamma'_e S - 2S \mathbf{J}'_e S + S \mathbf{A} \mathbf{I} - B_0 \gamma_n \mathbf{I} + \mathbf{I} \mathbf{J}_n \mathbf{I} + \mathbf{I} \mathbf{Q} \mathbf{I} + \dots \quad (5.19)$$

Here S and \mathbf{I} are now quantum operators of total electronic spins and nuclear spins, respectively. The tensorial magnetogyric ratios γ'_e [slightly modified from (5.17) by spin-orbit coupling, the detail of which is given in Sect. 5.4.2] and γ_n or the corresponding tensorial g -factors describe the Zeeman splitting, respectively, \mathbf{J}'_e the direct exchange interaction between spins (slightly modified by spin-orbit coupling), \mathbf{J}_n the nuclear spin-spin indirect interaction, \mathbf{A} the effect of the environment of the spins (e.g., anisotropic crystal field), \mathbf{Q} the nuclear quadrupole interaction between the electric quadrupole moment associated with $I > 1/2$ nuclei and an electric field gradient at the nuclear position. Due to the large difference between the particle mass of electrons and nuclei, $\gamma'_e \gg \gamma_n$. Therefore, electron spins feel only small perturbations by nuclear spins, but the EPR spectra exhibit quite informative fine structures arising mainly from the third term of (5.19). On the contrary, since the presence of electronic spins has enormous effects on the nuclear spin states, NMR spectra become too complicated in paramagnetic samples.

In the absence of electronic spins, the interaction of nuclear spins with the environment is so weak that the nuclei have a long spin lifetime, a quantity expressing how long the spin coherence once established is maintained as long as the nuclei are stationary in space. In other words, the decrease of nuclear spin lifetime with dynamic motion of the nuclei gives ample information of the dynamics. This unique feature of NMR provides the basis of NMR studies of impurity diffusion in solids (Sect. 5.3.1) and of molecular architecture (Sect. 5.4.2).

There are many other experimental methods that may be classified as magnetic resonance spectroscopy. Optically detected magnetic resonance (ODMR) (Sect. 5.3.1), magnetic circular-polarized emission (MCPE) (Sect. 5.3.1), and magnetic circular dichroic absorption (MCDA) (Sect. 5.3.1) are optical spectroscopic versions of EPR. Muon spin resonance (μ SR) (Sect. 5.3.1) and perturbed angular correlation (PAC) (Sect. 5.3.1) may be regarded as NMR of exotic or

radioactive particles. However, these techniques will be described in a more relevant section (Sect. 5.3.1).

Electron Spectroscopy

Electron Energy-Loss Spectroscopy (EELS). Nowadays, transmission electron microscopes are often equipped with an electron energy spectrometer for routine analysis of electron energy loss. Like photons, electrons injected into solid samples lose their energy by exciting quanta of various forms, but the main loss arises from excitation of other electrons. Among them, the excitation of plasmons with a loss energy of ≈ 20 eV is the most efficient process, whereas this is not the case in photoabsorption, determining the limited penetration power of the electrons through the sample. The plasmon energy is not sufficiently sensitive to the material, so the plasmon loss does not give significant information other than the thickness of the thin samples used for TEM observations. If the energy of incident electrons exceeds the energy necessary for a core electron excitation, another energy-loss mechanism takes place. Since the electron energy used in TEM is high enough, the corresponding thresholds are observed in the EELS spectrum, which is a common technique for element analysis by TEM.

X-Ray Electron Spectroscopy. On core excitations by X-rays, electrons may be emitted from the solid via two different mechanisms. Direct photoelectron emission occurs when the X-ray photon energy is high enough to excite the core electrons to vacuum levels (electronic energy levels just outside the solid surface). The energy of the photoelectrons measured relative to the Fermi level of the sample, therefore, directly reflects the energy of the core electrons. Another mechanism is Auger electron emission that occurs when a hole generated at the core level is annihilated with an electron in an upper level. The energy released on the electron-hole annihilation is spent either by creation of a photon (X-ray fluorescence) or an excitation of another electron (Auger electron) to a vacuum level. The processes are competitive but the Auger process dominates in elements lighter than $Z \approx 30$. Whether through direct photoelectron emission or Auger emission, when the energy of the electrons is of the order of 10 eV, the electronic mean free path is so short due to the plasmon loss that they cannot escape from deep positions in the sample. For this reason, X-ray photoemission spectroscopy (XPS) and Auger electron spectroscopy (AES) are surface-sensitive techniques, being powerful for studies of surfaces but not suitable for bulk samples.

Mechanical Spectroscopy

Mechanical spectroscopy is the generic term for characterization methods of anelastic behavior such as elastic aftereffect, internal friction and ultrasonic attenuation. Anelastic spectroscopy is a synonym of mechanical spectroscopy. In the elastic range, the strain response to applied stress is composed of the (instantaneous) elastic strain ε_e and the (delayed) anelastic strain ε_a , where the ratio $\varepsilon_a/\varepsilon_e$ is indicative of anelasticity. The measurement time scale is quasistatic for elastic after effect, below $\approx 10^4$ Hz for internal friction and above $\approx 10^4$ Hz for ultrasonic attenuation. Interaction of acoustic waves with phonons is out of the present scope. Thermoelastic relaxation is associated with the adiabatic temperature change induced by application of a stress and can be commonly observed in solid materials, but its magnitude is negligibly small except in the vicinity of the resonant condition. Mechanical spectroscopy can be applied to detect the recoverable motions of/in atoms, lattice defects, interfaces, magnetic domain walls and so on when they modify the strain response. The value of $\varepsilon_a/\varepsilon_e$ is a function of the anelastic strain for each process and the concentration of participating agents, which may be a function of the strain amplitude ε , frequency f and temperature T . For example, the value of $\varepsilon_a/\varepsilon_e$ at room temperature is of the order of 10^{-7} in silicon single crystals, 10^{-1} in highly damping metals and more than unity in polymers.

The anelastic relaxation is characterized by the relaxation time τ and $\varepsilon_a/\varepsilon_e$, where the relaxation peak exhibits a maximum at $\omega\tau = 1$ ($\omega = 2\pi f$). Thermally activated anelastic relaxation is studied as a function of temperature or frequency. The elastic aftereffect is isothermally measured as a function of elapsed time, where τ and $\varepsilon_a/\varepsilon_e$ at a given temperature are found directly. In subresonance measurements, internal friction is isothermally measured as a function of frequency, e.g., in the range between 10^{-3} and 10 Hz. These methods are applicable for $\varepsilon_a/\varepsilon_e > 10^{-5}$ because of limitations on experimental accuracy. It is emphasized that these methods can also be applied to materials with $\varepsilon_a/\varepsilon_e > 1$. The resonance methods are applicable to cases of $\varepsilon_a/\varepsilon_e < 10^{-1}$, where internal friction is measured as a function of temperature. These methods are applicable to thin plates or rod specimens. Ultrasonic attenuation is applicable to bulky specimens, where the specimen length should be longer than the pulse length. In Sects. 5.3.1 and 5.3.2, some more detail of internal friction is described.

5.2 Crystalline and Amorphous Structure Analysis

The subject covered in this section will be structural analysis of ordinary metallic and semiconducting crystalline solids, molecular crystal, liquid crystals, amorphous solids, and quasicrystals. The subsections are divided according to the extent of structural order in space. Surface-specific problems are beyond the scope of this chapter.

5.2.1 Long-Range Order Analysis

Single Crystal Analysis

As mentioned in Sect. 5.1.1, the structure factor $F(\mathbf{K})$ in wavenumber space is related to the electronic density $\rho(\mathbf{r})$ in real space through a Fourier transformation. Since the electrons are concentrated at the atomic positions, knowing the electronic density $\rho(\mathbf{r})$ is to know the crystal structure. In principle, therefore, the crystal structure can be deduced by the inverse Fourier transformation of the structure factors if known experimentally. In practice, however, the only quantities we can measure in experiments are not $F(\mathbf{g}) = F_{\mathbf{g}} \exp(i\phi_{\mathbf{g}})$ but $|F(\mathbf{g})|^2$ (hereafter, reciprocal lattice vectors \mathbf{g} in structure factors implicitly indicate the structure factors integrated over the broadening width), which means that we lack the knowledge of the phase factors $\phi_{\mathbf{g}}$ to calculate the electronic distribution immediately. This phase problem is the main difficulty in structural analysis of X-ray diffraction, to which much effort has been devoted. The standard analytical methods to tackle this problem are the direct method, the heavy atom method and the anomalous dispersion method.

The direct method is based on a general relation (Sayre's formula)

$$F(\mathbf{h}) = a \sum_{\mathbf{g}} F(\mathbf{g})F(\mathbf{h} - \mathbf{g}) \quad a: \text{a real coefficient} \quad (5.20)$$

which holds for arbitrary structure factors. In many practical cases, diffraction intensities are concentrated in a limited number of diffraction spots. In the simplest case, where a single term containing a specific \mathbf{g} predominates in the sum,

$$F(\mathbf{h}) \approx aF(\mathbf{g})F(\mathbf{h} - \mathbf{g}), \quad (5.21)$$

we have a phase relationship of

$$\phi_{\mathbf{h}} \approx \phi_{\mathbf{g}} + \phi_{\mathbf{h}-\mathbf{g}} \quad (5.22)$$

approximately. Thus, having assumed two phase values, one could evaluate the other and so on, successively. In

the actual procedure, starting with an initial set of phase values for dominant diffractions, one repeats an iterative procedure to recalculate the phase values until convergence is achieved. Such procedures are attempted for many initial sets of $F(\mathbf{g}) = F_{\mathbf{g}} \exp(i\phi_{\mathbf{g}})$, or model structures that yield the sets, until the best fit with experiment is achieved.

The heavy atom method is based on the fact that the atomic scattering factor $f(\mathbf{K})$ increases with the number of electrons in the atom and hence the atomic number. This method can be efficient in those crystals containing metal complexes in which the structure factors are determined mainly by the arrangement of the heavy metal atoms. Exploiting this situation, we could estimate the approximate positions of the heavy atoms in the unit cell. The experimentally measured inverse Fourier transform of $|F(\mathbf{g})|^2$ is called the Patterson function, the autocorrelation function of the electron density $\rho(\mathbf{r})$,

$$P(\mathbf{u}) = \int \rho(\mathbf{r})\rho(\mathbf{r} + \mathbf{u}) d\mathbf{v}. \quad (5.23)$$

Therefore, the Patterson function has strong peaks at relative positional vectors connecting two heavy atoms in real space. From these peaks one could deduce the real positions of only the heavy atoms in the unit cell (for more details, see the relevant textbooks [5.8]). The heavy atoms may be intentionally introduced in the process of crystal growth or in the synthesis of chemicals for macromolecules that are to be grown into crystalline samples. Chemical substitution is a method commonly used in structural analysis of biomolecules (Sect. 5.4.1).

Instead of substituting atoms, in some cases the anomalous dispersion effect can be used. Anomalous dispersion is a phenomenon in which the complex atomic structure factor changes considerably at wavelengths around the core excitation edge. Therefore, if we use X-rays of an appropriate wavelength, we can effectively "substitute" atoms with different atomic scattering factors. Since the advent of synchrotron radiation sources, it has become possible to use strong monochromatic X-rays tunable to a specific wavelength so that the anomalous dispersion method now constitutes a powerful technique applicable to many materials.

In addition to the phase problem, measurements of $F_{\text{obs}}(\mathbf{K})$ for only a limited number of \mathbf{K} vectors could lead to spurious results due to a cut-off effect in the inverse Fourier transformation. These difficulties are

now being overcome by the application of the maximum entropy method (MEM) [5.30], a state-of-the-art technique that allows very precise analysis of diffraction data based on the method of least presumption and structural models of the crystal.

Regarding the sample, the availability of a single crystal is an essential prerequisite. As shown in (5.8), the intensity of the diffracted X-rays depends linearly on the number of atoms or the sample volume, in other words, it decreases rapidly as the third power of the sample dimension. If we use a conventional sealed X-ray tube, the size of single crystals must be larger than 0.1 mm, but if a synchrotron radiation source is available, the sample size may be reduced by one order of magnitude. The crystal quality must be high enough that peak broadening due to imperfections is small enough to allow peak separation. This is of particular importance in molecular crystals because the lattice constant of molecular crystals is likely to be so large that the diffraction peaks crowded one another.

The samples are mounted on a goniometer as shown in Fig. 5.37 and rotated around three Eulerian axes. Usually the ω - 2θ (θ - 2θ) scan scheme is employed: the angles ϕ and χ adjusted so that the sample can be rotated around a zone axis coincident with the ω -axis by increasing the incidence angle θ step by step while simultaneously rotating the detector by 2θ so as to maintain specular reflection conditions.

Powder Diffraction

Single crystal diffraction experiments using a relatively large crystal give a data set from which we could deduce the crystal structure with high accuracy. However, since most materials of technical interest cannot grow to large single crystals, one has to resort to the use of powder samples consisting of small crystallites. At this point,

Fig. 5.37 Rotation angles in a four-circle goniometer

one might suspect that, instead of using crystalline samples, one could use amorphous samples as the extreme of small crystallites. This view is totally wrong because for the Bragg diffraction, which is a consequence of constructive interference, to occur, the crystal must have a finite size. For crystal structure determination by powder diffraction, the crystallite size should preferably be larger than the micron scale. X-ray analysis of short-range order in amorphous solids will be described in Sect. 5.2.3.

In powder diffraction, the reciprocal lattice is randomly oriented with respect to the incident X-ray beam and the Ewald sphere. As a consequence, the X-ray diffraction by crystallographically equivalent lattice planes occurs in directions forming a cone with a common diffraction angle 2θ , as illustrated in Fig. 5.38a. The diffraction pattern thus obtained consists of rings (Debye rings) of different diameters the values of which are related to the interplanar spacings in the Bragg condition (5.1). The historical method of studying the Debye rings is to use a Debye-Scherrer camera (Fig. 5.38b) in which a slice of Debye rings is recorded on a strip of X-ray film placed around the sample. In modern experiments, the X-ray film is replaced with an X-ray detector turning on a diffractometer (Fig. 5.38c). If the Debye rings

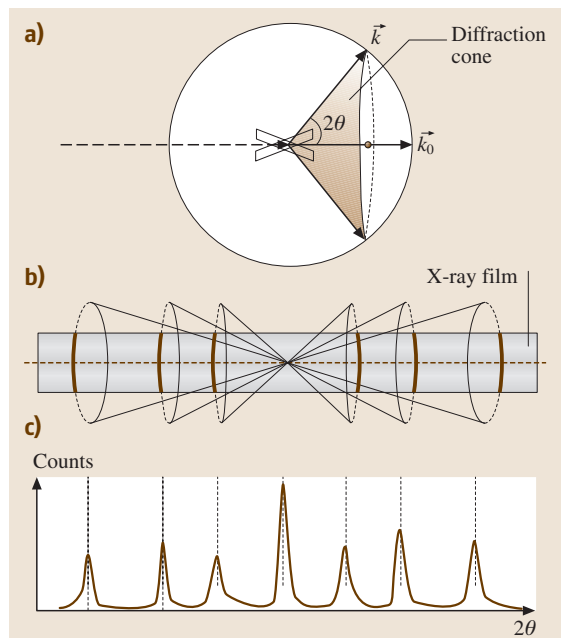

Fig. 5.38 (a) Ewald construction for powder diffraction, (b) Debye-Scherrer camera and (c) diffraction profile recorded by a diffractometer

or diffraction peaks are properly indexed with knowledge of the crystal structure and the extinction rule, the lattice parameter of the crystal can be determined with accuracy higher than 10^{-6} .

The sample requirements for powder diffraction measurements are as follows:

1. The sample must be an assembly of crystallites each smaller than $\approx 10\ \mu\text{m}$ (ideally $\approx 3\ \mu\text{m}$).
2. Individual crystallites must be oriented randomly.

Condition b is important because, if exceptionally large crystallites are present, they introduce bright spots in the Debye rings (as exemplified in Fig. 5.99), which introduces a spurious diffraction profile. Similarly, if the orientational randomness is lost, it is impossible to measure correct profiles. In such cases, the sample must be rotated to remove such artifacts. For assessment of orientationally textured materials see Sect. 5.5.1.

The main drawback of the powder diffraction method compared to methods using single crystals is the overlap of diffraction peaks that prevents the accurate determination of the integrated intensity of each reflection and hence the structure factor. The Rietveld method, which allows an effective separation of these overlapping peaks, is a standard technique routinely used nowadays in the analysis of powder diffraction data. For the phase problem, the power of MEM (Sect. 5.2.1) in the analysis of X-ray powder diffraction, combined with the Rietveld method, has also been progressively discovered [5.31]. Using powder diffraction, one can determine the structures of considerably large molecules such as metmyoglobin, the single crystal unit cell of which contains two molecules (≈ 5000 atoms) and ≈ 800 waters [5.32].

Selected Area Diffraction (SAD)

The general merit of using TEM is that one can investigate solid structures at a medium-scale range, but most of this matter is more relevantly addressed in the section on microstructure analysis (Sect. 5.5). Selected area diffraction in TEM corresponds to single crystal diffraction of monochromatic X-rays, displaying a two-dimensional projection of the reciprocal lattice in the zeroth-order Laue zone (ZOLZ). In this regard, there is no great difference in principle between X-ray diffraction and SAD. Nevertheless, the real-time graphic presentation of the reciprocal lattice in SAD may give us more chance to notice subtle changes in crystal ordering visually. Figure 5.39a shows a SAD pattern of an AuCu alloy ordered with a superperiodicity (b). The SAD pattern is characterized by satellite spots which are absent when

Fig. 5.39a–d Superlattice reflections (a) in the superperiodic ordered phase of AuCu alloy (b) and Fourier transform (c) of a periodically modulated sinusoidal wave (d)

the crystal is ordered but not in the long range. The origin of the satellites may be understood by examining Fig. 5.39c, which illustrates the Fourier transform of a periodically modulated sinusoidal wave (d) that mimics the superperiodic structure.

Similar satellites can be observed by X-ray diffraction of artificial superlattice thin films grown by the molecular beam epitaxial method. For the superlattice spots to be observed, X-ray diffraction experiments are conducted in a reflection configuration, where the X-rays incident to the front side of the films are Bragg reflected by lattice planes that are parallel to the film surface, as shown schematically in Fig. 5.2 (Sect. 5.1.1).

5.2.2 Medium-Range Order Analysis

Convergent Beam Electron Diffraction (CBED)

Although the selected area diffraction (SAD) (Sects. 5.1.2 and 5.2.1) in TEM gives us structural information of the local parts ($> 0.5 \mu\text{m}$ in size) of the sample selected by the objective aperture, the crystallographic information is limited compared with X-ray diffraction. The convergent beam electron diffraction (CBED) is even more informative than X-ray diffraction in some cases. In contrast to the parallel electron beam used in SAD, the electron beam used in CBED is focused onto a sample with a convergence semi-angle $\alpha > 10 \text{ mrad}$. Figure 5.40 illustrates how CBED patterns are obtained in reciprocal space (a) and in real space (b). The beam convergence not only improves the spatial resolution down to tens of nanometres but also changes substantially the information contained in the diffraction patterns if the sample thickness t is larger than the extinction distance ξ_g , the case in which the dynamical effect (Sect. 5.1.2) must be taken into account. Figure 5.41 shows a schematic CBED pattern: the zero-order Laue zone (ZOLZ) diffraction spots in SAD are observed as disks in CBED. If the convergence angle 2α is large enough, diffraction is also excited from higher-order Laue zones (HOLZ) outside of the ZOLZ disks (HOLZ is the general term for the first-order Laue zone (FOLZ), the second-order Laue zone (SOLZ), and so on). An effect of multiple reflections in CBED is the characteristic dynamical contrasts *within* the disks that are absent when $t < \xi_g$. In kinematical X-ray diffraction, centrosymmetric crystals and noncentrosymmetric ones cannot be distinguished because (h, k, ℓ) and $(\bar{h}, \bar{k}, \bar{\ell})$ diffraction spots are, in any case, observed with the same intensity. In CBED, however, the diffraction pattern exhibits the same symmetry as the point group of the crystal due to the dynamical effect, so that one may fully determine the point group symmetry from a set of CBED patterns obtained for different zone axes.

Measurements of lattice parameter by SAD is not as accurate ($\approx 2\%$) as in X-ray diffraction even if the camera length, which directly affects the diameter of the diffraction rings on the screen, is calibrated carefully by using a reference crystalline powder (e.g., Au). However, the accuracy could be enhanced to $\approx 0.2\%$ by measuring the positions of sharp CBED Kikuchi lines, another effect of dynamical diffraction in CBED. When the convergence semi-angle α is larger than the Bragg angle θ_B (Fig. 5.40c), some electrons in the beam may already satisfy the Bragg condition and hence be re-

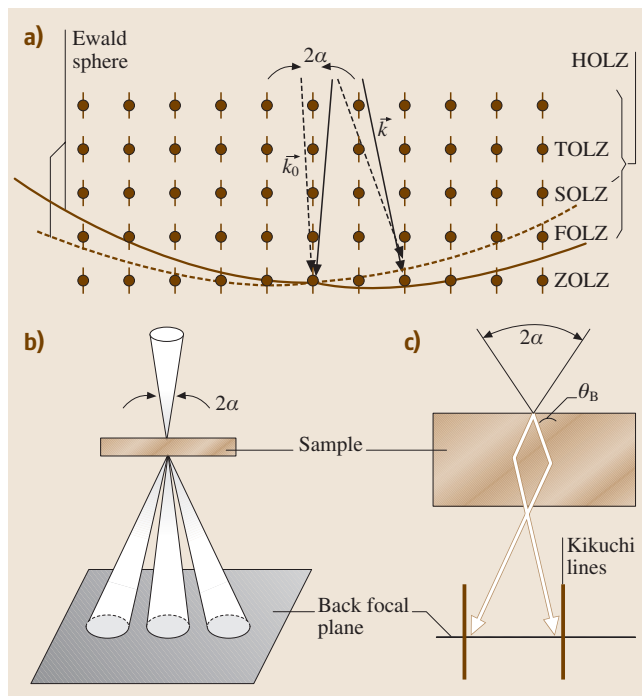

Fig. 5.40a–c Convergent beam electron diffraction (CBED) in reciprocal space (a) and in real space (b). If $\alpha > \theta_B$ (Bragg angle), CBED Kikuchi lines are formed (c)

flected by the net planes to form Kikuchi lines similar to those also observed in SAD. However, while the Kikuchi lines in SAD originate from inelastic scattering of incident electrons, the CBED Kikuchi lines are formed by elastically scattered electrons. There are two types of CBED Kikuchi lines, those bisecting each ZOLZ disk (ZOLZ Kikuchi lines) and those arising from HOLZ diffractions (Fig. 5.41). The Kikuchi lines of particular importance here are the deficient (dark) Kikuchi lines observed within the direct $(0, 0, 0)$ disk, which have their origins in the HOLZ Kikuchi lines. The positions of the HOLZ Kikuchi lines are more sensitive to lattice strain than ZOLZ Kikuchi lines because the larger $|g| = 1/d$ (d : interplanar spacing), the larger its shift $\Delta|g| = -(\Delta d/d)|g|$, which means the higher sensitivity to strain $\Delta d/d$. The sharpness of the CBED Kikuchi lines due to the smallness of the sampled area also serves to enhance the strain sensitivity.

Methods for Paracrystalline Solids

The term paracrystal is used as a model of disorder in crystalline solids. In this chapter, we use this term in a broader sense to mean materials that are intermediate

Fig. 5.41 A schematic CBED pattern featured by zero-order Laue zone (ZOLZ) disks, deficient HOLZ Kikuchi lines in the direct (0,0,0) disk, and reflections from higher-order Laue zones (HOLZ)

between three-dimensionally periodic crystals and completely amorphous structures. Most of the largest size macromolecules are polymers which are formed by the linear repetition of a group of atoms called a monomer. A polymer has no fixed configuration but takes an almost infinite variety of forms. Due to the flexibility of polymeric chains and the tendency for mutual entanglement, polymers are likely to solidify in an amorphous or glassy form and are difficult to crystallize perfectly. So it is common that the ordered structure, if present, extends only to a limited range, as illustrated in Fig. 5.42. For the assessment of the medium-range order, one of the most common methods is to use interference optical microscopes, in which phases having different optical properties in terms of refractive index, birefringence, the rotary power, etc. are imaged as different contrasts or colors.

Between completely three-dimensional crystals and glasses, some molecular solids have structures in which the crystalline order is lost in some dimensions. Solids belonging to this category are called liquid crystals. The molecules in liquid crystals are commonly elongated rigid rods with a typical length of ≈ 2.5 nm and a slightly flattened cross section of $0.6 \text{ nm} \times 0.4 \text{ nm}$. The upper drawings in Fig. 5.43 show various forms of liquid crystals in different degrees of order. The crystalline phase

Fig. 5.42 Structure of polymer solid with coexisting crystalline and amorphous domains

on the left and the amorphous phase on the right are completely ordered and disordered, respectively, in terms of both molecular position and orientation. In the so-called nematic phase in between, the molecules are orientationally ordered but positionally disordered, and in smectic phases, the molecules are orientationally ordered forming layers but the molecular positions are random within each layer. The lower drawings in Fig. 5.43 illustrate the schematic X-ray diffraction patterns of the aforementioned phases. Thus, we may infer the phase from its characteristic diffraction pattern.

Quasicrystals are noncrystalline solids condensed with no periodicity that are not fully amorphous but that have regularity different from crystals. Quasicrystals consist of unit cells with five-fold symmetry which is incompatible with any crystalline long-range order. In spite of the absence of crystalline order, however, quasicrystals exhibit clear diffraction, as demonstrated by the SAD pattern in Fig. 5.44a. This is due to the fact that, even if the crystalline periodicity is absent, there are atomic net planes regularly spaced as one may find in the model structure of a quasicrystal shown in Fig. 5.44b.

5.2.3 Short-Range Order Analysis

Diffraction Methods

Although the atomic arrangement in amorphous solids is extremely disordered, it is not completely random as in a gas phase but preserves a short-range order to some extent. This is evidenced by halo diffraction rings from amorphous solids, as shown in Fig. 5.45. For amorphous solids, the intensity of the diffracted wave is simply given by (5.7) where the unit cell extends over the whole solid.

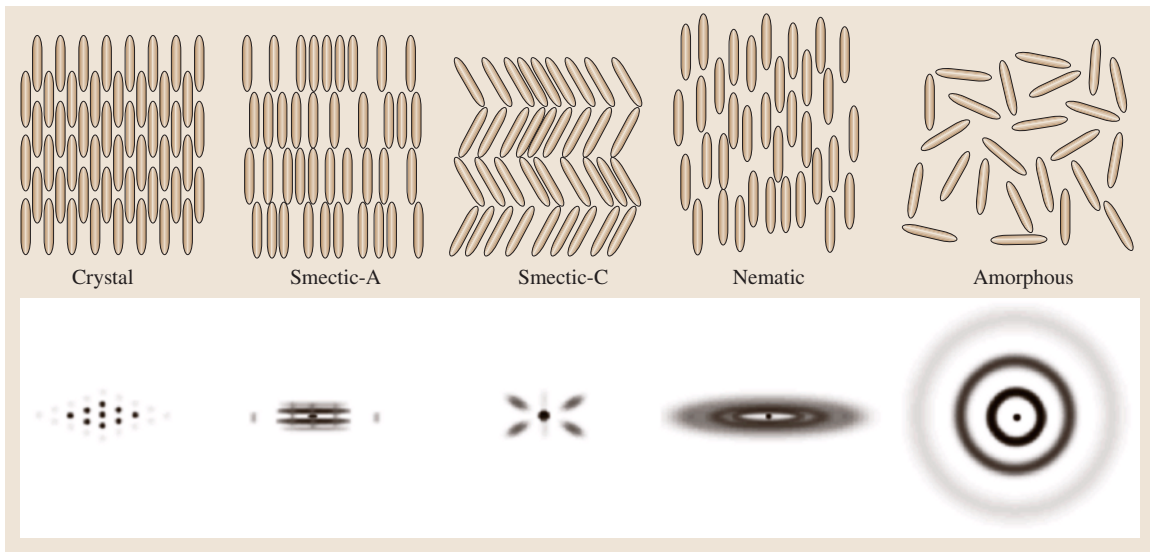

Fig. 5.43 Liquid crystal phases and their diffraction patterns (schematic)

Fig. 5.44a,b SAD pattern of a quasicrystal (a) and the model structure (b). Courtesy of Dr. K. Suzuki

Hence

$$I(\mathbf{K}) = I_e \left| \sum_j f_j(\mathbf{K}) \exp(i\mathbf{K} \cdot \mathbf{r}_j) \right|^2 \quad (5.24)$$

$$= I_e \sum_{m,n} f_m(\mathbf{K}) f_n(\mathbf{K}) \exp[i\mathbf{K} \cdot (\mathbf{r}_m - \mathbf{r}_n)] .$$

Fig. 5.45 Halo pattern of selected area electron diffraction from an amorphous carbon film

For single component solids ($f_m = f_n \equiv f$) consisting of N atoms, some calculations show that

$$K \frac{I(K)/N - f^2}{f^2} = 4\pi \int_0^\infty r [\rho(r) - \rho_0] \sin Kr \, dr, \quad (5.25)$$

where $\rho(r)$ is the radial distribution function, which is defined as the mean density of atoms located at distance r from an atom, and ρ_0 denotes the average density of atoms. The above equation means that the quantity $r[\rho(r) - \rho_0]$ is given by the inverse Fourier transformation of the quantity on the left, which is measurable in diffraction experiments.

For multicomponent solids, the similarly defined partial distribution functions are deduced from diffraction patterns if one uses techniques such as anomalous dispersion that allow one to enhance the atomic scattering factor f_j of only a specific element by tuning the wavelength of the X-rays. The atomic scattering factor for neutrons is generally quite different from that for X-rays (Sect. 5.1.1). So coupling neutron diffraction with X-ray diffraction, we could extend the range of elements that can be studied by using diffraction methods.

Extended X-Ray Absorption Fine Structure (EXAFS)

X-ray absorption occurs when the photon energy exceeds the threshold for excitations of core electrons to unoccupied upper levels. The core absorption spectrum has a characteristic fine structure extending over

Fig. 5.46 Interference of core-excited electron waves scattered by surrounding atoms giving rise to EXAFS

hundreds of eV above the absorption edge. The undulating structures within ≈ 50 eV of the edge is referred to as X-ray absorption near-edge structures (XANES) or near-edge X-ray absorption fine structures (NEXAFS), whereas the fine structures beyond ≈ 50 eV are called the extended X-ray absorption fine structures (EXAFS). The EXAFS is brought about by interference of the excited electron wave primarily activated at a core with the secondary waves scattered by the surrounding atoms (Fig. 5.46). Therefore, the EXAFS contains

Fig. 5.47 Analysis of short-range order by extended X-ray absorption fine structure. After [5.33]

information on the local atomic arrangement, neighbor distances and the coordination numbers, around the atoms of a specific element responsible for the core excitation absorption. Figure 5.47a shows an experimental X-ray absorption spectrum near the zinc K-edge of an amorphous $\text{Mg}_{70}\text{Zn}_{30}$ alloy, and Fig. 5.47b the oscillatory part of the EXAFS obtained by subtracting the large monotonic background in (a). Assuming appropriate phase shifts on electron scattering, we obtain Fig. 5.47c, a Fourier transform of a function modified from (b), from which we deduce Fig. 5.47d, the partial distribution function around Zn atoms. The area of deconvoluted peaks in (d) gives the coordination number for the respective atom pair. The element-selectivity of the EXAFS method provides a unique tool that enables one to investigate the local order for different atomic species in alloys, regardless of the long-range order or the crystallinity and amorphousness of the sample.

X-Ray Photoemission Spectroscopy (XPS)

Though X-ray photoemission spectroscopy (XPS) is surface sensitive, it may be used for studies of very short-range order around atoms. The energy of the photoelectrons measured relative to the Fermi level of the sample directly reflects the energy of the core electrons. The core level is slightly affected by how much electronic charge is distributed on the nucleus in the solid (chemical shift): the more negatively charged, the higher the core level and hence the smaller the photoelectron

energy. The spectral peak position and its intensity in XPS thus indicate the character of chemical bonding or the degree of oxidation of the selectively probed atoms.

Raman Scattering

Since the principle of Raman scattering has been described already (Sect. 5.1.3), we only mention an application of Raman scattering to studies of structural order in crystalline and amorphous solids. From the energy of Raman-active optical phonons, the material phases present in the sample can be determined. The selection rule in infrared absorption based on the translational symmetry of the crystal allows only optical modes near $k \approx 0$ in the Brillouin zone. Similarly the translational symmetry restricts the Raman scattering to limited modes. The presence of defects or disorder in crystals breaks the translational symmetry of the lattice, so that translationally forbidden Raman modes become active and detectable as an increase of the extended lattice phonon signal. Raman scattering is one of the standard methods for structural assessment of amorphous carbon [5.34]. This is owing to the fact that the blue–green spectral region (488–514.5 nm), the most widely used for Raman scattering experiments, is electronically resonant with graphitic crystals, enhancing the scattering signals. Two broad spectral bands each corresponding to crystalline and disordered graphitic phases are well separated for quantitative analysis of disorder.

5.3 Lattice Defects and Impurities Analysis

This section deals with methods for the study of atomistic structural defects and impurities in regular lattices. Section 5.3.1 covers point defects including vacancies, interstitial atoms, defect complexes, defect clusters, and impurities. Section 5.3.2 treats extended defects including dislocations, stacking faults, grain boundaries, and phase boundaries.

The sensitivity (or field of view) of the methods described here is not necessarily high (wide) enough for detecting a low density of defects, so in many cases the defects must be intentionally introduced into the sample by some means. For intrinsic point defects such as vacancies and self-interstitials, the most common method is to irradiate the sample with high energy particles such as MeV electrons and fast neutrons. For dislocations, the sample may have to be deformed plastically. However, one should always pay careful attention to the

possibility that the primary defects may react to form complexes with themselves or impurities and the plastically deformed samples may contain point defects as well.

5.3.1 Point Defects and Impurities

Diffraction and Scattering Methods

X-Ray Diffuse Scattering. The lattice distortion induced by the presence of point defects and impurities, as illustrated in Fig. 5.48a, causes a diffuse scattering in X-ray diffraction as well as a shift of the diffraction peaks. The diffuse scattering from such imperfect crystals generally has two components (Fig. 5.48b): Huang scattering, which appears near the diffraction peaks and represents a long-range strain field around the defects and impurities, and Stokes–Wilson scattering, which

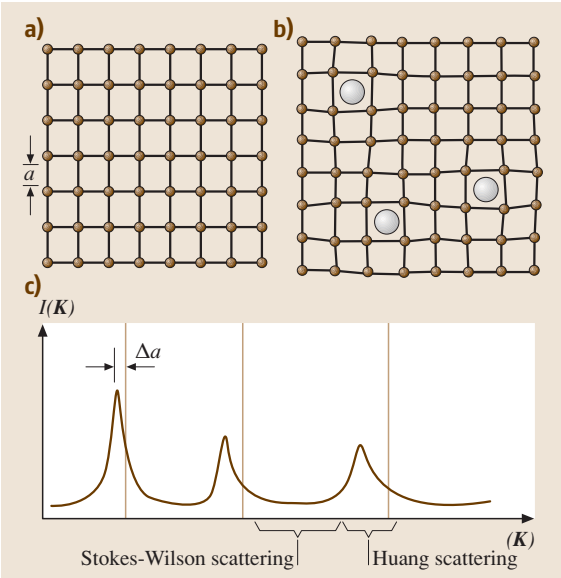

Fig. 5.48 (a) A perfect lattice and (b) a lattice distortion induced by point defects reflected in the X-ray diffraction (c) as shifts of Bragg peaks, Stokes–Wilson scattering for the short-range elastic fields and Huang scattering for the long-range fields

extends the between diffraction peaks and represents a short-range atomic configuration and hence its distribution in the reciprocal space reflects the symmetry of the strain field associated with the defect and impurity. Figure 5.49 shows the Stokes–Wilson scattering from an

electron-irradiated Al sample [5.35] experimentally deduced by carefully subtracting a background of different origins one or two orders of magnitude larger than the signal. The experimental profiles measured along different trajectories in the reciprocal space agree most with the theoretical curves predicted by self-interstitials split along the $\langle 100 \rangle$ direction.

Rutherford Back Scattering. When light ions such as H^+ and He^+ are incident on a solid, some of them are classically scattered by atoms in the solid, reflected backward and emitted from the sample, which is called Rutherford back scattering (Fig. 5.50a). These backscattered ions lose an energy depending on the atoms with which the ions collide and the collision parameters: the heavier the atoms, the larger the energy loss in an elastic collision. Figure 5.50b shows a schematic diagram of the energy distribution of the backscattered ions. If the sample contains impurity atoms much heavier than the atoms in the matrix, an additional component due to these impurities appears between the primary ion energy E_0 and the energy kE_0 ($k < 1$) representing the energy of an ion that has collided only once with a matrix atom. This provides a means to measure the depth profile of diffusant atoms from the surface. Furthermore, in single crystal samples, ions can penetrate, without scattered, over an anomalously large distance along specific crystallographic directions called channels. If an interstitial atom is present in the channel, the number of backscattered ions incident in the channeling directions is increased. The out-going backscattered

Fig. 5.49 Structural determination of selfinterstitial in Al by X-ray diffuse scattering [5.36, p. 87]

Fig. 5.50 (a) Light ions with primary energy E_0 are incident along a channel direction and inelastically scattered backward (Rutherford back scattering) with a reduced energy E . (b) The energy distribution of back scattered ions. When heavy impurities are present in the channels, a distribution arises for smaller losses

ions also feel the channeling effect, which enables the method of double channeling that allows determination of the crystallographic position of the interstitial atoms in the lattice.

Microscopic Methods

Scanning Tunneling Microscopy (STM). One of the microscopic methods currently available for direct observations of point defects is scanning tunneling microscopy (STM). As explained in Sect. 5.1.2, the tunneling current reflects the local density of states (LDOS) of electrons at the tip position above the surface. Therefore, if the wave functions associated with defects even beneath the surface extend out of the surface, we can image the defect contrasts using STM. Figure 5.51 shows an STM image obtained for an arsenic-related point defect located below the surface [5.37]. Defect studies by STM are in the early stages of promising applications for various material systems.

High-Angle Annular Dark-Field STEM (HAADF-STEM). An ambitious approach for rather indirect observations of point defects is high-angle annular dark-field STEM (HAADF-STEM). The progress of improvement of spherical aberration has achieved successful

Fig. 5.51 (a) Scanning tunneling microscopic image of an arsenic-related point defect beneath the surface and (b) the local density of states measured at the defect position [5.37]

atomic-scale imaging of impurity atoms [5.38] and vacancies [5.39] in each atomic column. Nevertheless, elaborate image simulations are necessary for decisive conclusions to be drawn.

Spectroscopic Methods

Relaxation Spectroscopy.

Mechanical Spectroscopy. When the lattice distortion induced by defects and impurities is anisotropic, such as the strain ellipsoid depicted in Fig. 5.52a, the stress-induced reorientation (ordering) of the anisotropic distortion centers can be detected as the Snoek relax-

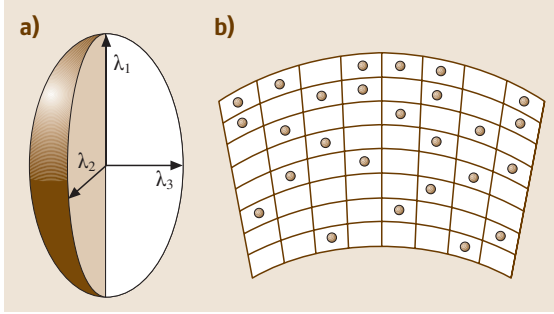

Fig. 5.52 (a) The strain ellipsoid, (b) hydrogen atoms in a bent specimen

ation (peak), which allows one to evaluate the λ tensor (Fig. 5.52a) and the relaxation time. The equilibrium anelastic strain $\varepsilon_a^{(eq)}$ is given by

$$\varepsilon_a^{(eq)} = \frac{C_0 v_0 \sigma}{3kT} \left[\sum_p (\lambda^{(p)})^2 - \frac{1}{3} \left(\sum_p \lambda^{(p)} \right)^2 \right] \quad (5.26)$$

with

$$\lambda^{(p)} = (\alpha_1^{(p)})^2 \lambda_1 + (\alpha_2^{(p)})^2 \lambda_2 + (\alpha_3^{(p)})^2 \lambda_3, \quad (5.27)$$

where C_0 is the concentration of the anisotropic distortion centers, v_0 is the molar volume, and $\alpha_1^{(p)}$, $\alpha_2^{(p)}$ and $\alpha_3^{(p)}$ are the direction cosines between the stress axis and the three principal axes of the λ tensor. A typical application is to carbon, nitrogen and oxygen interstitial atoms in bcc metals which occupy one of three equivalent interstitial sites (octahedral sites) inducing tetragonal distortions in different crystallographic directions. The concept of the Snoek relaxation is also applied to the hydrogen internal friction peak in amorphous alloys.

A pair of differently sized solute atoms in the solid solution in the nearest-neighbor configuration can be an anisotropic distortion center. For such cases, the anelastic relaxation (peak) associated with the stress-induced reorientation (ordering) of the anisotropic distortion centers is referred to as the Zener relaxation (peak). The Zener relaxation provides a tool for the study of atomic migration in substitutional alloys, without radioisotopes, at temperatures much lower than in conventional diffusion methods.

When the lattice distortion induced by an applied stress is not homogeneous, a stress-induced redistribution of interstitial impurities takes place resulting in an anelastic strain (Fig. 5.52b). Such relaxation is referred to as the Gorsky relaxation and provides a tool for the study of long-range migration of interstitial impurities.

The relaxation time τ and the relaxation strength Δ_E for a specimen of rectangular section are given by

$$\tau = d^2 / \pi^2 D \quad (5.28)$$

and

$$\Delta_E = (C_0 v_0 E / 9kT \beta) (\text{tr } \lambda)^2, \quad (5.29)$$

where D is the diffusion coefficient of the impurity, β is the number of interstitial sites per host atom, and d and E are the thickness and the Young's modulus of the specimen, respectively. This method is applied to hydrogen diffusion because of the rapid diffusion rate.

Dielectric or Magnetic Relaxation. Quite similar relaxation processes occur in the dielectric or magnetic response of defects and impurities. Tightly bound pairs in ionic crystals have in some cases, such as in F_A centers (pairs of anion vacancy and isovalent cation impurity atom) in alkali halides, an electric dipole moment along the bond orientation [5.40]. Therefore, responding to the application and the removal of an electric field, the dipole moment reorients by a movement of constituent atoms, which is detected as a dielectric relaxation. Magnetic aftereffects are also brought about by movements of point defects and impurities. Since interstitial atoms in bcc metals diffuse in response to an external magnetic field through magnetostriction, essentially by the same mechanism as the Snoek effect, the Snoek relaxation can be studied by measurements of the magnetic relaxation.

Noise Spectroscopy. Relaxation and fluctuation represent two aspects of statistical behaviors of a physical quantity q that is under stochastic random forces [5.41, 42]. Debye-type relaxation behavior, which is characterized by a time constant τ_r with which the quantity responds to a stepwise stimulation, is described by an autocorrelation function

$$\varphi_q(\tau) = \langle q(t)q(t+\tau) \rangle \propto \exp(-\tau/\tau_r). \quad (5.30)$$

Generally, the autocorrelation function in the time domain is related to the fluctuation power spectrum $S_q(\omega)$ in the frequency domain through the Wiener–Khinchine theorem

$$S_q(\omega) = 4 \int_0^\infty \varphi_q(\tau) \cos \omega \tau d\tau. \quad (5.31)$$

Therefore, from measurements of the fluctuation power spectrum without intentional stimulation, we can deduce the relaxation time. The fluctuations may be detected in the form of electrical noise. The source of the

noise varies from case to case. In semiconductors containing impurities or defects forming deep levels in the band gap, we may observe a generation–recombination (g–r) noise arising from the fluctuations of carrier density on random exchange of carriers between the deep levels and the band states. Since the fluctuation or relaxation time constant is determined, in many cases, by the rate of thermal activation of carriers from the deep level to the band, measurements of the noise intensity as a function of temperature give spectroscopic information about the depth of the deep level from the relevant band edge. Since such noise becomes more significant as the number of carriers becomes smaller, noise spectroscopy is useful for studies of small systems such as nanostructures.

Infrared Absorption Spectroscopy (IRAS). The optical photon energy that IRAS detects is determined by the atomic mass and the strength of the bonds with the surrounding atoms. Therefore, the local vibrational frequency of impurity atoms of mass similar to the matrix easily overlap with the lattice phonon band and form a resonance mode that is hard to detect in IRAS due to the strong background. Since the local vibrational modes (LVM) associated with intrinsic point defects behave similarly, few studies have been reported for IRAS experiments of LVM of intrinsic point defects. (This is also due to the fact that simple intrinsic point defects are usually easily formed secondary defects such as complexes with impurities.) Instead, IRAS experiments on light elements such as oxygen in Si have been intensively carried out and the experimental data documented. Hydrogen is an exceptionally light element which is used indirectly to detect point defects, such as self-interstitials and vacancies in Si for example [5.43], through the LVM associated with hydrogen defect complexes. The detection limit of impurities by IRAS is $\approx 0.01\%$.

Raman Spectroscopy. Since Raman scattering is a two-photon process, the scattering signal is generally very weak, as mentioned in Sect. 5.1.3. Therefore, Raman scattering has so far rarely been used for studies of local vibrations associated with defects at low density. However, when resonant Raman scattering is used, the detection limit could be reduced down to several ppb under good conditions if the fluorescence or luminescence background is low. Figure 5.53 demonstrates the power of resonant Raman scattering, which enables detection of the LVM of As-related point defects in GaAs [5.44]. Generally, for LVM to be detected clearly by Raman scattering, the vibrational energy of the LVM must

Fig. 5.53 Defect-selective resonant Raman spectra of a low-temperature grown GaAs crystal measured at 200 K by using two different excitation lasers. The wavelength of the Nd:YAG laser (1064 nm) is resonant with the intra-center electronic excitation of the As-related EL2 centers. (Courtesy of Dr. A. Hida)

be well separated from those of the resonance modes (the local mode in resonance with the lattice phonon bands) which have relatively large intensities. The F-center (a neutral anion vacancy trapping an electron) in KI [5.45] is such an exceptional case in which the masses of potassium and iodine are so different that the gap between the acoustic and the optic bands is wide enough to accommodate the gap mode induced by defects.

Visible Photoabsorption and Photoluminescence (PL).

In contrast to IRAS and Raman scattering, photoabsorption and photoluminescence (PL) in the visible to near-infrared region are widely used for studies of defects in nonmetallic solids. If the sample yields strong PL, the sensitivity can be as high as ≈ 0.1 ppm. The spectrum of PL is complementary to the photoabsorption spectrum, with both representing electronic dipolar transitions. Defects in semiconductors and insulators often introduce electronic states in the band gap. The classic examples are color centers in alkali halides. When the electronic state is deep in the gap, the electronic wave function tends to be localized in space. In such cases, the electronic energy is sensitive to the local arrangement of atoms at the defect. This effect is referred to as strong electron lattice coupling, the degree of which is reflected in the optical transition spectra. Fig. 5.54a and b illustrate the situations by using con-

figuration coordinate diagrams: each curve indicates the (adiabatic) potential energy of the system, consisting of the electronic energy and the nuclear potential energy, drawn as a function of the nuclei positions in the system that are expressed by one-dimensional coordinate (configuration coordinate). The lower curves represent the adiabatic potentials for the electronically ground state while the upper curves the adiabatic potentials for an electronically excited state. The ladder bars indicate the vibrational states in each electronic state. If the electron–lattice coupling is weak (Fig. 5.54a), the stable configurations do not differ much between the ground state and the excited state. In this case, the optical transitions take place with spectra characterized by a sharp zero-phonon line reflecting transitions with no phonon involved, as shown in Fig. 5.54c. If the electron–lattice coupling is strong (Fig. 5.54b), the stable configurations differ considerably between the ground state and the excited state. The consequences are a broad bandwidth and a large Stokes shift (red shift) as shown in Fig. 5.54d.

Generally, the dipolar optical transition is not as efficient as competitive nonradiative processes, including Auger processes, multiphonon emission processes, and

thermally activated opening of different recombination channels. The last process is common in many systems, so samples for PL measurements must usually be cooled to a low temperature (≤ 20 K) to obtain a detectable PL intensity. The sample cooling is also beneficial for both photoabsorption and PL measurements to resolve the spectral fine structures.

Scanning electron microscopy using cathodoluminescence as the signal (SEM-CL) allows one to observe the distribution of radiative centers in semiconducting crystals. Figure 5.55 shows monochromatic SEM-CL images of semiconductor quantum dots [5.46] from which we can determine from where in the dots each luminescence arises. Similar images can be obtained by STEM equipped with a light collecting system. An advantage of STEM-CL is that one can also obtain crystallographic information about the defect.

Electron Paramagnetic Resonance (EPR). The second term $-2\mathbf{S}_e\mathbf{J}_e\mathbf{S}$ in (5.19) represents the spin–spin exchange interaction that is of fundamental importance in magnetic (ferromagnetic and antiferromagnetic) materials. In paramagnetic substances where the exchange

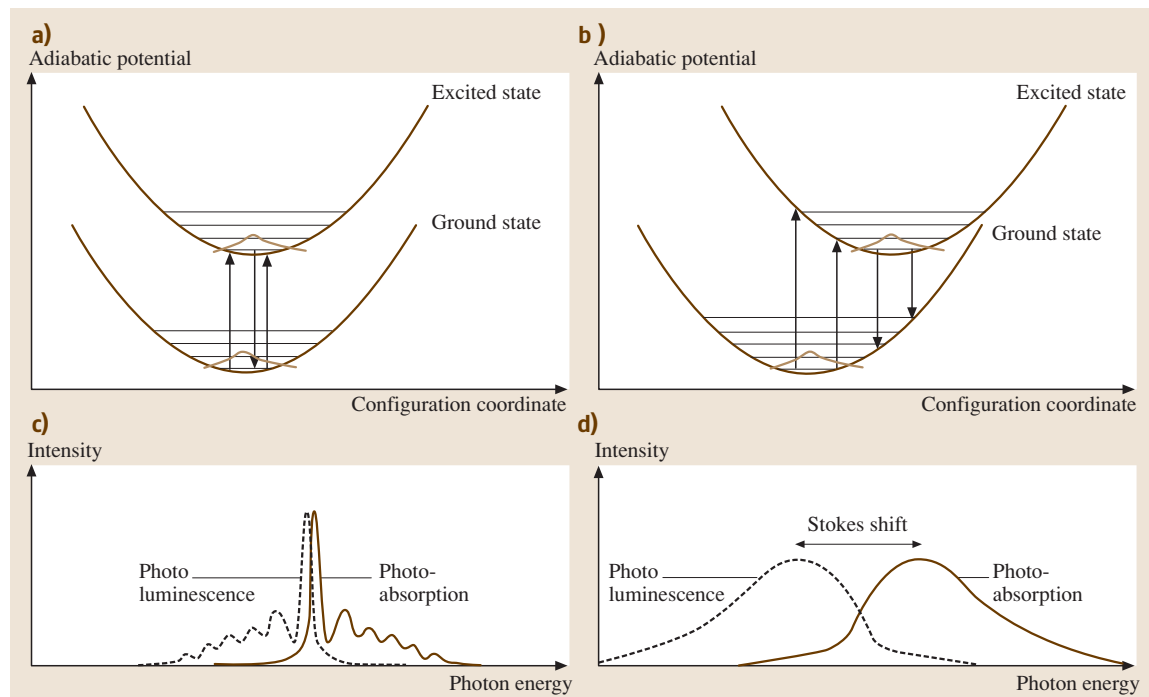

Fig. 5.54a–d Configuration coordinate diagrams and corresponding spectra of photoabsorption and photoluminescence (PL) for two cases in which electron–lattice coupling is weak (a),(c) and strong (b),(d). Note that the absorption and PL spectra are almost mirror symmetric, regardless of the electron–lattice coupling

interaction is absent, the effective spin Hamiltonian relevant to electron paramagnetic resonance (EPR) is

$$H = B_0 \gamma'_e S - \lambda^2 S \mathbf{A} S + S \mathbf{A} \mathbf{I}. \quad (5.32)$$

Here the term $-\lambda^2 S \mathbf{A} S$, though formally similar to $-2S \mathbf{J}_e S$, now represents the magnetic dipole interaction between electronic spin S and orbital momentum L (spin-orbit coupling) of magnitude $\lambda(L \cdot S)$. For the systems with $S = 1/2$ encountered in most cases, this term is absent. Still, however, the effective magnetogyric ratio $\gamma'_e \equiv \gamma_e(1 - \lambda \mathbf{A})$ is modified from that of an isolated electronic spin $\gamma_e = \mu_B g_e$ ($\mu_B \equiv e/2m_e c$: Bohr magneton) to

$$\gamma'_e \equiv \gamma_e(1 - \lambda \mathbf{A}) = \mu_B g_e(1 - \lambda \mathbf{A}) \equiv \mu_B g. \quad (5.33)$$

Since a static magnetic field B_0 induces a Zeeman splitting of unpaired electrons much larger than that of nuclear spins, a measurable microwave absorption is observed when the microwave frequency becomes resonant with the Larmor frequency. Unlike Fourier-transform NMR (Sect. 5.4.2), an EPR spectrum is measured by sweeping the external magnetic field applied to the sample placed in a microwave cavity resonant at a fixed frequency of ≈ 10 GHz. Usually the signal is detected by a magnetic field modulation technique so that the resonance field is accurately determined as the fields at which the signal crosses the zero base line (Fig. 5.56a).

The symmetry of the defect can be determined by the dependence of the electronic g -tensor or the corresponding resonance field on the direction of the crystallographic axis with respect to the direction of the external magnetic field. Some point defects in semiconductors form electronic levels in the band gap and could change their charge states according to the Fermi level. If the levels are degenerate with respect to the orbitals due to the point symmetry of the center, a symmetry-breaking lattice distortion (Jahn–Teller distortion) may occur depending on the charge state so as to lift the degeneracy and consequently lower the electronic energy. An historical example in which the EPR method shows its power is seen in structural determination of vacancies in Si in different charge states [5.47].

The chemical environment of the center or the lattice position of the defect can be identified from the knowledge of hyperfine structures arising from the last term $S \mathbf{A} \mathbf{I}$ in (5.32) that originates in the magnetic dipole–dipole interaction between the electronic spin and the nuclear spins over which the electron cloud is mostly distributed. Figure 5.56b illustrates how the hyperfine structure is brought about by the interaction of the

Fig. 5.55 Monochromatic SEM-CL images of semiconductor quantum dots and the CL spectrum [5.46]

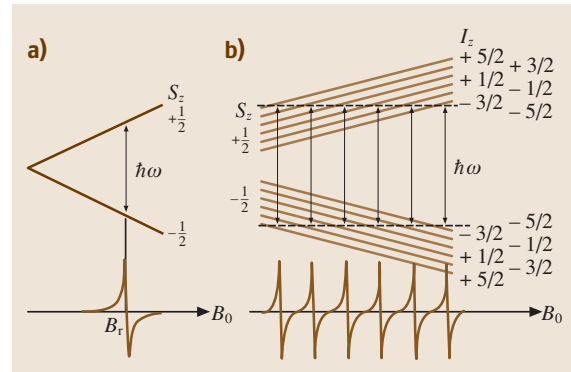

Fig. 5.56a,b Spin resonance of isolated electrons (a) and electrons interacting at the hyperfine level with a nucleus with $I = 5/2$ (b)

electron with a nucleus of $I = 5/2$. As a concrete example [5.48], we consider oxygen vacancies in ionic MgO crystals as shown in Fig. 5.57. The vacancy of the oxygen ion O^{-2} is double-positively charged and EPR insensitive because all the electrons are paired. But if it traps an electron and becomes single-positively charged, EPR signals arise from the unpaired $S = 1/2$ spin. Since no nucleus is present at the center of the

Fig. 5.57 Oxygen vacancy in MgO

vacancy, the hyperfine interaction is due only to the surrounding six equidistant Mg^{2+} ions. Among abundant isotopes, only the ^{25}Mg nucleus (10.11% abundance) has nonzero nuclear spin of $I = 5/2$. Therefore, the relative intensity of hyperfine signals is determined by the occupation probability of ^{25}Mg ions among the six Mg ion sites. For example, the probability that all the Mg sites are not occupied by ^{25}Mg ions is $(0.8989)^6 = 52\%$, so 52% of the vacancies should show no hyperfine splitting, as shown in Fig. 5.56a. Similarly the probability of finding one ^{25}Mg ion ($I = 5/2$) in the neighborhood is $6 \times (0.8989)^5 \times (0.1011) = 35.6\%$, so that 35.6% of vacancies should exhibit $(2I + 1) = 6$ hyperfine splitting signals, as illustrated in Fig. 5.56b following the selection rule in EPR $\Delta s_z = \pm 1$ and $\Delta I_z = 0$. The probability of finding two ^{25}Mg ions ($I = 5$) is $(6!/4!2!) \times (0.8989)^4 \times (0.1011)^2 = 10\%$, so that 10% of vacancies should exhibit $(2I + 1) = 11$ hyperfine splitting signals. The intensity of the hyperfine signals in this case differs depending on the degeneracy of the spin configurations: only one configuration $(5/2, 5/2)$ contributes to the $I_z = 5$ signal, two configurations, $(5/2, 3/2)$ and $(3/2, 5/2)$, to the $I_z = 4$ signal, three configurations, $(5/2, 1/2)$, $(3/2, 3/2)$ and $(1/2, 5/2)$, to the $I_z = 3$ signal, and so on, resulting in the relative intensity ratio $1 : 2 : 3 : 4 : 5 : 6 : 5 : 4 : 3 : 2 : 1$, which is verified experimentally.

The electron–nuclear interaction represented by the term \mathbf{SAI} in (5.32) can be extended to include indirect interactions $\sum_k \mathbf{SA}_k \mathbf{I}_k$ with nuclei k beyond the nearest neighbors, giving rise to the super-hyperfine structures around each hyperfine signals. One major drawback of EPR spectroscopy is the low resolution ($\Delta\nu \approx 10 \text{ MHz}$) compared to NMR ($\Delta\nu \approx 50 \text{ kHz}$), which is a disadvantage in the analysis of crowded or overlapped signals. Due to the electron–nuclear interaction, the EPR intensity of each super-hyperfine structure changes when nuclear magnetic resonance oc-

Fig. 5.58 Electron nuclear double resonance (ENDOR) in $I = 1/2$ nuclei

curs in the nucleus responsible for the super-hyperfine EPR signal (Fig. 5.58). This EPR-detected NMR spectroscopy is called electron nuclear double resonance (ENDOR) [5.49] which also improves the low sensitivity of conventional NMR [5.50]. ENDOR is used to investigate the spatial extent of the electron cloud probed by EPR.

In semiconductors, unpaired spins as sparse as 10^{14} to 10^{16} cm^{-3} can be detected by EPR provided that the density of free carriers is below 10^{18} cm^{-3} so that the microwave can penetrate the sample well. In metals, the presence of free electrons limits the penetration depth below the sample surface due to the skin effect. It should be stressed that EPR signals can be detected only when *unpaired* electrons are present.

Optically Detected Magnetic Resonance (ODMR).

Optically detected magnetic resonance (ODMR) is applicable to studies of electronic states in which a magnetic field lifts the degeneracy of energy levels differing only in magnetic spin. ODMR is a double resonance technique that allows highly sensitive EPR measurements and facilitates the assignment of the spin state responsible for the magnetic resonance. The most common experimental schemes are either detecting circular polarized photoluminescence (PL) or magnetic circular dichroic absorption (MCDA) in response to magnetic resonance. Figure 5.59 illustrates a simple case in which the ground state and an excited state are spin degenerate in the absence of a magnetic field. When a static magnetic field is applied, these states are split to Zeeman levels. Due to the selection rule, optical transitions (PL and photoabsorption) occur either between the excited down-spin state and the ground up-spin state with a right-hand circular polarization (σ^+), or between the excited up-spin state

Fig. 5.59 (a) Magnetic circular polarized emission (MCPE) and (b) Magnetic circular dichroic absorption (MCDA)

and the ground down-spin state with a left-hand circular polarization (σ^-). In the relaxed excited state in which the occupancy of the up-spin level is higher than that of the down-spin level, the σ^- PL is stronger in intensity than σ^+ PL. However, if we apply an electromagnetic field in resonance with a spin flip transition between the excited Zeeman levels, the occupancy of the down-spin excited state becomes somewhat increased, which is detected by an increase of the σ^+ emission at the expense of the σ^- emission. Thus, the PL-detected magnetic resonance or magnetic circular polarized emission (MCPE) measurements (Fig. 5.59a) allow the detection of EPR in the electronically relaxed excited state. MCPE is also possible when the nonradiative recombination is spin-dependent. An example is found in studies of dangling bonds in amorphous Si : H solids [5.51] and of relaxed excited state of F-centers in alkali halides [5.49]. MCPE can be more sensitive than ordinary EPR as long as the PL intensity is high. However, the concentration of the centers studied successfully by MCPE is limited by the concentration quenching effect, a decrease of PL intensity due to an energy transfer mechanism (cross relaxation) starting to operate between nearby centers in close proximity (Sect. 5.4.3).

Similarly, ODMR based on magnetic circular dichroic absorption (MCDA) shown in Fig. 5.59b facilitates the assignment of the ground state spin. MCDA has

advantages over MCPE in its applicability to nonluminescent samples. Other signals used in ODMR include such spin-dependent quantities as spin-flip Raman scattering light, resonant changes of electric current affected by the spin state of the defect centers that determines the carrier lifetime. Especially the last electrically detected magnetic resonance (EDMR) technique allows one to detect selectively a very few paramagnetic centers that are located along the narrow current path [5.7].

Muon Spin Rotation (μ^+ SR). A muon is a mesonic particle which is created during the decay of a π -meson generated by a high energy particle accelerator. The muon is a Fermion having spin 1/2, whose mass is 207 times the electron mass. There are two types of muon, μ^+ and μ^- , differing in the electric charge $+e$ and $-e$, respectively. The muon disintegrates to an electron (or positron) and two neutrinos in a mean lifetime of $\approx 2 \mu\text{s}$ emitting a γ -ray with a characteristic angular distribution relative to the spin direction, as shown in Fig. 5.60a. Therefore, the rotation of spins under a static magnetic field during the lifetime can be observed as a signal oscillating at the Larmor frequency detected by a γ -ray counter placed in an appropriate direction (Fig. 5.60b). Since the negatively charged μ^- are strongly attracted to nuclear ions, they behave as if forming a nucleus of atomic number $Z-1$. In contrast, since the positively charged μ^+ are repelled by nuclear ions in solids, they migrate along interstitial sites or become trapped at vacancies, behaving like a light “isotope” of protons. In ferromagnetic solids, μ^+ feel an internal magnetic field specific to the site on which the μ^+ spend their lifetime. This provides a means to detect the diffusion

Fig. 5.60 (a) Directional emission of γ -rays from μ^+ spin and (b) a setup of μ^+ SR experiments

of vacancies introduced by irradiation with high energy particles [5.52]. At low temperatures, the diffusion of μ^+ along interstitial sites is so slow that they exhibit a characteristic rotation frequency corresponding to the internal magnetic field at the interstitial site. As the temperature increases, however, μ^+ become mobile, and once trapped by a vacancy, show a different rotation frequency. At temperatures where the vacancies are annihilated, the signal then disappears again. Thus, detecting the change of the μ^+ SR signal with temperature, one could study the recovery process of point defects.

Perturbed Angular Correlation (PAC). Some radioactive nuclei such as ^{111}Ag and ^{111}In emit two γ -rays (or particles) successively in the nuclear transformation process (Fig. 5.61a). If the lifetime of the intermediate state is short ($< \text{hundreds ns}$), there exists an angular correlation between the two rays. In the absence of external fields such as a magnetic field and an electric field gradient, the direction of the second γ -ray is oriented principally in the direction of the nuclear spin at the time of the first γ -ray emission. As illustrated in Fig. 5.61b,

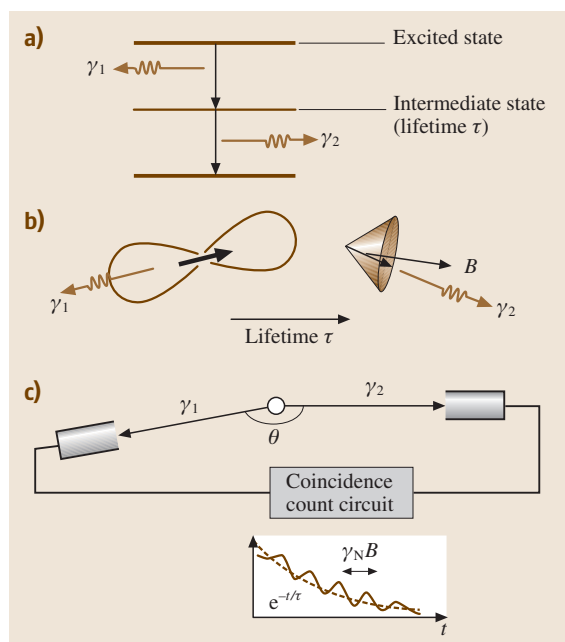

Fig. 5.61a–c In perturbed angular correlation (PAC) experiments, each direction of two γ -rays successively emitted (a) indicates the direction of the intermediate nuclear spin, which may rotate under an internal magnetic field (b). The spin rotation during the lifetime is detected by coincident count electronics (c)

when an external field is present as a perturbation and if the intermediate nuclei have a magnetic moment, the spins rotate during the intermediate lifetime. This is detected as a signal oscillating at the Larmor frequency by a counter for the second γ -rays emitted in coincidence with the first ones (Fig. 5.61c). This perturbed angular correlation (PAC) method allows one to study the recovery process of point defects in a manner similar to μ^+ SR.

Solid-State NMR. A famous example of applications of NMR spectroscopy to solids is the measurement of the diffusion rate of atoms. Nuclei feel a local magnetic field of various origins (Sect. 5.4.2) other than a large external magnetic field. The fluctuations of the local magnetic field due to the motion of nuclei in solids gives rise to lateral alternating fields with a frequency component that causes resonant transitions between Zeeman levels. This fluctuation-induced transition results in an energy relaxation of the spin system and shortening of the spin-lattice relaxation time T_1 . The reduction of T_1 occurs most efficiently when the correlation time of fluctuations τ satisfies $\omega_L \tau \approx 1$, where ω_L denotes the Larmor frequency. The fluctuation time constant τ represents the time constant of atomic jumps and therefore depends on temperature if the atomic jumps are thermally activated. So, if one measures T_1 as a function of temperature, one finds that T_1 becomes minimum at a certain temperature Θ_{\min} . Since ω_L can be varied by changing the external magnetic field, the activation energy and the frequency prefactor of atomic jumps could be evaluated from an Arrhenius plot of $\omega_L (= \tau^{-1})$ versus Θ_{\min} obtained for various magnetic fields. In ordinary measurements, however, the jump rate τ^{-1} is limited to the narrow range of Larmor frequencies $\omega_L \approx 10^6 - 10^8 \text{ s}^{-1}$. Experimentally this range can be expanded down to 1 s^{-1} by employing the rotating field method [5.53] in which the effective field is given by a rotating magnetic field with a small amplitude which is resonant with the Larmor frequency. The range of the jump rate τ^{-1} covered by such NMR measurements may be further reduced to $10^{-3} - 10^{-2} \text{ s}^{-1}$ in ionic crystals due to the absence of the free electrons that would induce additional relaxation in metals limiting the correct measurement of T_1 .

Positron Annihilation Spectroscopy (PAS). The positron is the antiparticle of the electron with the same mass as the electron but an electric charge of $+e$ [5.54, 55]. Positrons are created as a decay product of some radioactive isotopes such as ^{22}Na , ^{58}Co and ^{64}Cu . For the case

of the parent nucleus being ^{22}Na shown in Fig. 5.62, a positron e^+ is emitted from the source with an energy of hundreds of keV on the β^+ decay of the ^{22}Na to an intermediate nucleus of $^{22}\text{Ne}^*$ (* indicates that the nucleus is in an excited state). The unstable $^{22}\text{Ne}^*$ immediately, within 0.3 ps, relaxes to the stable ^{22}Ne by emitting a γ -ray of 1.28 MeV in energy. The generated positron, if injected into a solid, loses its energy rapidly within ≈ 1 ps by inelastic collision with the lattice (thermalization), and after some duration (100–500 ps) is annihilated with an electron in the solid. On this positron annihilation, two γ -rays of 0.511 MeV are emitted in almost opposite directions.

Among various schemes of positron annihilation spectroscopy (PAS), the simplest is the positron lifetime measurement. The lifetime can be measured as the time difference between the emission of the 1.28 MeV γ -ray, that indicates the time of the introduction of a thermalized positron into the sample, and the emission of the 0.511 MeV γ -rays that indicates the occurrence of an annihilation event. The positron lifetime reflects the density of the electrons with which they are annihilated. Since e^+ is positively charged, if the crystalline sample contains no imperfections, they migrate along interstitial sites until they are annihilated with electrons along the diffusion path. However, if the crystal contains vacant defects (vacancies, microvoids, dislocation cores etc.), the positrons are trapped by them because the missing ions form an attractive potential for positrons. Once the positron is trapped at a vacant site, it has less chance of being annihilated with an electron and as a result the lifetime is elongated significantly. Figure 5.63 shows the positron lifetime calculated for multiple vacancies of various sizes. From comparison of the experimental value of positron lifetime with the theoretical predictions, one can reliably infer the number of vacancies if it is smaller than ≈ 10 . When vacancies of different sizes coexist in the sample, the positron lifetime has a spectrum consisting of different components each rep-

Hasegawa

resenting one type of the site where they are annihilated. A successful example of positron lifetime spectroscopy is its application to measurements of thermal vacancy concentration as a function of temperature [5.62]. When the sample contains only monovacancies, the component with long lifetime increases proportionally with the increasing vacancy concentration, as long as the vacancies are not saturated with positrons. Owing to the preferential trapping of positrons to vacancies, the detection limit of vacancy concentrations is enhanced by 2–3 orders of magnitude compared to the dilatometric method [5.63]. Since PAS experiments can be conducted irrespective of sample temperature, the vacancy concentration can be measured in thermal equilibrium, which is an advantage over the resistometric techniques that need sample quenching from various annealing temperatures.

The directions of the two γ -rays emitted on positron annihilation are not completely opposite due to the fact that the electrons to be annihilated have a finite momentum whereas the momentum of thermalized positrons is negligible: the larger the electron momentum, the larger the correlation angle (Similarly, the energy of γ -rays emitted on positron annihilation reflects the kinetic energy of the electrons through a Doppler effect. The Doppler shift measurements provide information similar

to that given by the γ - γ angular correlation. The coincident Doppler broadening technique is found to be useful for the identification of impurities bound to vacancy defects [5.64]). Figure 5.64 illustrates a schematic γ - γ angular correlation curve which consists of a parabolic component, which arises from annihilation with conduction electrons whose momentum is relatively small, and a Gaussian component, which is due to annihilation with core electrons whose momentum extends to larger values. The potential felt by conduction electrons at vacancy sites is shallower and the electron momentum is smaller than the perfect sites. So, if the positrons are trapped by vacancy-type defects, the parabolic component becomes sharper and increases its intensity at the expense of the core component. Various line shape parameters have been proposed to quantify this curve shape change and used to investigate, for example, the agglomeration of vacancies in electron-irradiated crystal upon isochronal annealing [5.65]. Nowadays, γ - γ angular correlation experiments are conducted in two-dimensions by using two position-sensitive detectors in a coincidence arrangement. The 2D-angular correlation of annihilation radiation (2D-ACAR) is a modern method that allows one to investigate nanosize crystalline phases such as G-P zones enriched with transition metals in noble metals such as Cu and Ag [5.66].

The detection limit of vacancies by PAS is usually around 10^{-6} in metals. In semiconducting materials, it may be enhanced by two orders of magnitude at low temperatures when the vacancies are negatively charged. Since the positrons initially emitted from the positron source (e.g., ^{22}Na) have an energy of the order of hundreds of keV, they can penetrate deep into the sample

Fig. 5.64 Setup of γ - γ angular correlation experiments and a schematic correlation spectrum

(≈ 1 mm in Si, ≈ 0.2 mm in Fe), so the thickness of the samples must be of the order of 1 mm. The use of slow positron beams, with energy ranging between a few eV and several tens of keV, enables one to study the depth profile of point defects, a problem of particular importance in semiconductor device technology.

Mössbauer Spectroscopy. The Mössbauer spectroscopy is based on the recoil-less radiation and absorption of γ -rays by Mössbauer nuclei embedded in solids with an extremely narrow natural width ($\approx 5 \times 10^{-9}$ eV). Semi-classically, the conservation of the momentum and the energy of the emitted (or absorbed) γ -ray and the solid suspending the nucleus requires that a part of the γ -ray energy

$$E_R = \frac{E_\gamma^2}{2Mc^2} \quad (5.34)$$

must be transferred to the nucleus as a recoil energy. Here E_γ is the energy of the γ -ray, M the nuclear mass, and c the light velocity. Quantum mechanically, however, the motion of nuclei is quantized in the form of phonons, so if $E_R < \hbar\Omega$ (phonon energy), the emission and absorption of γ -rays occurs free of recoil. The condition for this recoil-less radiation and absorption is $k_B\theta_D > E_\gamma^2/Mc^2$, where k_B is the Boltzmann constant, and θ_D the Debye temperature of the crystal. The most common combination of an emitter and an absorber satisfying this condition is Co (half life = 270 d) and ^{57}Fe (natural abundance = 2.17%) between which 14.413 keV γ -rays are transferred.

Figure 5.65 shows a typical setup for Mössbauer experiments. The γ -ray source (e.g., ^{57}Co) is mounted on a stage that can be moved with various velocities (0 to \pm several mm/s) so as to change the γ -ray energy by the Doppler effect. A sample containing the γ -ray absorber (^{57}Fe for ^{57}Co source) is irradiated with the γ -rays and the absorbance is measured by a γ -ray detector as a function of the γ -ray energy. Although the experiments are

Fig. 5.65 Experimental setup for Mössbauer spectroscopy

applicable only to limited stable isotopes (^{40}K , ^{57}Fe , ^{61}Ni , ^{67}Zn , ^{73}Ge , ^{119}Sn , ^{121}Sb , ^{184}W) Mößbauer spectroscopy places no severe restrictions on the temperature and the environment of the samples, other than that the sample thickness should be in the range 2–50 μm depending on the concentration of the absorber.

The degeneracy of the states of a nucleus in a solid is lifted under the influence of the local environment. For absorber nuclei having a nuclear spin, the internal magnetic field, if present, can be evaluated by measuring the nuclear Zeeman splitting, which is more than one order of magnitude larger than the natural width of the γ -rays. This provides a good probe of ferromagnetic phases, which is demonstrated for the case of quenched iron steel ([5.67]) in Fig. 5.66. For absorber nuclei having a quadrupole moment ($I > 1/2$), the Mößbauer spectroscopy allows one to assess the electric field gradient at the nuclei by measuring the quadrupole splitting. This can be applied to the detection of symmetry breaking of crystal field by the presence of point defects in the vicinity of the absorber nuclei. Since the thermal motion of absorber nuclei causes a Doppler shift, a careful analysis of the spectral line shape gives us information on the lattice vibrations that may be affected by lattice defects.

Deep-Level Transient Spectroscopy (DLTS). Point defects in semiconductors often form deep levels in the band gap. Deep-level transient spectroscopy (DLTS) allows quantitative measurements of the density and the position of the gap levels with respect to the relevant band edge. The charge state of deep-level centers can be changed by various means such as impurity doping,

electronic excitations, and carrier injection. The thermal occupation of a deep level, once disturbed by some means, is recovered by a thermally activated release of the carriers trapped at the centers by the disturbance. The recovery rate is determined by the depth of the electronic level from the relevant band edge (the conduction band edge for electron traps or the valence band edge for hole traps). In standard DLTS experiments, the objects to be measured are deep-level centers located in the depletion layer beneath a metal–semiconductor contact fabricated on the sample surface. The change of the electronic occupancy of the centers is detected by the change of the electrostatic capacitance associated with the contact, and the electronic disturbance is caused by carrier injection through the contact or photocarrier generation. From the temperature dependence of the rate of capacitance recovery, we can evaluate the energy depth of the gap level, and from the amount of recovery, we can measure the density of the center. An advantage of DLTS over optical spectroscopic methods is that, from the sign of the capacitance change, we can determine which carriers (electrons or holes) are transferred between the gap level and the related band, and therefore can definitely know from which band edge the level depth is measured. The capacitance spectroscopic methods including DLTS have a sensitivity as high as $\approx 10^{14} \text{ cm}^{-3}$ in moderately doped samples.

5.3.2 Extended Defects

For extended defects, most diffraction methods are coupled with microscopic methods based on crystal diffraction. Also, spectroscopic methods are not specific to extended defects, other than that the number of the “centers” in extended defects to be studied is generally too small unless the sample is prepared by intentionally introducing the defects at a high density. The description in this subsection, therefore, is limited to microscopic methods.

Chemical Etching

A simple method for direct observation of extended defects is chemically etching the sample surface to reveal the defects as etch pits, hillocks, and grooves that develop according to the difference in the chemical reactivity at the defect sites. Figure 5.67 demonstrates an example of such etching patterns observed by optical microscopy on a chemically etched surface of a plastically deformed CdTe crystal. The left diagram shows the traces of the pits positions tracked by successive removal of the surface. The linear nature of the traces proves that these defects are dislocations. The chemical etching

Fig. 5.66 Mößbauer spectra of iron-4.2% carbon martensite (dots A) and of pure α -iron (broken line B). The central peak is due to the presence of paramagnetic austenite phase [5.67]

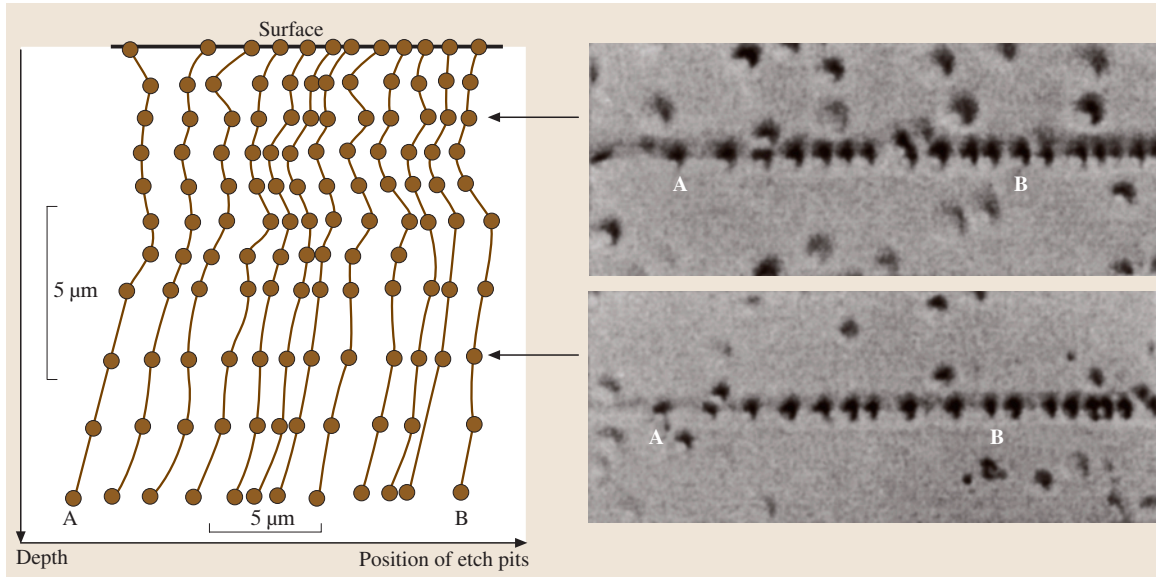

Fig. 5.67 Optical microscopic images of dislocation etch pits revealed on a plastically deformed CdTe surface by wet chemical etching [5.68]

method is also applicable to planar defects, such as grain boundaries and stacking faults that intersect the surface. The resolution may be enhanced by the use of SEM-SE if etching is stopped before etching patterns overlap.

Transmission Electron Microscopy (TEM)

Dislocations. Among extended defects, dislocations are the most common objects, for which TEM displays its full capability. A standard scheme for observations of dislocations is to employ a two-beam condition in which the sample crystal is tilted in such orientations that only one diffraction g is strongly excited, as shown schematically in Fig. 5.68. For plan-view imaging an edge dislocation lying nearly in parallel to the sample surface (Fig. 5.69a), we tilt the sample to the direction parallel to the Burgers vector b so as to bring the sample to a two-beam condition. Then, we tilt the sample slightly further away from the Bragg condition, so that we allow lattice planes *only near* the dislocation to satisfy the Bragg condition. In this configuration, the primary (direct) beam is diffracted strongly near the dislocation, and as a result, if we are looking at the bright field image, the dislocations are observed as dark lines as shown in Fig. 5.70. For screw dislocations (Fig. 5.69c), since the lattice planes normal to the dislocation line and hence the Burgers vector b are inclined near the core, the plan-view dislocation contrast arises from the same mechanism. Thus, regardless of whether disloca-

Fig. 5.68 Two-beam diffraction condition; s denotes the deviation from the Bragg condition

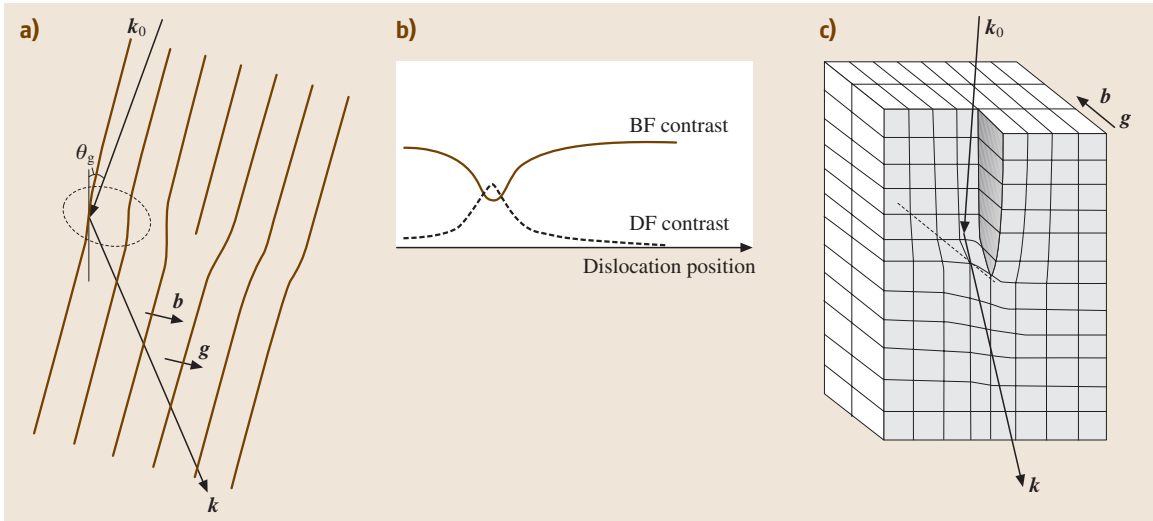

Fig. 5.69a–c Imaging dislocations (a) edge, (c) screw under two-beam conditions. The diffraction is locally enhanced at a position near the dislocation core where the lattice planes are tilted so that the Bragg condition is locally satisfied. The Burgers vector can be determined by the invisibility criterion ($\mathbf{g} \cdot \mathbf{b} = 0$)

Fig. 5.70 TEM image of dislocations in plastically deformed 6H–SiC

tions are of edge or screw type, the dislocation contrasts are obtained when $(\mathbf{g} \cdot \mathbf{b}) \neq 0$. In other words, when

$$(\mathbf{g} \cdot \mathbf{b}) = 0 \quad (5.35)$$

the dislocation contrasts diminish, as demonstrated in Fig. 5.71. More precisely, dislocations are not necessarily invisible even if $(\mathbf{g} \cdot \mathbf{b}) = 0$ when $(\mathbf{g} \cdot \mathbf{b} \times \mathbf{u}) = 0$, where \mathbf{u} denotes the unit vector parallel to the dislocation line. Examining this invisibility criterion for various \mathbf{g} vectors, one can determine the direction of the Burgers vector. It should be noted that, for determination of the sense and the magnitude of the Burgers vector, we need some additional information [5.14].

Fig. 5.71 TEM images of dislocation lines in Mo acquired for two different diffraction conditions. The invisibility criterion is used to determine the Burgers vector [5.69]

When the dislocations are dissociated into partial dislocations separated by a narrow stacking fault, imaging in the normal two-beam condition is enough neither to resolve each partial dislocation nor give the correct position of the cores. In such cases, the weak-beam dark-field method is useful for imaging dislocation lines with a width of ≈ 1.5 nm and a positional deviation of only ≈ 1 nm from the real core. Figure 5.72 demonstrates a weak-beam image of dissociated dislocations in a CoSi_2 single crystal.

Fig. 5.72 A weak-beam TEM image of dissociated dislocations in CoSi_2 (Courtesy of M. Ichihara)

High-resolution transmission electron microscopy (HRTEM) is applicable to imaging edge dislocations. As explained in Sect. 5.1.2, under an appropriate (Scherzer) defocus condition, HRTEM images approximately represent the arrangement of atomic rows viewed along the beam direction. Figure 5.73a shows an HRTEM lattice image of an end-on edge dislocation penetrating a ZnO sample film. The presence of the dislocation can be recognized by tracing a Burgers circuit drawn around the dislocation core. One should note that the HRTEM is not

applicable to imaging screw dislocations, because screw dislocations would not be visible as such a topological defect in the end-on configuration. A modern HRTEM technique has been shown to be able to visualize the strain field around a single dislocation [5.70].

Planar Defects. There are many types of planar defects, stacking faults, antiphase boundaries, inversion domain boundaries, twin boundaries, grain boundaries, and phase boundaries, each of which is characterized

Fig. 5.73 (a) HREM image of an edge dislocation in ZnO (b) the diffraction spots encircled were used for HREM imaging (Courtesy of M. Ichihara)

by a translation vector \mathbf{R} , a crystal rotation, lattice misfit and so on by which the crystal on one side of the boundaries is displaced relative to the other. In this subsection, we confine ourselves mainly to stacking faults (SFs), representative planar defects in crystals, which are characterized by only a constant translation vector \mathbf{R} .

As mentioned in Sect. 5.1.2, the dynamical theory in perfect crystals under two-beam conditions may be extended to imperfect crystals by introducing an additional phase shift

$$\alpha = 2\pi \mathbf{g} \cdot \mathbf{R} \quad (5.36)$$

into the arguments. Here $\mathbf{R}(\mathbf{r})$ is the displacement of atoms from the perfect positions \mathbf{r} due to the presence of the defects. Therefore, quite generally, if $\alpha = 0$, there arises no TEM contrast of the defects. Also as mentioned in Sect. 5.1.2, the Pendellösung effect is a consequence of beating between the two Bloch waves excited on the two dispersion branches. Arriving at a planar defect, the two Bloch waves each generates two other Bloch waves with a phase shift interfering with the other. A detailed analysis (see for example [5.15, p.381]) shows that fringe contrasts as illustrated in Fig. 5.74 should be observed by TEM with a period that is half of the thickness (Pendellösung) fringe expected for a wedge-shaped sample of the upper part of the crystal above the SF plane.

Stacking faults are grouped into two types, intrinsic SFs, which are formed by interplanar slips of lattice planes with a translation vector (\neq lattice periodicity) parallel to the SF planes or by coalescence of vacancies with a translation vector normal to the SF planes, and extrinsic stacking faults, which are formed by coales-

Fig. 5.74 TEM fringe contrasts of a stacking fault when absorption is neglected. The period is half that expected from the thickness fringe. The contrast is reversed in X-ray topography

cence of self-interstitial atoms with a translation vector normal to the SF planes. All types of SFs, if closed in a crystal, are bounded by a loop of partial dislocation. In fcc crystals, the so-called sessile (unable to glide) Frank partial dislocations bounding the vacancy-type and the interstitial-type SFs have Burgers vectors, \mathbf{R} , of $\pm 1/3[111]$ equal in magnitude but opposite in direction, while the so-called glissile Shockley partial dislocations bounding the other type of intrinsic SFs have a Burgers vector, \mathbf{R} , of $1/6[11\bar{2}]$. The invisibility criterion is, therefore, different for the Shockley-bounded SFs and the others. To determine experimentally whether the SFs are interstitial loops or vacancy loops and the sense of inclination of SF planes in the sample, the inside–outside contrast method illustrated in Fig. 5.75 is used [5.15, p.410]. The same method is also useful for determining the sense of the Burgers vectors of general dislocations. Figure 5.76 shows a TEM image of intrinsic stacking faults in a 6H–SiC crystal in which the formation energy of SF is so low that wide SFs are observed after plastic deformation.

Fig. 5.75 Inside–outside contrast method for distinguishing interstitial- (upper) and vacancy-type (lower) stacking faults

Fig. 5.76 TEM image of intrinsic stacking faults bounded by Shockley partial dislocations (PD₁ and PD₂). The sample is a plastically deformed 6H-SiC single crystal

Small-angle grain boundaries are imaged by TEM as a densely arrayed dislocations. In some cases, grain boundaries are visible as Moiré patterns of two overlapping crystals. Modern TEM studies of planar defects, however, are often conducted by imaging end-on the defects by HRTEM. Recently, for example, cross-sectional HRTEM imaging of epitaxial thin films (a kind of phase boundaries) has become a standard routine in assessment of these materials. Cross-sectional HRTEM not only presents straightforward pictures for nonspecialists but also provides quantitative information that cannot be collected with conventional TEM. In particular,

atomic arrangements at grain boundaries can be directly deduced by comparing end-on HRTEM images and simulations. The density of stacking faults can be evaluated by cross-sectional HRTEM even if the density is too high for plan-view observations to be possible.

X-Ray Topography (XRT)

Dislocations and stacking faults are observable also by X-ray topography (XRT) based on essentially the same principle in TEM, although there is some difference due to differences in the “optical” constants between electrons and X-rays. Roughly speaking, XRT images correspond to dark-field images in TEM. Figure 5.77 shows a transmission XRT image of dislocations in a Si ingot crystal introduced in the seeding process. Here the dislocations are imaged as white contrasts. The important parameter to be considered in interpretation of XRT images is the product μt , where t is the sample thickness and μ is the absorption coefficient. If $\mu t \gg 1$, we need the dynamical theory to understand images correctly, but if μt is of the order of unity or less, the kinematical theory is sufficient, which is the case in Fig. 5.77 ($\mu t \approx 1$ for $t = 0.6$ mm). The mechanism of white dislocation contrasts in Fig. 5.77 is essentially the same as that of dark contrasts in TEM bright-filled images due to the kinematical effect that the diffraction beam is directly reflected from the close vicinity of the dislocation cores where the Bragg condition is locally satisfied. Figure 5.78 shows another transmission XRT image of dislocations now in a plastically deformed GaAs crystal. In this case, the dislocations are imaged as dark contrasts. Though the sample thickness is 0.5 mm, even smaller

Fig. 5.77 A transmission X-ray-topographic image of dislocations in a Si ingot crystal introduced in the seeding process. The sample thickness is 0.6 mm. (Courtesy of Dr. I. Yonenaga)

Fig. 5.78 An anomalous transmission X-ray topographic image of dislocations in GaAs introduced by plastic deformation. The sample thickness is 0.5 mm (Courtesy of Dr. I. Yonenaga)

than the case of Fig. 5.77, the absorption coefficient is much larger and as a result $\mu t \approx 10$. The anomalous transparency despite the large μt is owing to a dynamical effect (Borrmann effect), the anomalous transmission of the channeling Bloch wave. Although the quantitative interpretation of the image needs the dynamical theory, the origin of the dark dislocation contrasts in this case is the loss of crystallinity in the severely deformed regions that results in the reduction of the diffraction intensity.

Scanning Electron Microscopy in Cathodoluminescence Mode (SEM-CL)

Dislocations in semiconductors in many cases act as efficient nonradiative recombination centers. In such cases, they are observed as dark spots or lines in SEM-CL images when the matrix emits luminescence. Figure 5.79 shows an SEM-CL image of an indented CdTe surface and an OM image of the same area the surface of which was chemically etched to reveal dislocations after the SEM-CL image was acquired. In some exceptional cases, the dislocations themselves emit light which gives rise to bright contrasts. TV scanning allows one to observe in situ the dynamical motion of dislocations. Similar images may be obtained by using OM if the defect density is sufficiently low.

Fig. 5.79a,b Dislocation contrasts observed in an indented CdTe surface. (a) SEM-CL image showing dislocations in dark contrast and (b) OM image showing dislocation etch pits developed after (a) was recorded

X-Ray Diffraction Analysis of Planar Defects

The density of planar defect such as stacking faults can be assessed by quantitative analysis of the X-ray diffraction profile with proper corrections for instrumental and particle size broadening. The presence of planar defects introduces phase shifts of scattering waves resulting in diffraction peak broadening and peak shifts along the direction normal to the defect planes. Analogously to the effect of finite crystal size on diffraction, the peak broadening width is inversely proportional to the mean distance between adjacent fault planes. Unlike the size effect, however, the effects are different depending on the nature of the defects. The peak broadening is symmetric in stacking faults but asymmetric in twin boundaries. The peak shift is absent for some types of stacking faults but is induced in directions that depend on the types of stacking faults in other cases. The analytical detail may be found in a comprehensive textbook by Snyder et al. [5.71].

Mechanical Spectroscopy

Internal friction (Sects. 5.1.3 and 5.3.1) provides a sensitive tool to study the motion of dislocations at very low stresses. A typical application is to elementary processes of dislocation motion in metals and ionic crystals. Dislocation pinning is applied to detect the migration of defects and impurities.

Recoverable atomic motion in grain boundaries can be studied by means of mechanical spectroscopy (Sect. 5.1.3), e.g., the anelastic relaxation of grain boundaries is observed above room temperature in coarse-grained fcc metals but below room temperature in nanocrystalline fcc metals.

5.4 Molecular Architecture Analysis

The materials in the scope of this section include simple molecules, polymers, macromolecules (super-molecules) as well as biomolecules such as proteins. The rapidly advancing techniques relating to DNA analysis are out of the scope of this section. Molecules on large scales can have higher-order structures that perform important functions, especially in biopolymers. The primary structure of proteins, for example, is a sequence of amino acids (peptide) that constitutes secondary structures in forms such as helices and sheets. The secondary structures linked in a protein are usually folded to tertiary structures that may further become associated to a quaternal structure that brings about such bioactivity as allosteric effects. This section addresses mainly nuclear magnetic resonance (NMR) in considerable detail for its unique power in the analysis of the architecture of macromolecules. Although single crystal X-ray diffraction is another important technique for structural determination of macromolecules, we only briefly mention some points specific to macromolecular samples. The large molecules may be pretreated by chromatographic techniques to separate or decompose them into constituents or smaller fragments that can be analyzed by simpler methods. After the pre-processing, the molecules or the fragments may be subjected to standard analysis such as FT-IR, Raman scattering, and fluorescence spectroscopy for identification of the constituent bases, as described in other sections (Sects. 5.1.3 and 5.2.3). In this section, we mention only optical techniques based on the circular dichroism exhibited by helix molecules and the fluorescence resonant energy transfer (FRET) that provides information on the proximity of two stained molecules.

5.4.1 Structural Determination by X-Ray Diffraction

The principle of structural analysis by X-ray diffraction in macromolecules is essentially the same as that of single crystal diffraction and powder diffraction already described in Sect. 5.1.1. For the growth of molecular crystals, the synthesis of the material molecules is necessary. Thanks to progress in genetic engineering such as the advent of the polymerase chain reaction (PCR) technique, even large biomolecules such as proteins can be synthesized in sufficient amounts. However, macromolecules and polymers tend to be condensed to amorphous or very disordered aggregates (Sect. 5.2.2);

the growth of single crystals at high quality is generally difficult for such materials. The direct method is applicable only to molecules of 100 or fewer atoms because, as molecular size increases, the ambiguity in phase determination rapidly increases. The heavy atoms substitution method works for molecules larger than 600 atoms. So a gap is present for molecules in the intermediate size range. In principle, as long as a good single crystal sample is obtained, there is no limitation on the molecular size. The maximum size so far achieved by making full use of up-to-date methods is as large as that of ribosome (4×10^6 in molecular weight), though normally, the maximum size subject to routine analysis is $\approx 10^4$ in molecular weight. The powder diffraction technique is also applicable to large molecules, but the accuracy is limited due to the difficulty in separation of diffraction peaks, which are more crowded than from small molecules. The maximum molecular size is several thousands of atoms. For more details on X-ray structural analysis of macromolecules, see [5.72].

5.4.2 Nuclear Magnetic Resonance (NMR) Analysis

Standard structural analysis by NMR proceeds following (1) sample preparation, (2) NMR spectra measurements, (3) spectral analysis to assign NMR signals to the responsible nuclei and find the connectivity of the nuclei through bonds and space, (conventionally the term “signals” is used rather than “peaks” because NMR resonances are not always observed as peaks.) and finally (4) the deduction of structural models using the knowledge obtained in (3) as well as information from other chemical analyses as a constraint in the procedure of fitting model to experiment. The final step (4) is like forming a chain of metal rings of various shapes (e.g., amino acid residues in proteins) on a frame having knots in some places linked to others on the chain. For this reason, particularly for macromolecules such as proteins, it is difficult to determine the complete molecular structure uniquely from NMR analysis alone. Since we can only deduce possible candidates for the structure, it is better to refer to “models” rather than “structures.” This is in marked contrast to structural analysis by X-ray diffraction in which the crystal structure is more or less “determined” from the diffraction data alone. Nevertheless, NMR has advantages over X-ray diffraction methods in many respects such as

1. Single crystal samples are *not* needed. The samples may be amorphous or in solution.
2. Effects of intermolecular interactions, that may change the molecular structure, can be avoided if samples are dispersed in solution.
3. Dynamic motion of molecules can be detected.
4. A local structure can be selectively investigated without knowing the whole structure.
5. Fatal damage due to intense X-ray irradiation, that is likely to happen in organic molecules, can be avoided.

Points 5.4.2 to 5.4.2 are of particular importance for proteins that function in solution, changing their local conformational structure dynamically.

In this chapter, we will describe only steps (2) and (3) in some detail, leaving (1) and (4) to good textbooks [5.74–76] except for a few words on step (1). Before proceeding to the experimental details, we briefly summarize the information that NMR spectra contain.

Information Given by NMR Spectra

Nuclei other than those containing both an even number of protons and neutrons (such as ^{12}C and ^{16}O) have a nonzero nuclear spin I . The magnetogyric ratio γ_n giving the nuclear magnetic moment (Sect. 5.1.3) is a natural constant specific to the nuclear species. Table 5.4 lists isotopic nuclei commonly contained in organic molecules having hydrocarbons in the backbones. Among them, proton ^1H , carbon ^{13}C and nitrogen ^{15}N are characterized by the smallest nuclear spin $1/2$. As explained later, this fact, together with the fact that ^1H in very high natural abundance has a large γ_n value, provides the reason why mainly these isotopes are used for

high-resolution NMR measurements. As far as stated in the following, we consider only the case of $I = 1/2$ for simplicity. The values of the Larmor (not angular) frequency at a typical magnetic field of 2.35 T are listed in the fourth column in Table 5.4 for various isolated nuclei. It should be noted that, with increasing γ_n , the energy difference of the two spin states, and hence the population difference and the magnetization to be detected in experiments, increase, so the sensitivity of NMR is high particularly for protons that have a large γ_n value.

The magnetic field B_0 felt by the nuclear spins may differ from the external field due to many causes.

Chemical Shift. The external magnetic field is shielded by the diamagnetic current of s electrons or enhanced by the paramagnetic current of p and d electrons surrounding the nucleus. In contrast to the shielding field from s electrons (Fig. 5.80a), which is isotropic in the sense that it is directed along the magnetic field due to the isotropic nature of s electrons, the shielding field is anisotropic when the electrons are, e.g., π electrons in double bonds (Fig. 5.80b). In all these cases, the applied magnetic field induces a screening current of electrons surrounding the nucleus which exerts an additional local field on that nucleus. Since the degree of screening depends on the chemical environment of the nucleus, the difference in the nuclear environment results in a small shift, called the chemical shift δ , of the resonance frequency. As illustrated by a schematic NMR spectrum in Fig. 5.81 of protons in a molecule which contains two protons at different positions, the chemical shift can differ depending on the chemical environment. Thus, the chemical shift is used to discriminate the position in a molecule at which the probed nuclei are situated. Since

Table 5.4 Properties of nuclear species commonly used for NMR analysis of macromolecules. After [5.73]

Nuclear species	Nuclear spin I (\hbar)	Magnetogyric ratio γ_n ($10^8 \text{ rad s}^{-1} \text{ T}^{-1}$)	Natural abundance (%)	Larmor frequency (MHz) ^a
^1H	1/2	18.861	99.985	100.000
^2H	1	2.895	0.015	15.351
^3H	1/2	20.118	radioactive	106.663
^{12}C	0	—	98.0	—
^{13}C	1/2	4.743	1.1	25.144
^{14}N	1	1.363	99.634	7.224
^{15}N	1/2	−1.912	0.366	10.133
^{16}O	0	—	99.762	—
^{17}O	5/2	−2.558	0.038	13.557
^{18}O	0	—	0.200	—

^aNMR resonance frequency of isolated nuclei at a typical magnetic field of 2.35 T

Fig. 5.80a,b The magnetic shielding by electrons inducing the chemical shifts in NMR. **(a)** Isotropic shielding by s electrons, **(b)** anisotropic shielding by π electrons

the chemical shift increases proportionally with the external field, the shift is usually expressed by a fraction (in unit of ppm) of the Larmor frequency of the nucleus, which also increases linearly with the field.

Spin–Spin Coupling (Connection through Bonds). In Fig. 5.81, the two sets of spectral signals corresponding to different chemical shifts further splits to two signals with small separations. This is due to the spin–spin coupling mediated by electrons contributing chemical bonds linking the two spins: as shown in the top left illustration in Fig. 5.82, a nuclear spin interacts with electrons surrounding the nucleus, then the spins of the electrons interact with other electrons through an exchange interaction when chemical bonds are formed, and the latter electrons interact with another nuclear spin. Unlike the direct dipole–dipole interaction between magnetic moments that operates only in a small distance, such indirect spin–spin coupling extends to a larger distance of up to 3–4 bonds. In contrast to the chemical shift, the magnitude of the spin–spin coupling is independent of the external magnetic field and therefore the splits of the

Fig. 5.81 Chemical shifts and J -coupling in molecules containing two protons in different environments (schematic)

resonance frequency due to the spin–spin coupling are expressed by a coupling constant J scaled in units of microwave frequency. Due to the origin of the spin–spin coupling (hereafter called J -coupling), the value of J can vary and even change its sign depending on the character and the number of chemical bonds intervening between the two spins. Some typical values of J are indicated in Fig. 5.82 between two ^1H nuclei or ^1H and ^{13}C connected with different types of chemical bonds. Thus, the value of the spin coupling constant J reflecting the *interaction through bonds* provides information of the steric local configuration of the molecule.

Nuclear Overhauser Effect (Connection through Space). In contrast to the spin–spin interaction mediated by electrons, the magnetic moments associated with two nuclei can directly interact through the classical dipole–dipole interaction. Since the strength of the dipole–dipole interaction depends quadratically on the

Fig. 5.82 J -coupling in various bases

product of the magnetogyric ratios and decays rapidly with the internuclear distance d as d^{-3} , the dipole–dipole interaction acts virtually only between two proton nuclei within a distance of $\approx 5 \text{ \AA}$ in diamagnetic molecules. Since electrons inducing paramagnetism have a large magnetogyric ratio, they interact so strongly with nuclear spins that NMR becomes very broad or unobservable.

The dipole–dipole interaction gives rise to the following nuclear Overhauser effect (NOE) that provides powerful methods for structural determination. Generally, systems of nuclear spins, once disturbed, attempt to recover their equilibrium state. The recovery or relaxation takes place via two different processes: the spin–lattice relaxation in which the excited energy is released to the heat bath (usually lattice) by flipping of spins, and the spin–spin relaxation in which only the coherence of spins is lost without energy dissipation. The relaxation processes are characterized by first-order time constants, called the vertical time constant T_1 for the former and the transverse time constant T_2 for the latter.

As an illustrative relevant example, we consider two protons, I and S, that are supposed not to be J -coupled, for simplicity. The energy level diagram of the two-spin system in thermal equilibrium is shown in Fig. 5.83a, in which the state $\alpha_I\beta_S$, for example, indicates that the spin of I is up (α) while the spin of S is down (β). In the absence of J -coupling, the levels $\alpha_I\beta_S$ and $\beta_I\alpha_S$ are nearly degenerate with a small difference due to possible chemical shifts in I and S. The number of dots on each level indicates the level population. Now, we assume that, as shown in Fig. 5.83b, the S spins are selectively irradiated with microwaves at the resonance frequency so that the populations are equalized between the levels linked by W_{1S} , called single-quantum processes, achieved by the flipping of a single spin. Once the populations are disturbed this way, spin–lattice relaxation occurs via single-quantum transitions between $\alpha_I\alpha_S$ and $\beta_I\alpha_S$, $\alpha_I\beta_S$ and $\beta_I\beta_S$ for I, and between $\alpha_I\alpha_S$

and $\alpha_I\beta_S$, $\beta_I\alpha_S$ and $\beta_I\beta_S$ for S, both observable as singlet NMR spectra. The spin–lattice relaxation may also occur by transitions between $\alpha_I\alpha_S$ and $\beta_I\beta_S$, called double-quantum processes W_2 , that correspond to simultaneous flipping of both spins. The populations may also be recovered by the transition between $\beta_I\alpha_S$ and $\alpha_I\beta_S$, called a zero-quantum process W_0 , which causes spin–spin relaxation. The relaxation through W_0 and W_2 are normally forbidden but becomes allowed when there are magnetic field fluctuations that act as an alternating field at various frequencies, which induces spin flipping. The field fluctuations are generated by the diffusional or rotational motion of nuclei and molecules (Fig. 5.83c) that cause fluctuations in the local field affected by the dipole–dipole interaction. Generally, the fluctuation-induced relaxation rate becomes maximum when the resonance condition $\omega_0\tau_c \approx 1$ is satisfied, where τ_c is the correlation time of the fluctuation and $\hbar\omega_0$ is the relevant transition energy. Since $\omega_0 = \omega_L$ for W_1 and $\omega_0 = 2\omega_L$ for W_2 , normally $\omega_0\tau_c \gg 1$ in large molecules or molecules in viscous solution for which τ_c is large, and hence relaxation through W_1 and W_2 is inefficient in such systems. For the process W_0 , however, the two levels are close in energy ($\omega_0 \approx 0$) so that relaxation through W_0 can be efficient when $\omega_0\tau_c \approx 1$ is satisfied, thereby dominating the spin–spin relaxation. In any cases, the excited spin systems recover their thermal populations with a rate affected by the cross relaxation processes W_0 and W_2 due to the dipole–dipole interaction, if present. This NOE effect, originating from an *interaction through space*, is exploited for determination of the conformation of macromolecules.

Experimental Methods

Vector Model in Rotating Frame. In modern NMR experiments, we do not anymore measure the absorption of a continuous microwave, but instead measure a response of the spin system to a sequence of microwave pulses and Fourier transform the oscillatory current sig-

Fig. 5.83a–c Level diagrams illustrating the nuclear Overhauser effect (NOE), which operates between nuclei close in space. For details, see the text

nal response to the pulses to obtain an NMR spectrum. Experimentally, in addition to the static magnetic field along the z -axis, we apply another magnetic field to the spins with a small intensity $2B_1$ alternating at an angular frequency ω with a coil (transmitter) that is wound around the sample with its axis (taken as x -axis) normal to the z -axis. One of the circularly rotating fields of intensity B_1 gives rise to two effects: it forces the precession of the spins to synchronize and to tip away from the z -axis. A simple calculation shows that, if one views the precessing spin from the coordinate system $O-x'y'z$ rotating around the z -axis at the alternating frequency ω , the spin feels an effective magnetic field composed of a static field B_1 directing along the x' -axis and a constant field $B_0 - \omega/\gamma_n$ along the z -axis. Therefore, if we prepare spins under a static field B_0 and at time $t = 0$ we apply a rotating field B_1 that satisfies the resonance condition $\omega = \omega_L (= \gamma_n B_0)$, only the field B_1 remains and causes the spins to turn coherently around the x' -axis at a small angular frequency of $\gamma_n B_1$. Therefore, if we focus on the magnetization, the average of the magnetic moments associated with spins rather than the spins themselves, we can draw pictures like Fig. 5.36a–c, in which the magnetization is represented by a thick vector. Hereafter we will repeatedly use such classical vector models in rotating frames for intuitive interpretation.

High-Resolution NMR. As mentioned already, the absolute magnitude of chemical shifts becomes larger as the external magnetic field B_0 is increased while the fine structure due to J -coupling is fixed in magnitude. Therefore, the use of a higher magnetic field allows one to resolve overlapping signals closely split with very small differences in chemical shifts (Fig. 5.84). Especially in macromolecules such as proteins, substantial overlapping of NMR spectra are common and the removal of the overlaps is requisite. One experimental solution is to use an extremely high-field (superconducting) magnet the strength of which being, in terms of the equivalent ^1H resonance frequency, as high as, e.g., 800 MHz.

One-Dimensional (1-D) NMR. Free Induction Decay (FID). An extensive range of modern techniques developed for NMR experiments are solely devoted to separate complicated signals, such as shown in Fig. 5.85, without artifacts. Some of the tasks can be solved, as well as through the use of high-field magnets, by one-dimensional NMR (1-D-NMR) schemes that are illustrated by pulse sequence diagrams. The simplest case,

Fig. 5.84 Chemical shifts $\Delta\delta$ increasing with magnetic field and invariable spin–spin couplings J_1 and J_2 . The use of high field enhances the resolution of NMR

though rarely encountered in practice, is illustrated by a vector model shown in Fig. 5.86a–c. In the initial state (Fig. 5.86a) the magnetization vector is aligned along the z -axis, and in the second step (Fig. 5.86b) we apply a rotating field at a reference frequency ω for a duration Δt that just satisfies $\gamma_n B_1 \Delta t = \pi/2$ so that the magnetization is tipped onto the y' axis. We may not be able a priori to set the reference frequency ω identical to the resonance Larmor frequency ω_r to be measured. In such off-resonance cases, the magnetization vector in the rotating frame would rotate with a rate $\omega_r - \omega$. In the third step (Fig. 5.86c), since the rotating field is switched off (free), the coherent magnetization remains in the y' axis. This means that the magnetization starts to rotate in the laboratory frame with the Larmor frequency ω_r and can be detected as an oscillatory induction current flowing the transmitter coil, now acting as a receiver coil, as illustrated in Fig. 5.86d, with a decay due to relaxation processes. When the nuclei are

Fig. 5.85 NMR spectrum showing chemical shifts and J -coupling in cyclic-GRGDSPA peptides (Courtesy of Prof. I. Shimada)

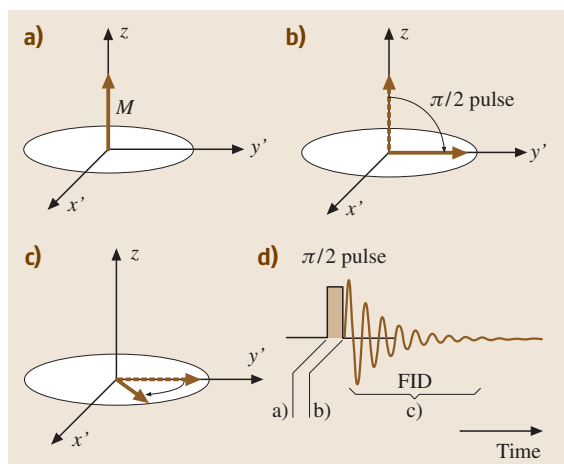

Fig. 5.86 (a)–(c) The magnetization response in vector model in the rotation frame and (d) free induction decay (FID)

isolated such that they have a single Larmor frequency, the Fourier transform of the free induction decay (FID) curve has a signal at the Larmor frequency, as shown in Fig. 5.87a, which represents the NMR spectrum of the nuclei.

When multiple resonance signals coexist, the duration of the $\pi/2$ pulse Δt should be short enough ($\approx 10 \mu\text{s}$, with B_1 being correspondingly large) for the alternating frequency to spread over a range covering the chemical shifts of the nuclei concerned, so that all the nuclei can be tipped nonselectively with a single pulse. Such pulses are called hard pulses. In contrary, the longer and weak pulses, called soft pulses, tip a specific nucleus selectively. The FID and NMR spectrum in Fig. 5.87b are those obtained by using a hard $\pi/2$ pulse. Conventionally NMR spectra are displayed with the frequency axis increasing to the left.

More general procedures of 1-D-NMR consist of first to perturb the spin system from equilibrium somehow (preparation), to allow it to evolve after the perturbation for various periods (evolution), and then to detect what has happened in the evolution period by collecting the subsequent FID (detection). If the evolution is spin relaxation, we can measure the spin relaxation time. In practice, however, the FID decays more rapidly than expected from the true spin relaxation time. The main cause is the spatial inhomogeneity of the external magnetic field. In this case, the spin echo technique allows us to avoid the artifact. The idea of spin echoes is embedded in various schemes of pulse NMR experiments.

Fig. 5.87a,b Fourier transform NMR spectra (right) obtained from FID curves (left)

Since there are too many variations of 1-D-NMR having their own acronyms, only two schemes are presented here to touch on some of the ideas.

Spin Decoupling. If we can determine whether or not a pair of neighboring signals are really coupled to each other, this method allows the assignment of the signals. Also if the doublet splitting can be suppressed, it allows the simplification of complex spectra. Consider two spins A and X that are J -coupled with a coupling constant J . If the spin X is irradiated selectively but strongly with a microwave pulse at the resonance frequency, the resonance A loses its doublet splitting (spin decoupled) because the spin X flips so rapidly that the A spin feels only the average of the spin states of X. If we examine the presence or the absence of such spin decoupling effects for pairs of doublets in a complex NMR spectrum, we can identify J -coupled pairs within a distance of 3–4 bonds in the molecular network.

Selective Polarization Inversion (SPI). Another example is given by again considering a J -coupled pair of spins, A and X, but in this case, the pair is supposed to be heteronuclear, e.g., A is ^{13}C and X is ^1H , as illustrated by an energy level diagram in Fig. 5.88a. The level notation $\beta\alpha$, for example, indicates that the A (^{13}C) spin is down (β) while the X (^1H) spin is up (α). Due to the large difference in γ values between A and X, the level population in thermal equilibrium differs considerably. The bottom diagram in Fig. 5.88a shows the schematic NMR spectrum with the vertical bars representing the intensity. Now, consider that the resonance between $\alpha\alpha$ and $\alpha\beta$ is selectively excited by a soft pulse so as to invert the populations, as shown in Fig. 5.88b. Then the NMR signals are drastically changed, as illustrated by the bottom spectrum, because the signal intensity is determined by the population difference. The negative signal means that the FID component

Fig. 5.88a,b Heteronuclear selective polarization inversion (SPI). (a) in thermal equilibrium, (b) when ^1H is selectively excited

is out of phase by π with the positive signal. Such changes would not be observed if A and X are completely independent, which signifies that the two spins are coupled somehow. Unlike the NOE effect, the change is immediate in the case of J -coupling, so we can distinguish whether they are dipole-coupled or J -coupled. A subsidiary merit of polarization transfer techniques is that weak NMR signals, such as that of ^{13}C , can be enhanced.

Two-Dimensional (2-D) NMR. In small molecules, signal assignment may be possible through 1-D-NMR experiments, but in large molecules such as proteins that yield bewilderingly complex spectra, we need more sophisticated NMR measurement schemes. Two-dimensional NMR (2-D-NMR) is a successful solution to this problem. The idea is to sort out crowded NMR signals in a two-dimensional map according to which pairs of signals are coupled to each other. The methods may be regarded as double resonance techniques that can be extended to multidimensional NMR by using appropriate relays of pulse sequences. Two representative schemes that are most commonly used are explained briefly.

An example of pulse sequence diagram for 2-D-NMR experiments is shown in Fig. 5.89a, in which two heteronuclear spins of ^{13}C and ^1H are assumed to be J -coupled. Before FID is detected for ^{13}C spins, two $\pi/2$ pulses separated by a time t_1 are applied to the ^1H spins. Figure 5.90 depicts what happens in the vector model. After the magnetization of ^1H is turned to the y' -axis by the first $\pi/2$ pulse, the ^1H spins start to rotate in the rotating frame at a rate $\Omega_{\text{H}} = \delta_{\text{H}} \pm J_{\text{CH}}/2$, where δ_{H} is the chemical shift of the ^1H spins and J_{CH} is the constant of J -coupling with ^{13}C , provided that the reference frequency is set at the Larmor frequency

of the isolated ^1H . The diagrams in the second column indicate this rotation at time t_1 increasing downward. By the second $\pi/2$ pulse, the ^1H spins have turned further around the x' -axis, as shown in the third column. At this moment, the FID of ^{13}C spins, not of ^1H , is acquired by applying a $\pi/2$ pulse on ^{13}C . When $t_1 = 0$, the magnetization of ^1H is inverted, so the ^{13}C signal changes drastically reflecting the inverted population of ^1H , as in the case of SPI experiments in Fig. 5.88 (the x' -component, not turned by the second $\pi/2$ pulse, does not affect the J -coupling). At the arbitrary time t_1 , the magnetization of ^1H after the second $\pi/2$ pulse on ^1H has a z -component of magnitude $M \cos \Omega_{\text{H}} t_1$, as shown in the second line of the third column in Fig. 5.90, so the ^{13}C signal intensity (schematically shown in the right column) is modulated accordingly. Since the ^{13}C signal modulation has a period of $2\pi\Omega_{\text{H}}^{-1}$, if we repeat such measurements systematically changing the time t_1 , the Fourier transform of the ^{13}C signal intensity with respect to t_1 gives the NMR spectrum of the ^1H spins with a chemical shift δ_{H} and the doublet splitting magnitude J_{CH} . This may be regarded as a double resonance or ^{13}C -NMR-detected NMR of ^1H spins. In other words, the ^{13}C resonance signal acts as though it is labeled with the resonances of the ^1H spins that are J -coupled to the ^{13}C . If the $\pi/2$ pulses on ^1H are hard and hence nonselective, we will obtain an NMR spectrum in two dimensions for frequency ν_1 (corresponding to t_1) and for frequency ν_2 (corresponding to t_2), as illustrated in Fig. 5.91. The signals on the diagonal line (diagonal peaks) are always present, but the off-diagonal signals (cross peaks) indicate the presence of J -coupling between the corresponding ^{13}C nuclei and ^1H nuclei. It is obvious that, even if the 1-D spectra are complicated, the

Fig. 5.89a,b Pulse sequences for 2D-NMR; (a) heteronuclear 2D-NMR, (b) homonuclear 2D-NMR (COSY)

connectivity through J -coupling is more easily resolved in such 2-D spectrum.

The homonuclear version of the above scheme is called correlated spectroscopy (COSY) and is widely used to find J -couplings between ^1H nuclei. The pulse sequence, shown in Fig. 5.89b, is similar to that in Fig. 5.89a, except that the FID measured is now for ^1H itself. Although the precise interpretation needs a quantum mechanical description, the cause of the cross peaks may be inferred by analogy to the heteronuclear case above. Figure 5.92 shows an example of COSY (a more sophisticated double-quantum-filtered COSY) spectrum obtained for the same peptide molecules whose 1-D spectrum was shown in Fig. 5.85.

In the 2-D-NMR experiments discussed so far, the pulse sequence generally consists of preparation, evolution and detection stages. In Fig. 5.89a, the first $\pi/2$ pulse corresponds to preparation, the duration t_1 until the second $\pi/2$ pulse to evolution, and the acquisition of FID to detection. In more sophisticated schemes of 2-D-NMR, we add another stage, mixing, following evolution. Figure 5.93 shows the pulse sequence in NOESY (NOE spectroscopy) extensively used for analysis of macromolecules. The corresponding vector model is shown in Fig. 5.94. The sequence of the first $\pi/2$ pulse (Fig. 5.94a,b), an evolution time t_1 (Fig. 5.94b,c), and the second $\pi/2$ pulse (Fig. 5.94c,d) is the same as in Fig. 5.90 except that we consider two spins, I and S, having different resonance frequencies but coupled through a dipole–dipole interaction. During the mixing stage, which lasts for t_m (Fig. 5.94e,f), the z -components of the magnetization (the x' -components have no effect

Fig. 5.91 Schematic 2D-NMR spectrum of ^{13}C and ^1H J -coupled with each other

Fig. 5.90 Vector model for heteronuclear 2D-NMR. For details, see the text

and are not shown), which arise from the population difference of the spin states, exchange their populations due to the NOE effect. Thus, the intensity of the NMR signals measured in the detection stage (Fig. 5.94f,g) tells

Fig. 5.92 DQF (double quantum-filtered)-COSY spectrum of cyclic-GRGDSPA peptides (Courtesy of Prof. I. Shimada)

Fig. 5.93 The pulse sequence for NOESY experiments

us how rapidly the relaxation has occurred. Similarly to the COSY spectrum, the NOESY spectrum is displayed with one axis representing the frequencies of the I spin and another axis the frequencies of the S spin. The cross peaks indicate that the two nuclei giving the signals are closer than $\approx 5 \text{ \AA}$ in space so that they are dipole–dipole coupled.

Sample Requirements. Finally, some comments are added on the requirements for samples. Since NMR signals are proportional to the number of spins, for a sufficiently high signal-to-noise ratio to be achieved, the sample amount must usually be greater than several milligrams or 1 mM, which may be difficult. As mentioned before, nuclei with spin $I > 1/2$ are not very suitable for NMR experiments because the spectrum broadens due to the strong quadrupole interaction (Sect. 5.1.3). Even if we confine ourselves to $I = 1/2$ nuclei, however, there are other causes of spectral broadening that prohibit us from conducting high-resolution NMR measurements. In actual experiments, an inhomogeneity in the external magnetic field induces an apparently rapid decay in the FID or a broadening

of the NMR spectra. Although the effect of magnetic field inhomogeneity could be removed by the spin echo technique, there still remains a cause of spectral broadening due to the variation of molecular orientations, which gives rise to different degrees of anisotropic shielding and as a result continuously varying chemical shifts. When the molecules are so small that they rotate rapidly in the medium, the variation of chemical shifts is averaged and consequently the NMR spectral signals become sharpened. While small molecules in solution benefit from this motional narrowing effect, large molecules cannot do so if their rotation rate is too small. Thus, NMR analysis generally becomes difficult for large molecules that lack mobility. Although many techniques, such as sorting signals according to intentionally controlled spin relaxation lifetime, have been developed to escape the difficulty, an upper limit exists around 3×10^4 in molecular weight for which structural analysis by NMR is practically possible. This is in great contrast to X-ray diffraction methods in which much larger molecules, such as ribosome (4×10^6 in molecular weight), can in principle be analyzed if single crystals can be grown.

5.4.3 Chemophysical Analysis

Chromatography

Chromatography is a generic term for techniques that separate complex mixtures into their components, which are distributed with a variable probability between a stationary and a mobile phase; the methods are based on the percolation of the mobile phase through the solid phase in what is known as a column. The mobile phase

Fig. 5.94a–h Vector model of NOESY

is gaseous in gas chromatography (GC) and is liquid in liquid chromatography (LC). There are various schemes for chromatography further depending on the type of stationary phase (solid or liquid) and hence on the principle of molecular separation (ion exchange, affinity difference, gel-filtration, hydrophobic interaction etc.).

As illustrated in Fig. 5.95, chromatographic measurements are conducted by constantly injecting into a column a sample mixture carried by a mobile phase and recording a chromatogram, a chart that plots the amount of an analyte reaching a detector placed at the outlet of the column versus the time t starting from the sample injection. The retention time, t_r , is the time between sample injection and a peak in the chromatogram, while t_m is the time taken for the mobile phase just to pass through the column. The molecular species can be identified from their retention time and their total amount is measured from the integrated area of the corresponding peak. Among the various types of detectors, the most common are thermal conductive detectors, which are sensitive to any species. Using a mass spectrometer as the detector, one can obtain more structural information of the separated molecular species. GC is suitable for routine analysis and has high resolution, short measurement time, low cost, and requires a small amount of sample (1–10 μl in a liquid sample and 0.2–10 ml in a gaseous sample) as long as the boiling temperature of the sample is below 300 $^{\circ}\text{C}$; LC is applicable to multicomponent, less volatile or pyrolytic (thermally decomposable) samples that are not covered by GC. The limitation of ordinary chromatography is that peaks in chromatograms have no significant structure, unlike those observed in photospectroscopy methods that provide detailed information on the possible variety of

Fig. 5.95 General experimental configuration of chromatography

each components. Nevertheless, there is room for further improvements in detection techniques that allow chromatography to become useful as a preprocess for more sophisticated analysis.

Electrophoresis utilizes the difference in the drift mobility of ionic molecules in a stationary phase under an electric field. Electrophoresis using gel as the stationary phase is called gel electrophoresis (GE), and that using aqueous solution in a capillary is called capillary electrophoresis (CE). CE has advantages over GE because of reduced problems with Joule heating and the action of the capillary itself as the pumping system.

Circular Dichroism (CD)

Circular dichroism (CD) arises from the helicity or chirality of molecules that exhibit optical absorption due to electronic excitations at ultraviolet to visible wavelengths. CD spectra of chiral proteins, peptides and nucleic acids have distinct structures and are sensitive to conformational changes. Figure 5.96 shows a schematic diagram of experimental setup. Linearly polarized light can be regarded as a superposition of left- and right-hand circularly polarized light. Optically active substances such as chiral molecules transmit the opposite circularly polarized light with slightly different absorption coefficients. As a consequence, the linearly polarized light incident on the sample becomes elliptically polarized light without changing the main polarization axis. The degree of ellipticity (CD) depends on the difference in the absorption coefficients.

In contrast, optical rotation arises from differences in the index of refraction that cause a difference of the rotation angle between the opposite components of circularly polarized light. The optical rotary dispersion (ORD) spectrum, the dependence of rotation angle on wavelength, is related to the CD spectrum by a Kramers–Kronig transformation. The ORD curve changes sign at the extremum peak of the CD spectrum, known as the Cotton effect, as illustrated in Fig. 5.97.

Owing to the fact that CD/ORD curves exhibit features that are characteristic to the molecular structures, CD/ORD measurements provide structural information

Fig. 5.96 Experimental setup of circular dichroism (CD) and optical rotary dispersion (ORD) measurements

Fig. 5.97 Schematic spectra of circular dichroism (CD) and optical rotary dispersion (ORD)

about the molecule. In proteins, for example, CD signals are more sensitive to α -helical residues than those of random coils and β -sheets. Experimental data are fitted to reference model spectra to determine the amounts (composition) of the constituent secondary structure of proteins. The reliability of composition analysis is enhanced by the use of proteins of known structure as the basis set. More sophisticated analysis of molecular positions, conformation and absolute configuration can be conducted with detailed knowledge of the influence of these factors on the Cotton effect.

Samples are usually prepared as a solute in an optically nonactive solution. CD/ORD measurements allow quantitative analysis since the signal intensity is proportional to the molecular density in the solution. Structural analysis, however, is only possible at densities that yield an optical absorbance of 1–2 at the absorption maximum, where the Cotton effect is observed, in order to avoid signal weakening due to excessive absorption.

Although simple CD and ORD are observed only in optically active molecules, similar dichroic effects are also induced in achiral substances under a magnetic field

Fig. 5.98 Spectral overlap necessary for fluorescence resonant energy transfer (FRET)

applied parallel to the measuring light beam. Magnetic circular dichroism (MCD) combined with photoabsorption measurements is most commonly used to analyze chromophoric groups in which the magnetic field lifts the degeneracy of optically excited energy levels differing only in magnetic spin (Sect. 5.3.1). In biology, MCD is also applicable to metalloproteins, protein molecules that contain a metal substance necessary for a certain reaction to take place.

Fluorescence Resonant Energy Transfer (FRET)

Fluorescence resonant energy transfer (FRET) occurs when the distance between a fluorescent donor dye molecule and a photoabsorbing acceptor dye molecule is close enough for the electronic excited energy of the donor molecule to be transferred to the acceptor molecule nonradiatively. Since the efficiency of FRET depends on the inverse sixth power of the intermolecular distance, it is useful for determining the proximity of the two molecules within 1–10 nm, which is a distance range of particular importance in biological macromolecules. For FRET to take place, the fluorescence spectrum of the donor and the absorption spectrum of the acceptor must overlap, as shown in Fig. 5.98. Based on this technique, the approach of two molecules can be detected by quenching the donor fluorescence, and one can study the conformation change of a single molecule by detecting FRET under a laser scanning confocal microscope (LSCM) (Sect. 5.1.2) or a total internal reflection fluorescence microscope (TIRFM) (Sect. 5.1.2) [5.77].

5.5 Texture, Phase Distributions, and Finite Structures Analysis

This section deals with materials that are inhomogeneous on a relatively large scale with respect to their composition, structure, and physical properties. Polycrystals are said to have a texture when they have a nonrandom distribution of grain orientations. The phase distribution or element distributions may play an important role in the macroscopic properties of the material. Another issue addressed is solid structures with finite three-dimensional size that may have their own functions, such as biological cells, nanoparticles, etc. In the last subsection, we describe some of the recent progress in stereology, an emerging field of three-dimensional analysis of materials.

5.5.1 Texture Analysis

Textures evolve by various mechanisms. Plastic deformation of crystals by glide motion of dislocations proceeds on preferential crystallographic slip planes, usually low-index planes with the largest spacing. If polycrystalline wires are drawn through a die, the wires have a texture (wire texture) such that the slip planes tend to align parallel to the wire axis, because otherwise each grain would be subject to further deformation. The texture of polycrystalline materials is of technological importance for various physical properties, mechanical properties such as strength and elastic constants, magnetic permeability, flux pinning in superconductors of the second kind, and so on.

Texture Analysis by X-Ray Diffraction

The best established technique for assessing textures is X-ray diffraction. In powder diffraction, each diffraction ring consists of fine spots which correspond to crystallites in different orientations. If the crystallites are randomly oriented, the spots or the diffraction intensity is uniformly distributed around the circle. If textures are present, however, one observes an inhomogeneous distribution of diffraction spots or diffraction arcs, as shown in Fig. 5.99. In modern experiments, the data are collected by using a diffractometer equipped with a four-circle goniometer (Fig. 5.37) that scans all orientations by a combinatorial rotation around the Eulerian ω - ϕ - χ axes. For thick or large-grained samples, neutron diffraction may offer an alternative to X-ray diffraction, if a facility is accessible. The merit of diffraction techniques is the ease with which good statistical data can be acquired.

The texture of materials is expressed by several different representations. The pole figure (Fig. 5.100)

Fig. 5.99 X-ray diffraction pattern from a mechanically drawn Al wire. Exposure time 30 s using X-ray source Mo K_{α} (50 kV, 40 mA) recorded on an imaging plate placed 10 cm from the sample (Courtesy of Rigaku Co)

presents the orientational distribution of a specific pole (crystallographic (0001) axis in Fig. 5.100a) with respect to the sample orientation, which is displayed on a stereographic projection with the surface normal at the origin, a specific direction along the sample surface (e.g., the rolling direction in rolled metals) at the north pole, and the transverse direction in the horizontal direction. Figure 5.101 shows an experimental pole figure of an aluminium sheet thermally annealed after mechanical rolling [5.78, p. 102]. The four crystallographically equivalent (111) poles are distributed in some dominant directions. Also widely used is the inverse pole figure that presents the orientation distribution of the specimen coordinate system with respect to the crystal coordinate system, the latter being reduced to a standard stereographic triangle. Whichever the case, however, the projection of the three-dimensional orientation distribution onto a two-dimensional figure causes a loss of information. The orientation distribution function (ODF) is a three-dimensional presentation thus devised for a full description of texture. The ODF can only be obtained by calculations from a data set of several pole figures. For details, see the textbook by *Randle and Engler* [5.78].

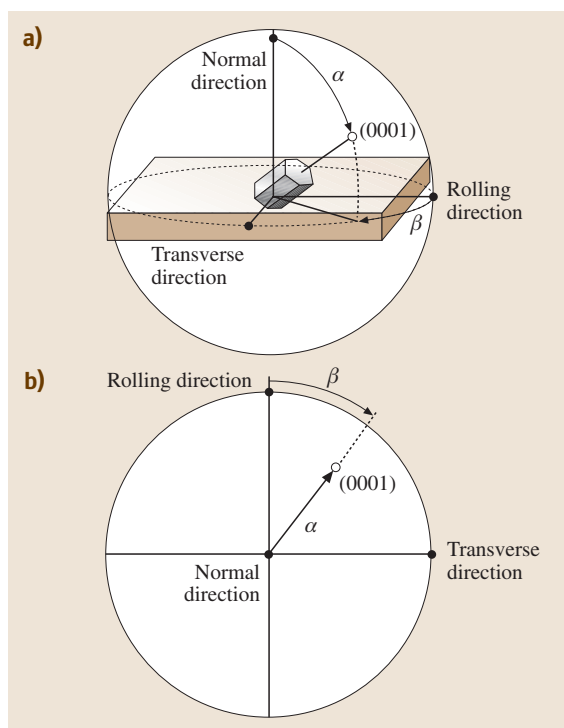

Fig. 5.100a,b A presentation of the texture (a) by the stereographic pole figure in (b)

Fig. 5.101 An experimental pole figure of an aluminum sheet rolled and annealed. After [5.78]

by microscopic techniques that also reveal the dimension of each grain directly [5.79]. TEM is a routine method to conduct such measurements, but the samples are limited to thin films. The electron channeling pattern (ECP), which can be obtained by scanning electron microscopy (SEM), is a more convenient approach for studies of texture using bulk samples.

SEM-ECP corresponds to the Kikuchi lines (Sect. 5.1.2) or bands observed in TEM. Figure 5.102 illustrates how the Kikuchi lines are formed. As mentioned in Sect. 5.1.2, the Bloch wave with its largest amplitude on the atomic column (Fig. 5.102b) interacts more strongly with the atoms and is more likely to be scattered inelastically, losing coherency with the direct wave. As shown in Fig. 5.102a, some of the electrons thus inelastically scattered in various directions will be reflected by lattice planes satisfying the Bragg condition and, if the specimen is moderately thick, propagate along the “channel” direction with an anomalously small absorption coefficient. The electrons are projected onto the back focal plane of the objective lens as a pair of traces of the diffraction cones. Line pairs (Kikuchi lines) or bands formed in this way indicate the orientation of the crystal. In a similar way to the Kikuchi lines in TEM, if the electron beam in SEM is incident to a crystalline sample in an orientation along a channeling direction (Fig. 5.102b), the electrons penetrate deeply into the sample and have less chance to be back scattered and detected by a back-scattering electron detector. If one rocks the beam direction as in Fig. 5.102b and synchronously displays a two-dimensional map of the intensity of back-scattered electrons in the SEM screen as a function of

Fig. 5.102a,b Formation of Kikuchi lines in TEM (a) and electron channeling pattern in SEM (b)

Texture Analysis by SEM Electron Channeling Pattern (ECP)

The disadvantage of diffraction techniques for the analysis of texture is the lack of direct information about the grain size. Local crystal orientations may be determined

Fig. 5.103a–d Electron channeling patterns (a),(b) and images (c),(d) at different tilt angles. After [5.17]

the beam orientation, one obtains patterns as shown in Fig. 5.103a, b. Since the SEM-ECP pattern reflects the crystalline orientation of the sample position at which the beam is rocked, beam scanning with the beam direction fixed gives ECP images, as shown in Fig. 5.103c, d. From such crystallographic orientation contrasts, one can determine the orientation distribution and the size of each grain.

5.5.2 Microanalysis of Elements and Phases

Dark-Field TEM Imaging

Dark-field (DF) TEM images (Sect. 5.1.2) formed by a diffracted beam of a specific diffraction vector provide the most standard technique for microscopic analysis of coexisting multiphases. Figure 5.104 shows a bright-field image of a metallic compound of Nb_3Te_4 and the corresponding DF images obtained for two different diffraction vectors. The lateral resolution is similar to that of BF-TEM images as long as the sample is thin enough for the overlap of different phases to be avoided.

Electron Probe Microanalysis (EPMA)

Another common method to investigate element distribution in solid materials is scanning electron microscopy operated in the X-ray fluorescence mode, usually referred to as an electron probe microanalyzer (EPMA). On the impingement of electrons in the energy range of 1–40 keV, the samples emit X-rays at wavelengths characteristic of the elements contained. The emitted X-ray is usually detected with an energy dispersive X-ray

Fig. 5.104 (a) Bright-field and (b),(c) dark-field images of multi-phase Nb_3Te_4 (courtesy of M. Ichihara)

(EDX) solid-state detector placed above the specimen (Fig. 5.105). Scanning the beam gives us a map of the element distribution with a spatial resolution of a few nm to 100 μm . The technique becomes more sensitive as the mass number increases.

Similar measurements could be conducted using TEM. In ordinary SAD, however, it is difficult to reduce the size of a selected area to smaller than several tens of nm, whereas in CBED the beam size can be reduced down to a subnanometer scale. The best choice is to use a focused beam in STEM that allows one to conduct CBED analysis as well as mapping element distribution over the scanned area. For heavy elements, STEM-EDX has advantages over the following techniques, though there are technical problems with the energy resolution (≈ 150 eV) and the time for data acquisition.

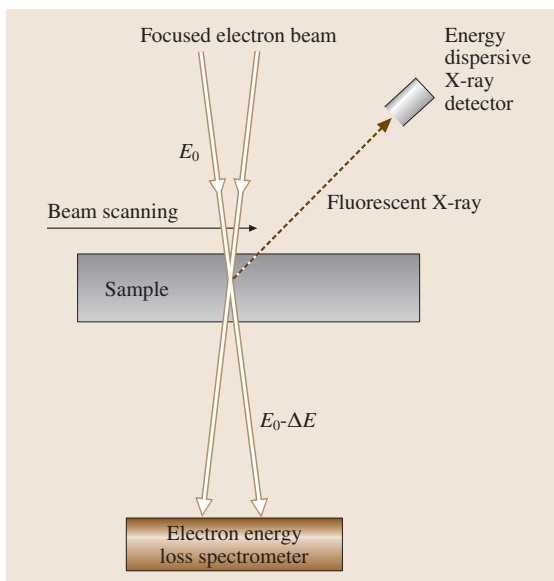

Fig. 5.105 Element analysis by an electron probe

Electron impingements induce the emission of Auger electrons whose energies are characteristic of specific elements (Fig. 5.67). Since the energy of Auger electrons is so small that the escape distance is as short as ≈ 1 nm (Fig. 5.59), Auger electron spectroscopy (AES) is overly sensitive to the surface.

Energy Loss Analysis

Energy filtering TEM (EFTEM) is a TEM or STEM equipped with an energy filter passing only electrons of a specific energy that are used to construct an image of the spatial distribution of the corresponding elements. The energy filter may be placed inside the optical column of the TEM (in-column type) or in front of the camera chamber (post-column type). EFTEM allows spectrum imaging of the element distribution with an energy resolution of ≈ 30 eV and a spatial resolution of down to ≈ 1 nm at 200 kV and ≈ 0.5 nm at 300 kV.

In contrast to EFTEM, the spatial resolution in STEM-EELS, if equipped with a field emission gun, is much higher owing to the fact that STEM generally does not need an objective lens to image the aberration that governs the spatial resolution of TEM micrographs. A disadvantage of STEM-EELS is the long acquisition time due to the scanning nature of the microscopy, but the use of a parallel EELS (PEELS) detector and the great assistance of a computer have advanced the progress of STEM-EELS as a tool able to identify even a single atom in small molecules [5.80], as demonstrated in Fig. 5.106. STEM-EELS has advantages over STEM-EDX for light elements.

Micro-Raman Scattering

Raman scattering measurements (Sects. 5.1.3, 5.2.3, and 5.3.1) can be coupled with optical microscopes to investigate the local distribution of particular phases with a spatial resolution of ≈ 1 μ m. The diffraction limit of OM is now overcome by the use of scanning near-field optical microscopy (SNOM) (Sect. 5.1.3), in which the enhancement of the optical field by surface plasmon resonance at the metallic tip allows the detection of Raman

spectra for even a single molecule [5.81] under good conditions.

Scanning Nano-Indenter

Materials often encountered may be in the form of thin films or nanoscale complexes of multiple phases. One may need to conduct mechanical tests for very thin films grown on a substrate. The difference in material phase may reflect the mechanical strength. The scanning nano-indenter is a modern version of the micro-hardness tester with which the local mechanical strength of crystallites smaller or thinner than ≈ 1 μ m can be measured with a lateral resolution of several hundreds nanometres from the indent size in situ observed by a microscope similar to an AFM and STM. The extremely tiny indenter can be driven into and retracted from the sample surface at a controlled rate, so that one can also deduce the local elastic modulus.

5.5.3 Diffraction Analysis of Fine Structures

Tiny objects such as precipitates, crystallites, and fine particles smaller than ≈ 100 nm can be investigated by not only microscopic but also diffraction and spectroscopic techniques.

Small-Angle Scattering Analysis of Tiny Phases

The Guinier–Preston (GP) zone, an extremely tiny precipitate with a thickness of only one atomic layer and lateral size of several atomic distances, is directly observable by HRTEM at present; it was originally discovered in X-ray diffraction as a source of diffuse scattering. In Guinier's approximation, in which a particle is a Gaussian sphere

$$\rho(\mathbf{r}) = \rho_0 \exp\left(-\frac{r^2}{a^2}\right) \quad (5.37)$$

with a representing the particle size, the diffraction intensity or the Fourier transform of (5.37) will be

$$I(\mathbf{K}) = \rho_0^2 a^2 \pi \exp\left(-\frac{a^2}{2} K^2\right). \quad (5.38)$$

The magnitude of (5.38) is small except for small $|\mathbf{K}|$ values or small scattering angles, which means that the primary beam is diffusely scattered within a small angle. In terms of the radius of gyration R_g , the root mean square of the mass-weighted distances of all subvolumes in a particle from the center of mass,

$$I(\mathbf{K}) \propto \exp\left(-R_g^2 K^2/3\right). \quad (5.39)$$

Fig. 5.106 STEM-EELS image of Gd (white) atoms in a carbon (gray) nanotube. Scale bar = 3 nm. After [5.80]

Thus, from the slope of the so-called Guinier plot, $\log I(\mathbf{K})$ versus K^2 , we can evaluate a measure of the particle radii R_g experimentally.

Line-Broadening Analysis of Crystallite Size and Stress

The broadening of X-ray beams occurs not only in the primary beam but also in diffracted beams when the crystallites or domains are small [5.82]. This arises from the fact that the diffraction intensity depends on the interference function, which reflects the external shape of the crystal (Sect. 5.1.1).

More generally, the line broadening is induced by causes other than the finite crystal size. The main causes are instrumental errors and the strain distribution. The instrumental broadening due to spatial, angular and wavelength distribution of the incident X-ray beam is experimentally evaluated by using a standard sample, usually a large and perfect single crystal such as Si. The line broadening due to lattice strain is in most cases due to lattice defects such as dislocations.

As a measure of the line broadening, we conveniently employ the integral breadth β , which is defined as the width of a rectangle having the same area A and height I_0 as the line profile of interest, or $\beta \equiv A/I_0$. For Gaussian broadening, the relevant breadth β_s of sample origin in our concern is estimated by

$$\beta_s^2 = \beta_m^2 - \beta_i^2, \quad (5.40)$$

where β_m and β_i are the experimental and instrumental breadths, respectively. The separation of the lattice strain component is achieved by plotting β_s vs. $\sin \theta$ for various diffractions. From the Bragg condition (5.1), the line broadening in terms of the diffraction angle 2θ due to a distribution of net-plane spacing Δd is given by

$$\Delta \theta = \tan \theta \frac{\Delta d}{d}. \quad (5.41)$$

When there is another contribution from the finite crystal, the experimentally measured integral breadth β_s is generally given by

$$\beta_s(\mathbf{g}) = a\varepsilon \tan \theta_g + \beta_p \quad (5.42)$$

where $\varepsilon \equiv \Delta d/d$ represents the strain and β_p the size contribution in our concern. Since the integral breadth β_p is related to the average size of crystallites L by Scherrer's formula [5.83, p. 102]

$$\beta_p(\mathbf{g}) = \frac{\lambda}{L \cos \theta_g}, \quad (5.43)$$

(5.43) is written as

$$\beta_s(\mathbf{g}) \cos \theta_g = a\varepsilon \sin \theta_g + \frac{\lambda}{L}. \quad (5.44)$$

Thus, by plotting $\beta_s(\mathbf{g}) \cos \theta_g$ versus $\sin \theta_g$ (the so-called Williamson–Hall plot), as shown in Fig. 5.107, we can evaluate the average size L of the crystallites from the θ_g -independent level.

Thus, the analysis of line broadening simultaneously enables evaluation of lattice strain ε or the internal stress in the crystallites. With access to costly facilities such as synchrotron radiation sources (for X-ray diffraction) or nuclear reactors (for neutron diffraction), one is able to conduct experiments with great advantages for probing the stress state deep into the sample [5.84].

Light Scattering Analysis of Particle Shape

The cloudy or milky appearance of latex and solid polymer reflects a heterogeneous structure with two co-existing phases [5.29] (colloid particles and liquid in latex; crystalline and amorphous domains in solid polymer) (Fig. 5.42). This is due to the high-angle scattering of light over a wide range of wavelength, called Mie scattering in contrast to the wavelength-dependent Rayleigh scattering. When the particle size is smaller than the light wavelength, we enter to a regime of surface plasmon resonance. The resonance frequency depends on the dielectric function of the particle material and the shape of the particle. As the particle is elongated in one direction, the resonance is shifted to longer wavelengths, so measuring the resonant wavelength of the scattering, we can determine how the particles are distorted from a sphere.

Fig. 5.107 A schematic Williamson–Hall plot for line broadening analysis

5.5.4 Quantitative Stereology

The great increase of computer power and resources has made it possible to process the enormous amount of data necessary for three-dimensional reconstruction of a sample structure. There are various types of stereological techniques, as listed in Table 5.5, differing in the reconstruction method.

Stereogram

Two micrographs are acquired for a sample that is tilted by $\pm 1-10^\circ$ in an eucentric way about a tilting axis at the center of the sample. If one views two such images placed side by side with an appropriate separation distance, three-dimensional stereovision of the object is obtained, as demonstrated in Fig. 5.108. The three-dimensional vision could also be provided by an anaglyph image, an overlaid image of the two micrographs that are superimposed with different colors, when viewed with red-blue glasses. Quantitatively, the surface profile is calculated from the disparity in the stereo image pairs. The reconstruction of three-dimensional structure is possible from such stereograms acquired in TEM and SEM.

Stacked Tomographs

Laser Scanning Confocal Microscopy (LSCM). The high depth resolution of $\approx 1\text{ }\mu\text{m}$ in laser scanning confocal microscopy (LSCM) enables reconstruction of 3D images from successively acquired optical images of optically *sliced* layers by changing the focal position. The great advantage of LSCM is that there are no special requirements for the test environment except that the sample medium must be optically transparent.

Ordinary LSCM is based on one-photon processes such as scattering or fluorescence of light. In thick samples, however, remaining light scattering deteriorates the spatial resolution. Nonlinear fluorescent

Fig. 5.108 A set of TEM stereograms showing dislocations in $\text{Si}_{0.87}\text{Ge}_{0.13}/\text{Si}(100)$

microscopy uses an intense laser light whose photon energy is too small for a one-photon excitation of a fluorochrome but is large enough for a two-photon excitation. Due to the quadratic dependence of the fluorescence intensity on the intensity of excitation laser, the focal point is effectively reduced so that the spatial resolution is enhanced whereas the background fluorescence is removed. Two-photon microscopy has the merit of avoiding photobleaching or optical damage that would be caused when excitation lights of higher photon energy in the ultraviolet range is used for one-photon excitation. Similar benefits are obtained in second-harmonic generation microscopy in which the dielectric response of the sample is nonlinear.

Three-Dimensional Atom Probe (3DAP) Microanalysis.

As described in (Sect. 5.1.2), the field ion microscope (FIM) [5.85] is an atom-resolving microscope in which an imaging gas projects the positions of step-edge atoms on a phosphor screen without destroying the surface. If the applied voltage is high enough, the step-

Table 5.5 Comparison of various stereology methods

Fig. 5.109 Experimental setup of 3D atom-probe FIM

edge atoms *themselves* evaporate due to the field. The field-evaporating atoms (positively charged ions) are conveyed by the bias field to the screen to form a direct image of the atomic distribution on the tip, now destructively. As illustrated by Fig. 5.109, this field evaporation can be induced by a pulse bias voltage applied to the sample that is triggered as the starting signal for time of flight (TOF) measurements of the evaporated ions. The use of a multichannel plate in front of the phosphor screen and a gated acquisition of the ion signal allows one to detect specific element atoms sorted by the TOF. Since the field evaporation takes place exclusively at step edges, the evaporation processes are repeated as if the atomic layers are being peeled back one by one. The layer-by-layer acquisition of such atom probe signals are used to reconstruct a three-dimensional map of elements in the sample tip. Figure 5.110 shows an example of three-dimensional atom probe (3DAP) images ob-

Fig. 5.110 Elemental mapping of Cu and Nd in $\text{Nd}_{4.5}\text{Fe}_{75.8}\text{B}_{18.5}\text{Cu}_{0.2}\text{Nb}_1$ alloy imaged by 3D atom-probe FIM (Courtesy of Dr. K. Hono)

tained for a multicomponent alloy. The lateral and depth resolution of 3DAP microanalysis is $\approx 0.2 \text{ nm}$, the best among the stereological methods developed so far.

Computed Tomography (CT)

Computed tomography is based on mathematical transformations that enable reconstruction of the two-dimensional distribution function $f(x, y)$ (e.g., of the absorption coefficient) of an object from a set of one-dimensional intensity profiles $p(r, \theta)$ detected by the detector of a transmitted beam that is emitted from a source in various directions θ , as illustrated in Fig. 5.111. The computed tomographs obtained for successive cross sections of the object are further stacked to form a three-dimensional reconstruction of the whole body.

X-Ray Computed Tomography (XCT). X-ray computed tomography (XCT) using an X-ray for the source beam is common equipment for clinical diagnosis, but can also be used for materials analysis. In XCT, the beam is fanned to scan an angle θ rather than scan position r . The resolution of recent X-ray CT is $\approx 1 \mu\text{m}$, comparable with that of OM.

Magnetic Resonance Imaging (MRI). Magnetic resonance imaging (MRI) or **NMR-CT** is also now common for clinical diagnosis. MRI is based on the principle that when the applied magnetic field in **NMR** has an intentional gradient (i.e., varies with position), the resonance frequency of an **NMR** signal becomes dependent on the position of the nucleus. The positional r -dependent **NMR** signal frequency constitutes the profile function $p(r, \theta)$ in which the angle θ is given by the direction of the magnetic field gradient.

The box size is $270\text{ nm} \times 270\text{ nm} \times 210\text{ nm}$. 120 digital images were acquired at tilt angles ranging from -60° to 60° with 1° steps on a computer-controlled JEOL JEM-2200FS operated at 200 kV (Courtesy of Dr. H. Jinnai)

Three-Dimensional TEM (3D-TEM). Although X-ray crystallography can provide structural information at atomic resolution, its application depends on whether we can obtain crystalline arrays of the molecules with good quality and analyze the diffraction data in light of relevant phase information [5.86]. Furthermore, a serious problem especially in biomolecules is that crystallization may alter the conformation of the molecules that could differ significantly from that in which the molecules function in the natural environment. In single-particle electron microscopy, the 3D structure of a single macromolecule ($\text{MW} > 250\,000\text{ Da}$) is reconstructed at a resolution of $1\text{--}2.5\text{ nm}$ from a set of TEM images obtained in many different sample orientations. In practice, sample damage due to electron irradiation is reduced by the use of cryo-microscopes and simultaneous observations of many sample molecules (usually embedded in ice for biomolecules) to overcome signal-to-noise problems. Figure 5.112 shows a graphical rendering of 3D-TEM image obtained for a selfassembled polymer material. 3D-TEM is applicable to amorphous solids, but not suitable for crystalline samples in which the TEM images are too sensitive to diffraction conditions for a simple three-dimensional reconstruction to be carried out.

Fig. 5.113 X-ray phase image of a tissue of a rat kidney. Tubules in the tissue, a part of which was clogged by protein (T), were depicted. Glomeruli (G) were also revealed (Courtesy of Drs. A. Momose, J. Wu, and T. Takeda)

X-Ray Phase Contrast Imaging (PCI)

The contrast of conventional X-ray transmission images, except for X-ray topography, is based on the positional difference of the absorption coefficient [5.87]. For materials consisting of light elements such as biological tissues and polymers, conventional X-ray transmission microscopy, unless staining with heavy elements is possible, is not efficient enough. Phase contrast imaging (PCI), as in optical microscopy (Sect. 5.1.2), is an approach to overcome this problem also in X-ray regions, though there is a difficulty due to the small size of the phase shift in light elements. However, in the soft X-ray region, the phase shift can be 10^3 times larger than in the hard X-ray region, so X-ray PCI has been introduced. Among the four schemes so far attempted, interferometric imaging, holography-like imaging, diffraction enhancement imaging, and Zernike-type microscopy, the interferometric method is most sensitive for acquiring phase contrasts. The method uses a Mach-Zehnder X-ray interferometer cut out of a large Si single crystal ingot which is mounted on a multiaxis goniometer set in the beam line of a synchrotron radiation source. X-ray phase shift computed tomography [5.88] exploiting the ability of phase retrieval allows one to reconstruct 3D images such as those shown in Fig. 5.113.

6. Surface and Interface Characterization

While the *bulk material properties* treated in Part C of this Handbook are obviously important, the surface characteristics of materials are also of great significance. They are responsible for the appearances of materials and surface phenomena, and they have a crucial influence on the interactions of materials with gases or fluids (in corrosion for example, Chap. 12), contacting solids (as in friction and wear, Chap. 13) or biospecies (Chap. 14) and materials–environment interactions (chapter 15). Surface and interface characterization have been important topics for very many years. Indeed, it was known in antiquity that impurities could be detrimental to the quality of metals, that keying and contamination were important to adhesion in architecture and also in the fine arts. In contemporary technologies, surface modification or functional coatings are frequently used to tailor the processing of advanced materials. Some components, such as quantum well devices and X-ray mirrors, are composed of multilayers with individual layer thicknesses in the low nanometer range. Quality assurance of industrial processes, as well as the development of advanced surface-modified or coated components, requires chemical information on material surfaces and (buried) interfaces with high sensitivity and high lateral and depth resolution. In this chapter we present the methods applicable to the chemical and physical characterization of surfaces and interfaces.

This chapter covers the three main techniques of surface chemical analysis: Auger electron spectroscopy (AES), X-ray photoelectron spectroscopy (XPS) and secondary ion mass spectrometry (SIMS) are all still rapidly developing in instrumentation, standards and applications. AES is excellent for elemental analysis at spatial resolutions down to 10 nm, and XPS can define chemical states down to 10 µm. Both analyze the outermost atom layers and, with sputter depth profiling, layers up to 1 µm thick.

Dynamic SIMS incorporates depth profiling and can detect atomic compositions significantly below

1 ppm. Static SIMS retains this high sensitivity for the surface atomic or molecular layer but provides chemistry-related details not available with AES or XPS. New reference data, measurement standards and documentary standards from ISO will continue to be developed for surface chemical analysis over the coming years.

The chapter also discusses surface physical analysis (topography characterization), which encompasses measurement, visualization and quantification. This is critical to both component form and to surface finish at macro-, micro- and nanoscales. The principal methods of surface topography measurement are stylus profilometry, optical scanning techniques, and scanning probe microscopy (SPM). These methods, based on acquiring topography data from point-by-point scans, give quantitative information on surface height with respect to position. The integral methods, which are based on a different approach, produce parameters that represent some average property of the surface under examination. Measurement methods, as well as their application and limitations, are briefly reviewed, including standardization and traceability issues.

6.1 Surface Chemical Analysis

The principal methods of surface chemical analysis are Auger electron spectroscopy (AES), X-ray photoelectron spectroscopy (XPS) and secondary ion mass spectrometry (SIMS). These three methods provide analyses of the outermost atomic layers at a solid surface but each have distinct attributes which lead to each having dominance in different sectors of analysis. Additionally, each may be coupled with ion sputtering, to erode the surface whilst analyzing, in order to generate a composition depth profile. These profiles may typically be over layers up to 100 nm thick or, when required, up to 1 μm thick or more. The depth resolutions can approach atomic levels. Useful figures to remember are that an atomic layer is about 0.25 nm thick and contains about 1.6×10^{19} atoms m^{-2} or 1.6×10^{15} atoms cm^{-2} . All of the above methods operate with the samples inserted into an ultrahigh vacuum system where the base pressure is designed to be 10^{-8} Pa (10^{-10} Torr) but, with fast throughputs or gassy samples, may degrade to 10^{-5} Pa (10^{-7} Torr). Thus, all samples need to be vacuum-compatible solids.

We shall describe the basics of each of the methods later but it is useful, here, to outline the attributes of the methods so that the reader can focus early on their method of choice.

In Auger electron spectroscopy (AES), the exciting radiation is a focused electron beam and, in the latest instruments, resolutions ≤ 5 nm are achieved. This provides elemental analysis with detectabilities reaching 0.1%, but not at the same time as very high spatial resolution. Additionally, the higher the spatial resolution, the more robust the sample should be, since the electron beam fluence on the sample is then very high. Thus, metals, oxides, semiconductors or some ceramics are readily analyzed, although at the highest flux density the surface of compounds may be eroded. In AES, there is chemical information but it is not as easily observed as in XPS. In XPS, the peaks are simpler and so quantification is generally more accurate, the chemical shifts are clearer, detectability is similar to AES, but the spatial resolution is significantly poorer. Typically, ≤ 5 μm spatial resolution is the best achieved in the latest instruments. In XPS, with the lower flux of charged particles, ceramics and other insulators may be analyzed more readily than with AES although, if spatial resolution ≤ 5 μm is required, AES must generally be used and efforts then need to be taken to avoid any charging or damage problems.

For layers with compositions that change within the outermost 8 nm, information on the layering may be obtained by XPS or angle-resolved XPS. If the compositions vary over greater depths, sputter depth profiling is used, generally with AES or, if more convenient or for particular information, with XPS. The sputtering is usually conducted in situ for AES and may be in situ or in a linked vacuum vessel for XPS.

Where greater detectability is required, as for studying dopant distributions in semiconductor device fabrication, SIMS is the technique of choice. Modern SIMS instruments have resolutions of around 100 nm, but critical to the semiconductor work is the ability to detect levels as low as 0.01 parts per million. In SIMS, the ion intensities depend sensitively on the matrix and so quantification is difficult for concentration levels above 1%, but in the more dilute regime the intensity is proportional to the composition. SIMS has thus found a dominant role here. The use of a mass spectrometer in SIMS allows isotopes to be separated and this leads to a useful range of very precise diffusion studies with isotopic markers. The above considerations for SIMS cover the technique that is often called dynamic SIMS or d-SIMS. Another form of SIMS, static SIMS or SSIMS, is used to study the outermost surface, and here detailed information is available to analyze complex molecules that is not available in XPS. This is less routine but has significant promise for the future.

Figure 6.1 [6.1] shows a diagram of the spatial resolution and information content of these and other techniques, which helps to place the more popularly used methods in context. Additional information is given in Table 6.1. These analytical techniques have all been in use in both industry and the academic sector since the end of the 1960s, but it is only more recently that fast throughput, highly reliable instruments have become available and also that good infrastructures have been developed to support analysts generally. Documentary standards for conducting analysis were started early by ASTM [6.2]. Just over ten years ago international activity started in the ISO in technical committee TC201 on Surface Chemical Analysis. Details may be found at the website given in reference [6.3] or on NPL's web site [6.4], following the route "ISO Standards and Accreditation". Table 6.2 shows the titles of ISO standards published to date and Table 6.3 the standards currently in draft. One-page articles on most of the published standards are given in the journal "Surface and Interface

Fig. 6.1 The resolution and information content of a range of analytical methods (*STM* = scanning tunneling microscopy, *AFM* = atomic force microscopy, *TEM* = transmission electron microscopy, *PEELS* = parallel electron energy loss spectroscopy, *SNOM* = scanning near-field optical microscopy, *μTA* = microthermal analysis, *EPMA* = electron probe microscopy) that can be used at surfaces (after *Gilmore et al.* [6.1])

Analysis". The relevant references are listed in the final column in Table 6.2.

Whilst consistent working depends on documentary standards, much quantitative measurement depends on accurate data and traceable measurement standards. This requires reference data, reference procedures and certified reference materials. Some of these are available at NPL's website [6.4], some on the website of the US National Institute of Standards Technology (NIST) [6.5],

and reference materials may be found from several of the national metrology institutes and independent suppliers. Further assistance can be found in essential textbooks [6.6–8] or online at usergroups [6.9]. We shall cite these as appropriate in the texts below. Of particular importance is ISO 18115 and the amendments in which over 400 terms used in surface analysis are defined and a further 300 are in draft. Relevant terms are used and defined here, consistent with that International

Standard. We first consider issues for measurement by AES and XPS and then for dynamic and static SIMS.

6.1.1 Auger Electron Spectroscopy (AES)

General Introduction

In AES, atoms in the surface layers are excited using an electron beam of typically 5 or 10 keV energy, but generally in the range 2 to 20 keV. In modern instruments this will typically be of 5 to 50 nA beam current, giving a spatial resolution in the range 20 nm to 2 μm and, in carefully designed instruments, below 5 nm. The surface atoms lose an electron from an inner shell and the atoms then de-excite either by an Auger transition –

emitting an Auger electron – or by filling with an outer shell electron and emitting an X-ray that would be detected in the complementary technique of electron probe microanalysis (EPMA). In the Auger process, an electron from a higher level, E_2 , fills the vacant inner shell level, E_1 , and the quantum of energy liberated is removed by a third electron from a level E_3 that is emitted with a characteristic energy, E_A , defined approximately by

$$E_A = E_2 + E_3 - E_1 \tag{6.1}$$

In (6.1), the energies of the bound levels E_1 , E_2 and E_3 are taken to be negative quantities. This is shown in Fig. 6.2a. Relaxation effects add small additional

TR = Technical report

XPS = X-ray photoelectron spectroscopy or spectrometer(s)

energy terms of the order of 5 or 10 eV, but (6.1) allows us to identify the characteristic peaks in the emitted electron energy spectrum and hence all the elements present except H and He. Core levels deeper than about 2.5 keV have weak ionization cross-sections and so Auger electrons with emitted energies greater than 2.5 keV are weak and are rarely analyzed. Additionally, Auger electrons with energies below 50 eV are superimposed on the large secondary electron emission background. Thus, the peaks used for analysis generally lie in the kinetic energy range 50 eV to 2500 eV and

this conveniently covers all of the elements except H and He.

The reason why AES is both surface-specific and surface-sensitive lies in the range of the Auger electrons before inelastic scattering causes them to be lost from the peak and merged with the background. In early work, this electron attenuation length, L , is given by [6.24]

$$L = \frac{538}{E_A^2} + 0.41 (aE_A)^{0.5} \text{ monolayers}, \quad (6.2)$$

where a^3 is the atomic volume in nm³. A typical value of a is 0.25 nm so that L ranges from one monolayer at low energies to ten monolayers at high energies.

Figure 6.3 shows a typical Auger electron spectrum from studies to characterize material used to aid quantification when analyzing the grain boundary segregation of phosphorus in steel. To obtain this spectrum, the material is fractured, in situ, in the spectrometer, to present the grain boundary surface for analysis. The peaks are labeled for both the direct mode and the differential mode of analysis. Historically, spectra were only presented in the differential mode so that the low energy peaks such as P and the minor constituents such as Cr, which occur on steeply sloping backgrounds, could be reliably measured. Simple methods of valid background subtraction are not generally available and so even though spectra may be recorded, today, in the direct mode, they are often subsequently differentiated using a mathematical routine with a function of 2 to 5 eV width [6.25, 26].

Fig. 6.2a,b Energy level diagram showing emission processes: (a) Auger electrons, (b) photoelectrons. The shaded region shows the conduction or valence bands to which the energy levels are referenced

Fig. 6.3a,b Auger electron spectra from the grain boundary fracture surface of a low alloy steel with 0.056 wt. % added phosphorus after a temper brittling heat treatment and analyzed using a cylindrical mirror analyzer, **(a)** direct mode presentation, with an *inset* magnified five times, and **(b)** differential mode presentation, with an *inset* magnified four times, after Hunt and Seah [6.33]. The fracture is made, in situ, usually by impact, in ultrahigh vacuum to stop the oxidation that would otherwise occur upon air exposure. Oxidation would remove the interesting elements from the spectra

The shapes of the spectra and the positions of the peaks may be found in relevant handbooks [6.27–31]. The transitions in AES are usually written using X-ray nomenclature so that, if the levels 1, 2 and 3 in (6.1) are the $2p_{3/2}$, $3p_{3/2}$ and $3d_{5/2}$ subshells, the transition would be written $L_3M_3M_5$ and, for the metals Ca to Cu, since M_5 is in the valence band, this is often written L_3M_3V . Auger electron peaks involving the valence band are usually broader than those only involving core levels and those involving two electrons in the valence band can be broader still. The precise energies and shapes of the peaks change with the chemical state. The transitions involving the valence band are the ones most affected by the chemical state and can show peak splitting and shifts of up to 6 eV upon oxidation [6.32]. The three large Fe peaks in Fig. 6.3 are LCC, LCV and LVV at 600, 651 and 700 eV, respectively, where C represents a core level. The LVV transition is the most strongly affected by oxidation in the series from Ti to Cu, with the effect strongest at Cr [6.32].

For quantitative analysis, many users apply a simple equation of the form

$$X_A = \frac{I_A/I_A^\infty}{\sum_i I_i/I_i^\infty}, \quad (6.3)$$

where X_A is the atomic fraction of A, assumed to be homogenous over the twenty or so atom layers of the analysis. In (6.3), the I_i^∞ are pure element relative sensitivity factors taken from the handbooks [6.27–31]. This gives an approximate result but suffers from three major deficiencies that may be resolved reasonably easily. We shall return to this later but will continue, for the present, to deal with the general usages of AES.

Two major uses that developed early concerned imaging and composition depth profiling using inert gas ion sputtering. Generally, in imaging, most analysts were content to use the peak intensity from the direct spectrum and then to remove an extrapolated background so that the brightness of each point in the image was proportional to the peak height. This is quick and easy in modern multi-detector systems. Earlier systems used the signal at the negative peak of the analog differential spectrum. These usages are simple and practical and can rapidly define points for subsequent analysis, but the interpretation of the contrast for samples with significant surface topography or for thin layers with underlying materials with different atomic numbers can be very complex.

Generally, in composition–depth profiling, argon ions in the energy range 1 keV to 5 keV are used with a current density of 1 to 30 $\mu\text{A}/\text{cm}^2$. Profiles could ei-

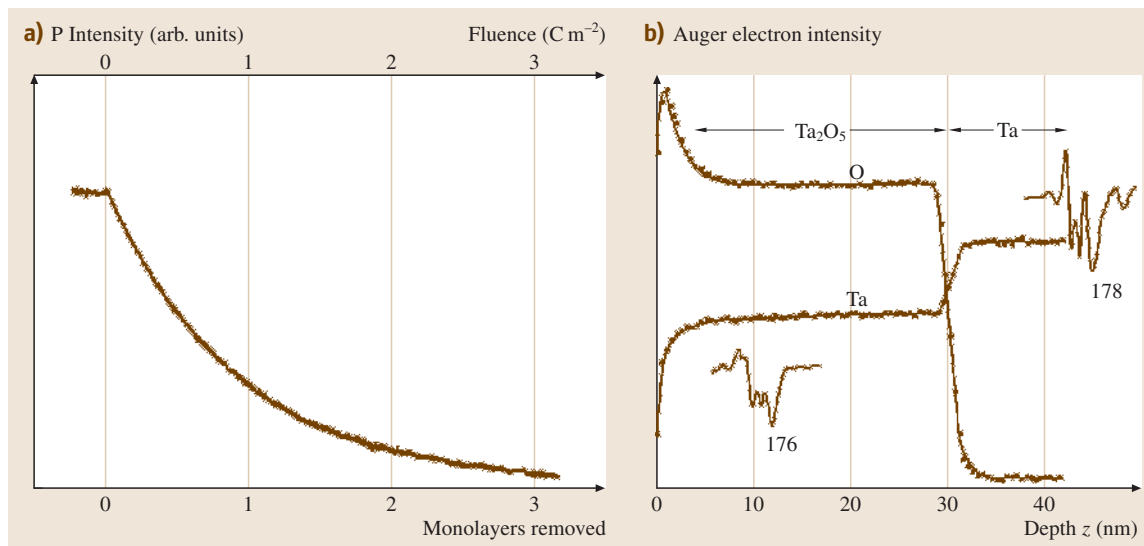

Fig. 6.4a,b Sputter depth profiles for differential signals in AES using argon ions (a) P signal at 120 eV from the low alloy steel in Fig. 6.3b using 3 keV ions [6.33], (b) O and Ta signals from a Ta_2O_5 layer 28.4 nm thick using 2 keV ions, after Seah and Hunt [6.36]. The steel sample is profiled after fracture, in situ, and so is not air-exposed, whereas the Ta_2O_5 layer had been prepared six months earlier, and been kept in laboratory air

ther be for monolayers, as exemplified in Fig. 6.4a by the profile for the segregated phosphorus shown in Fig. 6.3b, or for thicker layers, as exemplified in Fig. 6.4b for the tantalum pentoxide certified reference material (CRM) BCR 261 [6.34–37]. The quantification of the depth and the depth resolution are the critical factors here, and these we shall discuss in the section on sputter depth profiling.

Handling of Samples

In many applications of AES, the samples are prepared in situ in the ultrahigh vacuum of the instrument, and the user will be following a detailed protocol evaluated already in their laboratory or in the published literature. However, where samples have been provided from elsewhere or where the item of interest is the overlayer that is going to be depth-profiled, the samples will usually arrive with surface contamination. This contamination is usually from hydrocarbons and it attenuates all of the signals to be measured. It is useful to remove these hydrocarbons unless they are the subject of the analysis and, for most materials, HPLC-grade isopropyl alcohol (IPA) is a very effective [6.38] contamination solvent unless dealing with polymers or other materials soluble in IPA. This makes analysis of the surface both clearer and more accurate and, for sputter-depth profiling, removes much of the low sputter yield material that may

cause loss of depth resolution in the subsequent profile. Samples can then either be stored in clean glass containers [6.38] until needed or analyzed directly.

Details on how samples should be collected and supplied to the analyst are given in the draft ISO 18117 and for mounting them for analysis in draft ISO 18116 listed in Table 6.3. The guiding principle for mounting the sample is to reduce the presence of any material that causes gases in the vacuum system, contamination of the surface to be analyzed or local charging of insulating material.

We are now ready for analysis and need to consider the spectrometer.

Calibrating the Spectrometer Energy Scale

Depending on the type of spectrometer and its intended use, there are two ISO standards that provide procedures for calibrating the spectrometer energy scale. ISO 17973 is for medium-resolution systems designed for elemental analysis and is suitable for instruments with a relative resolution R of $\leq 0.5\%$, used in either the direct mode or the differential mode with a peak-to-peak differentiation of 2 eV. ISO 17974 is for high-resolution spectrometers intended for both elemental and chemical state analysis. With both standards, high-purity metal foils of the appropriate elements are used with their surfaces cleaned by a light ion sputtering. The exact peak energies are

Table 6.4 The reference kinetic energies, $E_{\text{ref } n}$, for kinetic energies referenced to the vacuum level. Values in brackets are referenced to the Fermi level

Peak number n	Assignment	Kinetic energy, $E_{\text{ref } n}$ (eV) Direct spectra	Differential spectra
1	Cu M _{2,3} VV	58 (62)	60 (64)
2	Cu L ₃ VV	914 (919)	915** (920**)
3	Al KL _{2,3} L _{2,3}	1388 (1393)	1390** (1395**)
4	Au M ₅ N _{6,7} N _{6,7}	2011* (2016*)	2021 (2026)

* For beam energies below 6 keV and for $0.25\% < R \leq 0.5\%$ add 1 eV
** For $0.27\% < R \leq 0.5\%$ add 1 eV
Table 6.4 is derived from work in [6.40–42]

Table 6.5 The reference values for the peak positions on the kinetic energy scale [6.42], $E_{\text{ref } n}^0$, for $R < 0.04\%$ if Al is used or $R < 0.07\%$ if Au is used

Peak number n	Assignment	$E_{\text{ref } n}^0$ (eV)
1	Cu M _{2,3} VV	62.37
2	Cu L ₃ VV	918.69
3	Al KL _{2,3} L _{2,3}	1393.09
4	Au M ₅ N _{6,7} N _{6,7}	2015.80

These kinetic energies are referenced to the Fermi level
Table 6.5 is a refinement of earlier tables [6.40,41,43]

defined by a simple, accurate protocol [6.39] and those are then compared with tabulated values obtained from traceable measurements.

For the medium-resolution spectrometers, the peak energies are given in Table 6.4 and, for most spectrometers, only Cu and Au foils are required. Note that values are given referenced to both the vacuum level and, in brackets, the Fermi level. In principle, energies can only be accurately referenced to the Fermi level, since the vacuum level – the level in the vacuum of the spectrometer

at which a stationary electron exists – varies from point to point in the spectrometer. This will change after bake-out, and depends on local surface work functions. This level generally exists at 4 to 5 eV above the Fermi level and, for convenience, a value of 4.5 eV is used in these ISO standards and elsewhere. The vacuum level is used here since all early work and the handbooks [6.27–31] use the vacuum level reference.

A few spectrometers do not measure kinetic energies above 2 keV and, for these, an alternative energy peak is provided in Table 6.4 using Al.

For high-resolution spectrometers, the vacuum level is too vague and data are Fermi level referenced. High-resolution spectrometers are often also used for XPS where only Fermi level referencing is used, and this enhances consistency. For high-resolution spectrometers, Cu and Au are again used, except in the exceptional circumstances where the spectrometer scale is limited to 2 keV and then the Au must again be replaced by Al, as shown in Table 6.5.

To obtain the necessary level of accuracy, either where the resolution R is poorer than 0.07% and when Au is used, or where R is poorer than 0.04% and when

Table 6.6 Corrections to the reference kinetic energies for resolutions poorer than 0.07% when Au is used, or poorer than 0.04% when Al is used

Peak number n	Assignment	c (eV)	d (eV)
1	Cu M _{2,3} VV	0.0	0.0
2	Cu L ₃ VV	0.2	–2.0
3	Al KL _{2,3} L _{2,3}	–0.3	–1.8
4	Au M ₅ N _{6,7} N _{6,7} : 5 keV $n(E)$	0.0	0.0
	5 keV $En(E)$	–0.3	4.4
	10 keV $n(E)$	–0.2	0.0
	10 keV $En(E)$	–0.1	0.0

Table 6.6 is a simplification of a more complex table [6.41]. Table 6.6 is consistent with the more complex table for relative resolutions in the range $0\% < R < 0.2\%$ to within 0.015 eV.

Al is used, a correction is required to the tabulated values such that the peaks are located at $E_{\text{ref } n}$ where

$$E_{\text{ref } n} = E_{\text{ref } n}^{\circ} + cR + dR^2. \quad (6.4)$$

The values of the coefficients c and d are given in Table 6.6, where the resolution R , given by $\Delta E/E$, is expressed in percent.

In these ISO standards, detail is provided of the signal levels to use, the contributions leading to uncertainties in the final calibration, and methods to ensure, as far as is reasonable, that the instruments are kept in calibration within their stated tolerance limits in order to be fit for purpose.

Repeatability of the Intensity Scale

All electron spectrometers use electron multiplier detectors and these, unfortunately, age with use. Thus, even though the analyst may use consistent spectrometer settings each time, the absolute intensity of the measured spectrum will slowly reduce. This reduction may be offset by increasing the detector multiplier voltage. However, then the user may observe that the relative intensities of peaks in the spectrum have changed and, if we quantify a spectrum via equations such as (6.3), the calculated value of X – the measured composition – will appear to have changed. These effects mean that the analyst needs to understand the behavior of the multiplier detector [6.44] in order to maintain long-term repeatability of measurements. Indeed, a failure to understand detector behavior can lead to gross spectral distortion [6.45].

With many pulse-counting systems, the electron multiplier is designed to give a sufficiently large output pulse that the detection electronics receives that pulse well separated in magnitude from the ambient noise in the system. However, the pulses from the multiplier have a distribution of intensities and so it is necessary to increase the multiplier gain until all of the pulses are clearly separated from the background noise. The gain is set by the multiplier voltage and the separation point is defined by a discriminator in the detector electronics. As the multiplier voltage is increased from a low level, at a voltage usually in the range 1800 to 2400 V, the count rate suddenly starts to rise, reaching 90% of its maximum over a range of about 250 volts. The count rate then rises more slowly to a saturation maximum value [6.46]. The transition from zero to the maximum count rate occurs rapidly except at high count rates [6.46]. At high count rates, the pulse height distribution broadens and the transition occupies a wider voltage range. NPL has

adopted a procedure, for single channel electron multipliers, of setting the multiplier voltage at 500 V more positive than the voltage required to observe 50% of the saturation count rate when set to measure around 100 kc/s. These values are not critical but do lead to precise setting of the multiplier voltage. This gives a reliable result and allows the user to track the multiplier behavior as it ages in order to replace the multiplier at a convenient time. If a significantly lower multiplier voltage than this setting is used, the count rates are lowered and the system becomes very nonlinear. If higher multiplier voltages are used, the linear counting range extends to higher counting rates but this occurs at the expense of the multiplier life [6.47].

In their normal use, all counting systems suffer some loss of counts at high counting rates arising from the counting electronics' dead time. Information on dead time may be found in references [6.46, 47] as well as ISO 21270. ISO 21270 also deals with the diagnoses of the gross nonlinearities that have been seen in the intensity scales of certain designs of detector [6.48, 49].

If the detector is correctly set, it is important to establish the constancy and repeatability of the instrument's intensity response. For AES, the ratio of the intensity of the Cu L_3 VV peak to that of the $M_{2,3}$ VV peak is a useful measure, particularly using the peak-to-peak differential heights. Providing sufficient intensities are acquired to be statistically meaningful, seven repeat measures of one peak followed by seven of the other allows the trend in the ratio during acquisition to be evaluated as well as the intensity ratio repeatability standard deviation. With around 2 M counts per channel at the peaks, ISO 24236 shows how a repeatability standard deviation of better than 0.5% may be attained if the data are recorded at 0.1 eV energy intervals and specific Savitzky and Golay smoothing [6.25] is used. Any drift in the absolute intensities or of the ratio between measurements may indicate a source, analyzer or detector instability that then needs to be investigated.

Calibrating the Intensity Scale

Interlaboratory studies to compare the shapes of spectra obtained in different laboratories unfortunately show that there are marked differences [6.50] that can lead to variations of a factor of two in quantification if the same relative sensitivity factors are to be used in all laboratories. These differences exist between similar models of spectrometer from the same manufacturer and arise mainly from the age-dependence of the detector efficiency, $D(E)$. $D(E)$ exhibits a curve that rises with the detected electron kinetic energy, E , from zero at $E = 0$

to a maximum in the energy range 200 to 600 eV and then to a slow decline at higher energies. In addition to the detector efficiency, there are electron optical terms to describe the spectrometer transmission function $T(E)$. These need to be combined to give the total instrumental response.

Formally, one may write the intensity/energy response function (IERF) as

$$\text{IERF} = T(E) D(E) \quad (6.5)$$

with additional terms, omitted here, that may arise from stray electron or magnetic fields [6.51]. The term $T(E)$ is usually approximately proportional to E for spectrometers operated in the constant $\Delta E/E$ mode and proportional to E^{-n} , where n ranges from 0 to 1, as the energy increases in the constant ΔE mode. In the constant $\Delta E/E$ mode, all voltages on electron optical elements of the spectrometer are scanned so that they remain in fixed proportion to each other. The resolution then deteriorates as the energy increases. This is the mode generally used for AES, unless high-resolution spectra are required, since very simple spectrometers may then be used with high efficiency and with high intensities at the high energies where the peaks are weak. On the other hand, the constant ΔE mode is used for high-resolution analysis so that ΔE , the spectrometer energy resolution, is maintained at, say, 0.25 eV at all energies. This is usually achieved by setting the pass element of the spectrometer to detect, say, 25 eV electrons, and then scanning this through the spectrum. If we know the IERF, the true spectrum that we need, $n(E)$, is given by

$$n(E) = \frac{I(E)}{\text{IERF}}, \quad (6.6)$$

where $I(E)$ is the measured spectrum.

In order to calibrate spectrometers for their absolute or relative IERFs, a series of studies were made using different configurations of an instrumented spectrometer with a Faraday cup detector to measure absolute reference spectra [6.50–53]. These spectra were measured for Cu, Ag and Au polycrystalline foil samples using a 5 keV electron beam at 30° to the surface normal. Using these spectra, the absolute IERF may be determined for any spectrometer. To facilitate this, a software system has been designed for users to self-calibrate their instruments based on their own measurements for these foils [6.54]. The reason for using three foils when, in principle, one would do, is to evaluate the scatter between the three independent IERF derivations in order to calculate the repeatability of the average IERF derivation. These derivations can be consistent to < 1%. In the

calibration, certain other diagnostics are important. For instance, internal scattering [6.55] may occur in some spectrometers and, if this has any significant intensity, it leads to uncertainty in the derived IERF. The above software diagnoses the extent of the internal scattering using the rules established in [6.55] with the Cu and Ag samples.

The true spectral shape obtained in this way will not change significantly with time provided the IERF is determined at appropriate time intervals. Being absolute, use may then be made of an extremely large volume of theoretical knowledge as well as background removal procedures based on physically meaningful algorithms [6.56, 57] in order to interpret different aspects of the spectra.

As noted earlier, many analysts do not use any significant theoretical evaluation of the spectra and simply use the peak-to-peak differential intensity. Relative sensitivity factors for (6.1) are available from several handbooks [6.27–31] but analysis shows that the lack of control of the IERF led to significant variability. Additionally, different choices of modulation energy for the differentiation increased that variability from source to source [6.58], so that half of the published sensitivity factors for each element differed from the average by more than a factor of 1.5. These issues are addressed below.

Quantitative Analysis of Locally Homogeneous Solids

It is useful to consider the basic derivation of sensitivity factors so that the user appreciates why things are done in certain ways and can link this text with older texts.

The Auger electron intensity per unit beam current into a small solid angle $d\Omega$ for a sample of pure element A involving the XYZ transition I_{AXYZ} may be calculated from the relation for homogeneous systems [6.59].

$$\begin{aligned} I_{\text{AXYZ}}^{\infty} = & \gamma_{\text{AXYZ}} n_{\text{AX}} \sigma_{\text{AX}}(E_0) \sec \alpha \\ & \times [1 + r_{\text{A}}(E_{\text{AX}}, E_0, \alpha)] N_{\text{A}} Q_{\text{A}}(E_{\text{AXYZ}}) \\ & \times \lambda_{\text{A}}(E_{\text{AXYZ}}) \cos \theta (d\Omega/4\pi) \end{aligned} \quad (6.7)$$

where γ_{AXYZ} is the probability that the ionized core level X in element A is filled with the ejection of an XYZ Auger electron, $\sigma_{\text{AX}}(E_0)$ is the ionization cross-section of the core level X in the element A for electrons of energy E_0 , n_{AX} is the population of the level X, α is the angle of incidence of the electron beam from the surface normal, $r_{\text{A}}(E_{\text{AX}}, E_0, \alpha)$ is the additional ionization of the core level X with binding energy E_{AX} arising from backscattered energetic electrons, $Q_{\text{A}}(E_{\text{AXYZ}})$ is a term

discussed later in this section, N_A is the atomic density of the A atoms, $\lambda_A(E_{\text{AXYZ}})$ is the inelastic mean free path (IMFP) for the XYZ Auger electrons with energy E_{AXYZ} in the sample A, and θ is the angle of emission of the detected electrons from the surface normal.

The inner shell ionization cross-section is often calculated using Gryzinski's formula [6.60], but a detailed analysis [6.61] shows that the formula of Casnati et al. [6.62] is significantly more accurate. Plots of these cross-sections may be found in [6.61].

The parameter γ_{AX} allows for the competing process of X-ray emission, where

$$\gamma_{\text{AX}} = 1 - \frac{Z^4}{Z^4 + Z_0^4} \quad (6.8)$$

and $Z_0 = 32.4$ [6.63] for X = K, 89.4 [6.63] for X = L, 155.9 [6.64] for X = M and 300 for X = the N shell [6.65].

The next term is the backscattering factor $r_A(E_{\text{AX}}, E_0, \alpha)$ and this is taken from the work of Shimizu [6.66]. General plots of this function may be found in [6.59]. Figure 6.4 in reference [6.67] shows the Z dependence of $[1 + r_A(E_{\text{AX}}, 5000, 30^\circ)]$ for various $E_{\text{AX}i}$, where the backscattering enhancement may reach over a factor of two. N_A values are evaluated from published data for elements [6.68, 69]. Figure 6.5 in [6.67] shows a plot of N_A vs. Z. This is strongly periodic and spans a range of values exceeding eight. The weak correction factor $Q_A(E_{\text{AXYZ}})$ is a term allowing for the reduction in overall escape probability of electrons from the solid arising from elastic scattering [6.70]. This parameter ranges from 0.9 to 1.0 and depends on the element and the electron energy. Values of Q may be taken from the plots of Seah and Gilmore [6.71]. The inelastic mean free path, $\lambda_A(E)$, can be taken from the TPP-2M formula [6.72] given by

$$\lambda_A(E) = \frac{E}{E_p^2 [\beta \ln(\gamma E) - (C/E) + (D/E^2)]} \text{ in } \text{\AA}, \quad (6.9)$$

where

$$E_p = 28.8(\rho N_v/A)^{0.5} \text{ in eV}, \quad (6.10)$$

$$\beta = -0.10 + 0.944(E_p^2 + E_g^2)^{-0.5} + 0.069\rho^{0.1}, \quad (6.11)$$

$$\gamma = 0.191\rho^{-0.50}, \quad (6.12)$$

$$C = 1.97 - 0.91W, \quad (6.13)$$

$$D = 53.4 - 20.8W, \quad (6.14)$$

$$W = \rho N_v/A. \quad (6.15)$$

In these equations, ρ is the density (in g cm^{-3}), N_v is the number of valence electrons per atom and A is the atomic weight. For metals, the value of E_g , the band gap, is zero. Recommended values for N_v have recently been published by Tanuma et al. [6.73]. Free software is available to facilitate this process [6.5, 74].

The above formulae allow us to calculate the intensity for a pure element and I_A^∞ (for simplicity, we now omit to define the particular transition XYZ) may be considered as a pure element relative sensitivity factor (PERSF). These are what one would obtain by measuring spectra in the reference handbooks [6.27–31], after correcting for the IERF. To compute the composition, one then needs to use not (6.2), but [6.59]

$$X_A = \frac{F_{\text{AM}}(I_{\text{AM}}/I_A^\infty)}{\sum_i F_{i\text{M}} I_{i\text{M}}/I_i^\infty}, \quad (6.16)$$

where the $I_{i\text{M}}$ are the intensities for the elements i measured in the matrix M of the sample. The matrix elements $F_{i\text{M}}$ are given by [6.59]

$$F_{i\text{M}} = \frac{N_i}{N_{\text{M}}} \frac{Q_i(E_i)}{Q_{\text{M}}(E_i)} \frac{[1 + r_i(E_i)]}{[1 + r_{\text{M}}(E_i)]} \frac{\lambda_i(E_i)}{\lambda_{\text{M}}(E_i)}. \quad (6.17)$$

The difficulty of calculating the $F_{i\text{M}}$ when the matrix is not known until the X_A are calculated leads most analysts to ignore the $F_{i\text{M}}$ and effectively replace them by unity. The $F_{i\text{M}}$ vary from 0.1 to 7 in different systems [6.67], and so this is the error involved by ignoring them.

In a recent formulation [6.67], Seah and Gilmore show that (6.2) is in fact valid if the PERSF, I_A^∞ , is replaced by the average matrix relative sensitivity factor (AMRSF) I_A^{Av} , given by

$$I_A^{\text{Av}} = \gamma_A n_A \sigma_A \sec \alpha [1 + r_{\text{Av}}(E_A)] N_{\text{Av}} Q_{\text{Av}}(E_A) \times \lambda_{\text{Av}}(E_A) \cos \theta \, d\Omega / 4\pi \quad (6.18)$$

In this equation, the items concerning effects inside the atom retain their original element A specificity and subscript A, but those outside, such as the number density, become that for an average matrix Av. Appropriate equations for the average matrix terms are given in references [6.67, 75] and may also be found in ISO 18118.

Many of the above numbers are difficult to calculate and so experimental databases are often used. However, we may now see why lack of calibration of the spectrometers and use of the wrong measures can lead to significant errors. Tables of data for AMRSFs and their constituent parts will be placed on the NPL website [6.3] in late 2006 for the convenience of analysts.

Quantification of Inhomogeneous Samples

The general quantification of inhomogeneous layers that vary over the outermost 8 nm is a complex issue dealt with in detail elsewhere [6.76, 77]. However, for AES there is a special case of particular interest to metallurgists and those studying catalysts; the case of the segregated layer one atom thick with partial coverage. Expressed as a fraction of a monolayer at the packing density of the substrate s , the fraction of the monolayer is given by θ_A where [6.59]

$$\theta_A = X_A \frac{L_s(E_A)}{a_s} \cos \theta, \quad (6.19)$$

where a_s^3 is the atomic volume of the substrate atoms and $L_s(E_A)$ is the attenuation length of electrons of energy E_A in the overlayer. $L_s(E_A)$ is related to $\lambda_s(E_A)$ [6.71], as discussed later at (6.21). In (6.19), θ_A is unity at a_s^{-2} atoms per unit area. Much early and some recent AES work in this area ignores the difference in concept between θ_A and X_A , leading to confusion and errors in the range 1 to 10.

Sputter Depth Profiling

The basic principle of sputter depth profiling is that one removes the surface layer-by-layer using inert gas ion sputtering, in situ, usually with 1 to 5 keV argon ions, whilst monitoring the remaining surface by AES. For samples with air-exposed surfaces there will be a level of hydrocarbon contamination that is first removed and, during this short period, the signals from the underlying material rise rapidly, as seen in Fig. 6.4b. This effect is not seen in Fig. 6.4a, as the surface there is not air-exposed. For elemental solids, the signal then remains constant until the layer is removed. The signal then falls to an appropriate level or zero for the next layer. If the layer is a compound, one element may be preferentially sputtered so that the quantified signal no longer reflects the composition prior to sputtering. For the Ta_2O_5 layer in Fig. 6.4b, we see the composition fall from Ta_2O_5 to approximately TaO as the oxygen is depleted. The compound is not stoichiometric TaO but a distribution of chemical states [6.78–80] over a thin layer of the order of the projected range [6.81] of the sputtering ion. This range is typically slightly more than the analysis depth [6.82].

The preferential sputtering of compounds has been a long and rather frustrating area of research where theoretical models have been proposed [6.79, 83–86] but predicting the effect in any quantitative way is currently not possible. To quantify a profile involving a compound, the best way is to sputter a reference layer of the com-

pound under identical conditions to the sample in order to evaluate the spectral intensities expected. Generally, those conducting profiles are less interested in quantifying compound layers that they know are there, and are more interested in changes in the layers as a result of, say, a heat treatment that leads to changes in the interface shape. Thus there is already a built-in reference layer. To measure changes at the interfaces, good depth resolution is required.

In early studies of sputtered metallic layers, the depth resolution, Δz , deteriorated roughly according to

$$\Delta z = kz^{0.5}, \quad (6.20)$$

where, for Δz and z in nm, k is approximately unity [6.79, 87]. This was caused by the development of topography, that can be measured by scanning electron microscopy (SEM), as described in Sect. 6.2.4, or atomic force microscopy (AFM) in Sect. 6.2.3. For single-crystal wafer studies, it was found that the depth resolution, which starts as an exponential decay of one monolayer (≈ 0.26 nm) for a submonolayer film, as shown in Fig. 6.4a, degrades and saturates at approximately 1 nm [6.87, 88] for thicker films.

A major development was made by Zalar [6.89], who suggested rotating the samples whilst sputtering in the same manner as when preparing samples for the transmission electron microscope (TEM). With rotation speeds of about 1 revolution per minute, excellent results of 5 nm resolution are obtained, even for the difficult polycrystalline metallic layers [6.90]. It is essential that the electron and ion beams are properly aligned to the same point on the sample surface, irrespective of the use of rotation or not, in order to obtain the best depth resolution [6.91].

In the above, we have used the term depth resolution without clearly defining it. In ISO 18115 it is defined as the depth range over which a signal changes by a specified quantity when reconstructing the profile of an ideally sharp interface between two media or a delta layer in one medium. In an attached note it adds that, for routine analytical use, a convention for the specified levels is 16% to 84% for layers such as those shown in Fig. 6.4b. These levels arise from the standard deviation points when the interface resolution is described by a Gaussian function. For very high-resolution profiles, the interface shape is described by exponentials [6.36, 90] and the above convention, although useful, then has no specific correlation with a physical model.

Above, we have considered Δz , but also critical is the measurement of the absolute depth z . Measurement

Fig. 6.5 Calculated sputtering yields of elements using argon ions at 45° to the sample surface for several energies as a function of the atomic number of the sample, Z_2 [6.3, 82, 93]

of the sputtered depth is covered in the ISO technical report ISO/TR 15969. Usually, a stylus profilometer is used as described in Sect. 6.2.1, but certain laboratories prefer optical techniques, as in Sect. 6.2.2, or AFM as in Sect. 6.2.3. The AFM can be particularly useful for small, shallower craters where the roughness of the crater base is also of interest. There are several issues that analysts need to be aware of that are of increasing importance at shallower depths. At the start of sputtering, some contamination is removed. This takes a brief time. Next, the incident ions are implanted, causing a slight swelling. As the beam particles build up in the sample, the sputtering yield changes until, after sputtering for approximately 1 nm, an equilibrium is established. After this, the system remains constant if rotation is used; if not, a surface topography may develop that slowly reduces the sputtering rate. For sputtering with argon ions, the build-up of argon is typically 2.5% [6.92] and so these effects are small and are generally ignored. A further effect, seen for samples that react with the air, is that the crater base will swell as it oxidizes on air exposure prior to the depth measurement. If a correlation of time and depth is made for many craters, a straight line correlation should be found but it may not pass through the origin. Typically, this offset may be up to 1 nm for Si wafers.

Where a system comprises layers of different types, the sputtering rate will change from layer to layer, and an elapsed time to depth conversion cannot be made with one sputtering rate. Figure 6.5 shows the sputtering

rate for argon incident at 45° for several energies and many elements. The rates for different elements clearly vary enormously. The rate then needs to be evaluated for each layer separately or evaluated through calculation of the relevant sputtering yields Y and a measurement of the ion beam current density J at the AES measurement point:

$$d = \frac{Jt Ya^3}{e}, \quad (6.21)$$

where t is the time for sputtering that layer, e is the electronic charge, and a^3 is the atomic volume deduced from

$$1000\rho Na^3 = A. \quad (6.22)$$

Ion beam currents generally need to be measured using a screened Faraday cup, but focused ion beam currents may be measured using an appropriately drilled hole in a sample or the sample stage [6.94]. In (6.22), ρ is the density of the element (kg/m^3) of atomic weight A , and N is Avogadro's number. Thus, d may be determined if Y is known. Values of Y have been tabulated for many elements and some compounds. Recent work has led to a significant improvements in the accuracy of calculating Y for elements for Ne, Ar and Xe bombarding ions at 0° and 45° angles of incidence [6.82, 92], with a typical uncertainty, as shown in Fig. 6.5, of 10%. The equations are rather complicated, and so plots of the yields may also be found as tables on the NPL website [6.93]. The uncertainty from this convenient route, however, means that it is not as accurate as a direct measurement of depth.

Fig. 6.6 X-ray photoelectron spectrum for Cu using an unmonochromated Al X-ray source. The photoelectron peaks are labeled “X” and the Auger electron peaks “A”. The positions of the Cu Fermi level (FL) and the photoemitted Fermi level electrons (XFL) are indicated [6.43]. The vacuum level, indicated by the start of the spectrum, is 4.5 eV above the Fermi level (FL) and is shown exaggerated here for illustrative purposes

For sputter depth profiling, Ar is most popular. Occasionally, if the argon AES peaks interfere with the peaks to be measured, Ne or Xe may be used [6.92]. Some analysts prefer Xe, as the depth resolution is then improved sometimes.

6.1.2 X-Ray Photoelectron Spectroscopy (XPS)

General Introduction

XPS has a considerable base in physics, in common with AES, and is often conducted in the same instrument. XPS uses characteristic X-rays to excite electrons that are energy-analyzed by the same spectrometer that is used for high-energy resolution AES analysis. Thus, XPS instruments often have an added electron gun for AES. The X-ray source is generally of Mg or Al K α X-rays or, in many modern instruments, monochromated Al K α X-rays. As shown in Fig. 6.2b, the X-rays of energy $h\nu$ directly eject core electrons from the solid with kinetic energy E given by

$$E = h\nu - E_1, \quad (6.23)$$

where it is these E_1 values, the core level binding energies, that are required in XPS. Thus, the E_1 values are usually taken to be positive values, unlike (6.1), and the

binding energy scale is usually used directly rather than the Fermi level referenced kinetic energy E . The values of E_1 provide information about the chemical state of the element analyzed. Tabulated binding energies for the elements may be found in Bearden and Burr [6.95] and for elements and compounds in handbooks [6.96–98], text books [6.99] and websites [6.100]. Note that whilst Bearden and Burr use the X-ray nomenclature for energy levels, as is common for AES, this is rarely used in XPS. Here, the level number and subshell letter with the spin orbit coupling number is given so that M_V or M₅ translates to 3d_{5/2}. After the initial excitation, the atom is left with a core hole that can be filled by an Auger process ejecting an Auger electron. This electron also appears in the measured spectrum. Figure 6.6 shows a photoelectron spectrum for copper with the photoelectron and Auger electron peaks labeled.

The photoelectrons are mostly in the kinetic energy range 500 to 1500 eV, and so XPS is similar to AES in its surface sensitivity. For a few (often important) elements, the characteristic peaks may have kinetic energies as low as 200 eV.

Handling of Samples

The handling of samples for XPS is generally the same as that for AES, except that the types of sample tend to be rather different. Environmental contaminants such as poly(dimethyl siloxane) (PDMS) and similar materials are often analyzed, and so it is rare for samples to be cleaned. More samples are insulating and so greater consideration needs to be given to charge control and charge correction. Information on most of the important methods for these is given in ISO 19318, but what is achievable often depends on the specific instrumental set-up. Samples can be in the form of polymer films or powders generally not studied by AES.

In some instruments, mounting the sample under a grid or aperture works well for charge control, but in others this leads to broader peaks. With monochromated X-rays, an electron flood gun or very low energy ion flux may be required for charge control. Whatever is used, the analyst should ensure that the sample is not exposed to unnecessary levels of radiation, since most of these samples are easily degraded by heat, electrons or ions [6.101, 102].

Calibrating the Spectrometer Energy Scale

As for AES, Cu and Au samples set with their angle of emission $\leq 56^\circ$ are sputtered clean, and the measured energies of the peaks listed in Table 6.7

Table 6.7 The reference values for peak positions on the binding energy scale [6.103, 105] $E_{\text{ref}n}$

Peak number n	Assignment	$E_{\text{ref}n}$ (eV)		
		Al $K\alpha$	Mg $K\alpha$	Monochromatic Al $K\alpha$
1	Au 4f _{7/2}	83.95	83.95	83.96
2	Ag 3d _{5/2}			368.21
3	Cu L ₃ VV	567.93	334.90	
4	Cu 2p _{3/2}	932.63	932.62	932.62

Table 6.7 is a refinement of earlier tables [6.43, 104]

are compared with the energy values given there. As for AES, the peak energy for the calibration is evaluated from the top of the peak without background subtraction [6.39]. In Table 6.7, peak number 3 is an Auger electron peak and, whilst this works well for unmonochromated X-rays, it cannot be used accurately with a monochromator. The lineshapes and energies of the $K\alpha_1$ and $K\alpha_2$ X-rays that characterize $h\nu$ in (6.23) appear to be the same in all unmonochromated instruments. However, the lineshapes and energies of the $K\alpha$ X-rays, when monochromated vary significantly and depend on the set-up of the monochromator and its thermal stability. By altering the monochromator settings, the measured energies of the peak may be moved over a kinetic energy range of 0.4 eV without too much loss of intensity [6.103]. Thus, for monochromated systems, in Table 6.7 the Cu Auger electron peak is replaced by the 3d_{5/2} photoelectron peak from Ag. This action requires the cleaning of an additional sample.

In ISO 15472, the calibration given in Table 6.7 is included into a full protocol that includes methods of conducting the calibration, assessing the uncertainties, establishing tolerance limits and evaluating a calibration schedule. For laboratories operating under a quality system [6.106], and for analysts trying to ensure the validity of their data, these are essential. Use of the standard with a modern, well-maintained spectrometer should result in calibration within tolerance limits of ± 0.2 eV over four months or ± 0.1 eV over one month before recalibration is required. For many purposes ± 0.2 eV is satisfactory.

Repeatability of the Intensity Scale

For XPS, the evaluation of the repeatability of the intensity scale is similar to that for AES in Sect. 6.1.1. Of critical importance are the comments made there in relation to detectors and especially ISO 21270 on the linearity of the intensity scale. For XPS, the inten-

sity ratio is determined from cleaned copper using the Cu 3p and Cu 2p_{3/2} peak areas after subtracting a Shirley background [6.107]. Smoothing of the end-points for establishing the Shirley background can improve the precision and enable repeatabilities as good as 0.2% to be achieved in a series of measurements. ISO 24237 describes the signal levels and procedures needed to get the best quality data from a sample of copper, how to build that into a monitoring protocol, and how to set up tolerance limits for a control chart to try to ensure that the intensity measurements remain fit for purpose.

Calibrating the Intensity Scale

Interlaboratory studies to compare the shapes of spectra obtained in different laboratories unfortunately show that there are marked differences [6.52]. These lead to variations of a factor of two in quantification if the same relative sensitivity factors were to be used in all laboratories.

The situation here and the rationale and protocol for evaluating and using the IERF are precisely the same as in the earlier section on calibrating the intensity scale for AES, except that instead of measuring the spectra from the Cu, Ag and Au reference foils using 5 keV electrons, we use the Al or Mg X-rays at incident angles in the range 0° to 50° from the surface normal.

Relative sensitivity factors for (6.3) are available from several handbooks [6.96–98], textbooks [6.108] and publications [6.58, 109]. Early sensitivity factors varied significantly [6.58] and it is not clear if these later values are consistent for the instruments intended or if significant uncertainties still persist. An analysis has not been made since the assessment in 1986 [6.58] showed that the sensitivity factor data sets were very variable. This partly arose because the IERFs of the instruments used were not measured in these handbooks. In the next section we address the basic concept of the peak intensities.

Fig. 6.7a,b Dependence of ω on Z for various electron kinetic energies: **(a)** at 200 eV intervals from 200 to 1000 eV and **(b)** at 400 eV intervals from 1000 to 2600 eV [6.71]

Quantitative Analysis of Locally Homogeneous Solids

Following the procedure for **AES**, the X-ray photoelectron intensity per photon of energy $h\nu$ into a small solid angle $d\Omega$ for a pure element A from the subshell X_i is given by

$$I_{AX_i}^{\infty} = n_{AX_i} \sigma_{AX_i} \sec \alpha N_A Q_A(E_{AX_i}) \lambda_A(E_{AX_i}) \times \left[1 + \frac{1}{2} \beta_{\text{effAX}} \left(\frac{3}{2} \sin^2 \gamma - 1 \right) \right] \times \cos \theta (d\Omega/4\pi), \quad (6.24)$$

where n_{AX_i} is the population of electrons in the subshell i of the core level shell X of element A, σ_{AX_i} is the ionization cross-section for that core level for the photons of energy $h\nu$, α is the angle of incidence of the X-ray beam from the surface normal, γ is the angle between the incident X-ray beam and the direction of the photoemitted electrons, and the other terms are as for **AES**. Values of the product of n_{AX_i} and σ_{AX_i} are taken from the data of *Scofield* [6.110]. Other cross-sections exist but have been shown to be less accurate [6.111].

At the magic angle, where $\gamma = 54.7^\circ$, the final term in square brackets in (6.14) is unity. However, at other angles this function is generally higher than unity for $\gamma > 54.7^\circ$. The values of β are tabled by *Yeh and Lindau* [6.112] and by *Reilman et al.* [6.113] as well as

others. The parameter β is valid for gas phase work, but in solids *Jablonski* [6.70] it has shown that β is reduced to β_{eff} by elastic scattering. *Seah and Gilmore* [6.71] reduce *Jablonski's* Monte Carlo data to sets of equations such as

$$\beta_{\text{eff}}(\theta) = \beta_{\text{eff}}(0)(1.121 - 0.208 \cos \theta + 0.0868 \cos^2 \theta), \quad (6.25)$$

where

$$\beta_{\text{eff}}(\theta)/\beta_{\text{eff}} = 0.876[1 - \omega(0.955 - 0.0777 \ln Z)], \quad (6.26)$$

where the value of ω may be read from graphs [6.71] or Fig. 6.7.

The above calculation gives the PERSFs for **XPS**. However, for quantification, as we discussed for **AES**, we really need AMRSFs and then we may use (6.3). If we use PERSFs in (6.3) and effectively ignore the relevant matrix factors, the errors involved range from 0.3 to 3 [6.75]. Using PERSFs we obtain (6.16) and (6.17), except that the $[1 + r(E)]$ term is replaced by the $[1 + \frac{1}{2} \beta_{\text{eff}}(\frac{3}{2} \sin^2 \gamma - 1)]$ term. Then [6.75, 114]

$$I_A^{\text{Av}} = n_{AX_i} \sigma_{AX_i} N_{\text{Av}} Q_{\text{Av}}(E_{AX_i}) \lambda_{\text{Av}}(E_{AX_i}) \times G_{\text{Av}}(E_{AX_i}), \quad (6.27)$$

where [6.114]

$$G_{\text{Av}}(E_{AX_i}) = 1 + \frac{1}{2} \beta_{\text{effAvAX}_i}(\theta) \left(\frac{3}{2} \sin^2 \gamma - 1 \right). \quad (6.28)$$

Here β_{eff} is calculated via (6.25) and (6.26) with $Z_{\text{Av}} = 41$ and ω_{Av} deduced from Fig. 6.7 or the NIST databases [6.5, 115].

In the past, the differences between the PERSFs and AMRSFs have not been recognized and, in general, the experimental data have been for compounds and not elements and so relate more closely to AMRSFs. But these had no spectrometer calibration and further were often blended with PERSF calculations, leading to parameters that were ill-defined but which were adjusted by manufacturers to give valid results on their equipment when tested against certain reference compounds. As noted in Sect. 6.1.1, tables of data for AMRSFs and their constituent parts will be placed on the NPL website [6.3] in late 2006 for the convenience of analysts.

Quantification of Thin Homogeneous Overlayers

An important use of XPS is the measurement of overlayer thicknesses of up to 8 nm. The intensities of a pure layer of A of thickness d on a substrate of B are given by

$$I_A = I_A^\infty (1 - \exp\{-d/[L_A(E_A) \cos \theta]\}) \quad (6.29)$$

and

$$I_B = I_B^\infty \exp\{-d/[L_A(E_B) \cos \theta]\}. \quad (6.30)$$

In the approximation of no elastic scattering, the L_A values would be the IMFPs λ_A . However, in the presence of elastic scattering, *Cumpson and Seah* [6.116] showed that λ_A should be replaced by the attenuation length L_A and that (6.29) and (6.30) were valid for $\theta \leq 58^\circ$. *Seah and Gilmore* [6.71] analyze these data to show, as an analog to (6.16), that elastic scattering leads to

$$\frac{L}{\lambda} = 0.979[1 - \omega(0.955 - 0.0777 \ln Z)]. \quad (6.31)$$

More detailed calculations by *Jablonski and Powell* [6.117] give similar results.

For general films, (6.29) and (6.30) are not easy to solve for d from values of I_A and I_B since, if $E_A \neq E_B$, the analysis must become iterative. For this reason, *Cumpson* devised the “Thickogram” to help solve this problem [6.118]. For metals and their oxides as overlayers, (6.29) and (6.30) can be used for the oxygen peak and the substrate in the metallic form. However, any adsorbed moisture on the surface adds to the oxygen peak [6.119], and a better method is to use the substrate metal intensities in the oxide (o) and elemental (e) states using XPS with peak synthesis. This has the advantage that $E_A = E_B$ sufficiently closely that their difference

may be ignored. Thus, in XPS:

$$d = L_o \cos \theta \ln(1 - R_{\text{expt}}/R_o), \quad (6.32)$$

where $R_{\text{expt}} = I_o/I_e$ and $R_o = I_o^\infty/I_e^\infty$. The value of R_o may be calculated but, for accurate measurements of d , it is recommended that R_o is measured experimentally using the same peak fitting as will be used for the analysis. If the samples can be reasonably cleaned, and if there is a significant range of thicknesses, a plot of I_o versus I_e gives the sought-after I_o^∞ and I_e^∞ as the intercepts of the axes since, from (6.29) and (6.30)

$$\frac{I_o}{I_o^\infty} + \frac{I_e}{I_e^\infty} = 1. \quad (6.33)$$

The use of (6.32) to quantify the thicknesses of thermal SiO₂ layers on Si wafers has been evaluated in a major international study [6.119, 120] involving comparison with medium energy ion scattering (MEIS), Rutherford backscattering spectrometry (RBS), elastic backscattering spectrometry (EBS), nuclear reaction analyses (NRA), secondary ion mass spectrometry, ellipsometry, grazing incidence X-ray reflectance (GIXRR), neutron reflectance (NR) and transmission electron microscopy (TEM). The thicknesses were in the range 1.5 nm to 8 nm to cover the range for ultrathin gate oxides. In order to use (6.32) reliably in XPS, the diffraction or forward-focusing effects of the crystal substrate need to be averaged or avoided [6.121]. To do this, a reference geometry (RG) is used with the emission direction at 34° to the surface normal in an azimuth at $22, 5^\circ$ to the [011] direction for (100) surfaces, and 25.5° from the surface normal in the [101] azimuth for (111) surfaces [6.121]. If these orientations are not chosen, R_o tends to be smaller and (6.32) gives a result that is progressively in error for thinner layers. Using the above approach, excellent linearity is obtained [6.122], and excellent correlations with the other methods show that L_o can be calibrated to within 1%, allowing XPS to be used with very high accuracy. Care needs to be taken, when working at this level, to ensure that the angles of emission are accurately known [6.123].

In the study, when matched against the XPS thickness d_{XPS} , most of the other methods lead to offsets c in the relation

$$d = m d_{\text{XPS}} + c. \quad (6.34)$$

These offsets, c , are shown in Fig. 6.8 [6.119]. For MEIS, NRA and RBS, the offset represents the thickness of the adsorbed oxygen-containing species, such as water, since these methods measure the total oxygen thickness

Fig. 6.8 The offsets c measured for various techniques, shown by their averages and standard deviations when compared to XPS from [6.119], updated for data in [6.123]. Note that one atomic layer is approximately 0.25 nm thick

rather than oxygen in SiO₂. The offset of 0.5 nm represents between one and two monolayers of water. For ellipsometry, where the measurements are in air, there is a further layer of hydrocarbon and physisorbed water that builds this up to around 1 nm. The offset for TEM is not understood and may arise from progressive errors in defining the thicknesses of the thinner films. The offsets for GIXRR and NR also arise from the contaminations but are weaker in NR and may, in future, be fully removed by modeling.

The analyses of more complex profiles are discussed by Cumpson [6.76] and by Tougaard [6.77].

Sputter Depth Profiling

There is essentially very little difference between sputter depth profiling using XPS and that using AES except concerning certain practical issues. Firstly, if unmonochromated sources are used, the larger area analyzed requires a larger area to be sputtered and generally a poorer depth resolution is obtained. This arises from the difficulty in retaining a flat, uniform depth over a larger area. With focused monochromators this should not be a problem, but the depth resolution is rarely as good as for AES. Secondly, the need to maintain a good vacuum environment around the X-ray source discourages the use of in situ, large-area ion guns with their higher gas loads.

Much of the advantage of XPS – of measuring the chemical state – is lost as a result of the changes in

composition brought about by preferential sputtering by the ion beam. Thus, XPS depth profiling is less popular than that for AES, but there is no reason, in principle, for not using XPS.

6.1.3 Secondary Ion Mass Spectrometry (SIMS)

General Introduction

In secondary ion mass spectrometry, atoms and molecules in the surface layers are analyzed by their removal using sputtering and subsequent mass analysis in a mass spectrometer. The majority of emitted ions come from the outermost atom layer. Unfortunately, most of the particles are emitted as neutral atoms and only 10⁻⁴ to 10⁻² are emitted as ions. Nevertheless, the detection capability of SIMS is generally far superior to those of AES or XPS. A second problem is that the intensity of the ion yield is extremely matrix-sensitive and there are, as yet, no methods for calculating this effect accurately [6.124]. These properties have led to SIMS becoming very important in two major fields and being used in two distinct ways.

Historically, the most important approach has been that of dynamic SIMS, and this has found major use in characterizing wafers for the semiconductor industry. It is here that measurement issues are critical, and so it is here that we shall focus. More recently, the second approach – that of static SIMS – has been able to provide unique information concerning complex molecules at surfaces. Static SIMS has been in use for more than 30 years, but recent instrumental developments have made the method reliable and more straightforward for industrial analysts to use. We shall treat these fields separately below, but note that their separation is reducing. In a recent analysis of publications for the biennial SIMS conferences (I.S. Gilmore, private communication, 2004), the historical dominance of dynamic SIMS has disappeared, and research effort is currently slightly biased in favor of static SIMS.

Dynamic SIMS

In dynamic SIMS, the use of well-focused ion beams or imaging mass spectrometers allows submicron images of the surface to be obtained with very high sensitivity and with isotope detection easily facilitated. At present, 50 nm spatial resolution can be achieved. High-resolution imaging is usually achieved with the removal of a significant amount of the surface material, and this is why it is called dynamic SIMS or (historically) just SIMS. The dynamic removal of material allows composition depth profiles to be measured, and it is

Fig. 6.9 Profiles of 500 eV boron and 500 eV arsenic implants in silicon using O_2^+ and Cs^+ ion beams, after *Hitzman and Mount* [6.125]. These show the benefit of very low energy primary ion beams

these profiles for the semiconductor industry that account for much of the routine industrial analysis. All of the ISO standards in this area (Table 6.2, Table 6.3), certified reference materials and two-thirds of the dynamic SIMS applications at meetings (I.S. Gilmore, private communication, 2004) concern depth profiling with semiconductors. There are two essential measurement issues that require quantification in sputter–depth profiles for dopants in semiconductors: the composition and the depth scale. However, these cannot be evaluated in many cases without considering the depth resolution. SIMS is very powerful when studying dopants, since the method has the high sensitivity required for the low concentrations, as shown in Fig. 6.9. Fortunately, the peak concentration levels are still sufficiently low that linearity of composition and signal can still, generally, be assumed. We shall start by considering the depth resolution.

Depth Resolution. In AES and XPS, we have defined the depth resolution from the profile width of a sample characterized by a step function composition. This is very useful for the small dynamic range of those spectroscopies, but in SIMS it is more useful to characterize the resolution by the slope of the exponentials describing the up or down slopes as the new region is entered or exited. These slopes are termed the leading edge decay length λ_c and the trailing edge decay length λ_t in ISO 18115, and are defined as the characteristics of the respective exponential functions. These have a physical basis, unlike the descriptions used for AES or XPS. Since one

is often dealing with dilute levels, the depth resolution is best characterized by the up and down slopes from delta layers. The method for estimating depth resolution in this way is described in ISO 20341, based on the analytical description of Dowsett et al. [6.126] and illustrated, with detailed data, by Moon et al. [6.127] using five GaAs delta layers in Si at approximately 85 nm intervals.

In Fig. 6.9, one clearly sees that the ion beam species, angle of incidence and energy all affect the depth resolution, and that this affects the tail of the dopant distribution, its half-width, and the position and magnitude of the peak. It is generally also true that the lower the beam energy and more grazing the incidence angle, the better the depth resolution. In many mass spectrometers, a high extraction field is used to focus all of the ions ejected from the sample into the mass spectrometer, and the consequent field around the sample effectively limits the choice of energy and angle of incidence. To avoid this limitation, the traditional quadrupole mass spectrometer has retained its popularity. With these mass spectrometers, the low extraction field allows very low energy ion guns to be utilized [6.128, 129]. For instance, Bellingham et al. [6.130] show that for a 1 keV ^{11}B implant, the trailing edge decay length λ_t , when profiled using O_2^+ at normal incidence, increased with the beam energy E approximately as

$$\lambda_t = 0.13 + 0.1E, \quad (6.35)$$

where λ_t is in nm and E is in keV. The lowest value, 0.14 nm, was obtained using a 250 eV O_2^+ beam (125 eV

per atom). For delta layers, the trailing edge decay length is always greater than the leading edge decay length as a result of the forward projection of the dopant atoms. Therefore attention is directed above to λ_t .

Considerable effort is expended designing focused ion beams that work at these low energies and yet still have sufficient current density to be able to profile significant depths in a reasonable time for practical analysis. Use of more grazing incidence angles is also beneficial [6.129, 130], but this can usually only be achieved by tilting the sample, and this generally detrimentally affects the ion collection efficiency. The choice of ion species also affects the depth resolution, and in general the larger the incident ion cluster, the lower the energy per constituent atom and the shorter the trailing edge decay lengths. Thus, Iltgen et al. [6.131] show that when profiling delta layers of B in Si with 1 keV ions and with O_2 flooding of the sample, SF_5^+ is better than O_2^+ , and that, in turn, is better than Xe^+ , Kr^+ , Ar^+ and Ne^+ .

Recognizing the limitation of λ_t for shallow implants being affected by the atomic mixing, many authors [6.132–134] now experiment with removing the substrate chemically and profiling the critical layer from the backside. This reduces the atomic mixing and should improve the detection limit, but issues then arise from the flatness of the substrate removal.

Depth. The depth scale may be obtained by using the signal from a marker layer at a known depth, or by measuring the depth of the crater after profiling, or by calculating from the sputtering yield. The latter route [6.82, 92] is very convenient but only accurate, as noted earlier, to some 10%. The usual route is to use a stylus depth-measuring instrument, as described in 6.2.1, to define the crater depth in the region from which the signal is obtained. Alternatively, as discussed in ISO 17560, optical interferometry, as described in 6.2.2, may be used. Both of these give an accurate measurement of the crater depth, d_o , at the end of the profile at time t_o . Analysts then generally scale the depth d at time t according to

$$d = \frac{d_o}{t_o} \quad (6.36)$$

using the assumption that the sputtering yield or sputtering rate is constant. Unfortunately, this is only true once equilibrium is established.

At the present time, we cannot accurately calculate how the sputtering rate changes as the surface amorphizes and the incident ions dynamically accumulate in the eroding surface layer, but the effect can be meas-

ured. Moon and Lee [6.135] show, for instance, that the sputtering yield of Si falls from 1.4 to 0.06 as a result of 3.5×10^{16} 500 eV O_2^+ ions cm^{-2} incident normally on an amorphous Si layer. Wittmaack [6.136] finds that the rate for O_2^+ ions at 1 keV and 1.9 keV, at 55° to 60° incidence, falls to 40% after sputtering 2–5 nm. In more recent work studying thermal SiO_2 films, Seah et al. [6.119] find that the rate, when using 600 eV Cs^+ , falls similarly by a factor of two over the initial 1.5 nm.

In a recent study by Homma et al. [6.137] using multiple BN delta layers in Si with pitches of 2 or 3 nm, it is shown that the sputtering rate for 250 eV O_2^+ ions falls by a factor between 1.2 and 1.43, depending on the delta layer pitch and the ion beam angle of incidence. At 1000 eV, a factor of 3.5 is seen for the 3 nm pitch delta layers. In an interlaboratory study of seven laboratories profiling these samples, this effect has been further studied by Toujou et al. [6.138]. Homma et al.'s data were repeated but, with the addition of O_2 flooding, the effect could be largely removed.

In addition to the nonlinearity occurring whilst the equilibrium is being established, a longer term nonlinearity arising from the development of surface topography also occurs. This occurs when using O_2^+ bombardment to enhance the ion yields and to homogenize the matrix. It has been found for both Si and GaAs [6.139]. The surface starts smooth but, at a critical depth, ripples develop on the surface, orientated across the incident beam azimuth [6.140]. The critical depth for the onset of roughening has been reviewed by Wittmaack [6.141], who shows that in vacuum, without O_2 flooding, the critical depth for impact angles in the range 38° to 62° falls from $10 \mu m$ at 10 keV approximately linearly with energy to $1 \mu m$ at 3 keV, but then approximately as $E^{4.5}$ to 15 nm at 1 keV beam energy. Once roughening has been established, the Si^+ and other signal levels used to normalize the sputtering rate change and, at the same time, the sputtering rate reduces. In many studies, O_2 flooding is used, but Jiang and Alkemade [6.142] show that this causes the roughening to occur more rapidly, such that for a 1 keV beam at 60° incidence and intermediate O_2 pressures, the erosion rate had fallen after a critical depth of 50 nm and, above 3×10^{-5} Pa, the critical depth reduces to 20 nm. Use of other ion sources, such as Cs^+ , does not improve things [6.143].

The final issue that affects the measured rate of sputtering is that the crater depth only measures the thickness of material removed for deep craters. For shallow craters, as noted for AES, there will be some swelling of the crater floor resulting from implanted primary ions as

well as post-sputtering oxidation when the sample is removed from the vacuum system for measurement. For inert gas sputtering, the swelling should be small since the take-up of inert gas is only some 2–3% over the projected range of the ion [6.92]. Similarly, on exposure to the air, for Si, approximately 1 nm of oxide will be formed, which will cause a net swelling of around 0.6 nm. The whole swelling, therefore, may be 1 nm and this is generally ignored for craters with depths greater than 100 nm. For other ion beams, the swelling arising from implantation may well be significantly higher than this, but data do not exist to estimate the effect, except for, say, O_2^+ where, if a zone 1 nm thick is converted to SiO_2 , we get the above 0.6 nm swelling but nothing further upon air exposure.

Even if we have the correct depth scale, there is a final issue that profiles appear to be shifted from their true positions, since the atoms of a marker layer of interest are recoiled to a different depth to that of the matrix atoms [6.144]. Further shifts in the centroids and the peaks of delta layers arise from the atomic mixing and interface broadening terms as well as the effects of nearby delta layers [6.145]. The shifts seen by Dowsett et al. [6.145] were all less than 3 nm and arise from the overall asymmetry of the measured profile for each delta layer.

Thus, obtaining a repeatable depth scale with modern instruments when profiling dopants in Si is relatively simple. The ion beam sources are reasonably stable and that stability may be monitored in situ via a matrix signal such as Si^+ . However, translating that to an accurate depth scale, particularly for ultrashallow depth profiles, is currently not routine and (depending on the sample) may involve significant errors.

Quantification. Quantification in dynamic SIMS is very important for semiconductor studies. Equations like (6.3) can be used, but it is found that the sensitivity factors cannot really be used from look-up tables since the factors vary too much from instrument to instrument and condition to condition. However, by using a reference material, this may be overcome. Two types of reference material are employed: bulk-doped and ion-implanted. Either type of sample may be used just prior to or following the sample to be analyzed with identical analytical conditions. If these analyses occur regularly, the data from the reference material may be used in statistical process control procedures to underpin a quality system and ensure consistent instrument operation.

ISO 18114 shows how to deduce relative sensitivity factors (RSFs) from ion-implanted reference

materials. At the present time, not many of these exist at the certified reference material level. NIST sells ^{75}As -, ^{10}B - and ^{31}P -doped Si as SRMs 2134, 2137 and 2133, respectively, with levels of around 10^{15} atoms/cm² but certified with 95% confidence limits ranging from 0.0028×10^{15} atoms/cm² for As to 0.035×10^{15} atoms/cm² for B. KRIS also provides B-doped Si thin films as KRIS CRM 0304-300. Using an implanted material, one measures the implant signal I_i^x as a function of the depth d through the profile until the implant or dopant signal has reached the background noise level I_∞^x . From the total implanted dose N atoms/m², the sensitivity factor S_x may be calculated

$$S_x = \frac{Nn}{d \sum_{i=1}^n \left(\frac{I_i^x - I_\infty^x}{I_i^m} \right)}, \quad (6.37)$$

where I_i^m is a normalizing matrix signal and n cycles of measurement are required to reach the crater depth d which must be measured after the profile using a profilometer or other calibrated instrument.

The concentration C_i^x at any point is then given by

$$C_i^x = S_x \frac{(I_i^x - I_\infty^x)}{I_i^m}. \quad (6.38)$$

Bulk-doped reference materials are also useful, and here, if the concentration of the reference material is K^x ,

$$S_x = \frac{K^x}{\left(\frac{I_i^x - I_\infty^x}{I_i^m} \right)}. \quad (6.39)$$

The background level I_∞^x in this case must be determined from a sample with a very low level, which may occur, for example, in part of the sample to be analyzed. In all of these situations, one must be aware that one is only measuring the intensity of one isotope and that the reference sample may have a different isotope ratio from that of the sample to be analyzed. If this is the case, corrections will be needed in (6.37–6.39) to allow for the relevant fractions. These issues are dealt with in detail for B in Si using bulk-doped material and ion-implanted reference materials in ISO 14237 and ISO 18114, respectively.

A number of interlaboratory studies have been made on these materials and it is useful to summarize the results here so that users can see the level of agreement possible. In very early studies for B in Si, Clegg and coworkers [6.146] showed very good results for a 70 keV ^{11}B ion-implanted wafer between ten laboratories using either O_2^+ or Cs^+ ion sources in the range 2 to 14.5 keV. For this relatively broad profile,

the average standard deviation of the widths at concentrations equal to 10^{-1} , 10^{-2} , 10^{-3} and 10^{-4} of the maximum concentration was 2.8%, the depth typically being 500 nm. Later work [6.147] using ^{66}Zn , ^{52}Cr and ^{56}Fe sequentially implanted into GaAs showed slightly poorer results. That work also showed that elements accumulating near the surface, where the sputtering equilibrium is being established, would lead to variable results. A later study by *Miethe and Cirlin* [6.148] analyzing Si delta-doped layers in GaAs found good results but that, to obtain meaningful depth resolution, laboratories at that time needed both better control of their scanning systems for the flat-bottomed crater, and to use sample rotation to avoid the degrading effects of developing sample topography.

To cover a wider range of dopant concentrations, *Okamoto et al.* [6.149] analyzed 50 keV $^{11}\text{B}^+$ -implanted wafers with doses from 3×10^{14} to 1×10^{17} ions/cm². Eighteen laboratories profiled these samples using $^{11}\text{B}^+$ and $^{27}\text{BO}^+$ when using positive ion detection with O_2^+ incident ions, or $^{39}\text{BSi}^-$ and $^{11}\text{BO}^-$ when using negative ion detection with Cs^+ incident ions. The signals are, of course, ratioed to those of the relevant matrix ions. These results showed good consistency but that the *RSFs* for $^{11}\text{B}^+$ and $^{11}\text{B}^-$ were affected by the matrix for the two higher B implant levels, the *RSFs* being slightly reduced. In an extension of this work for shallow implants for ULSI devices, *Toujou et al.* [6.150] note that, at 1×10^{16} ions/cm², the peak B concentration is over 10^{21} atoms/cm², in other words over 1% atomic fraction. They find that, for 4 keV O_2^+ at impact angles $\theta > 30^\circ$, the B and Si ion yields increased for concentrations $> 10^{21}$ atoms/cm³ but, under 4 keV Cs^+ bombardment, no increase occurred up to 60° . They therefore recommend using O_2^+ at $\theta < 20^\circ$ or Cs^+ at $\theta < 60^\circ$ incidence angle to avoid the nonlinearity at high concentrations. These angle issues are not discussed in the relevant *ISO* standards *ISO* 14237 and *ISO* 17560, but there it recommends measuring both $^{10}\text{B}^+$ and $^{11}\text{B}^+$ when using an oxygen beam and $^{10}\text{B}^{28}\text{Si}^-$ and $^{11}\text{B}^{28}\text{B}^-$ with a cesium ion beam. The ^{28}Si ion or its molecular ions should be used as the matrix ion and the ratios of the dopant and matrix ions are determined for each cycle of measurement as in (6.36–6.38).

In more recent work for a planned *ISO* draft, *Tomita et al.* [6.151] have studied the depth profiling of 100 keV $^{75}\text{As}^+$ implants in Si for doses between 3×10^{14} and 3×10^{16} ions/cm² with peak concentrations up to 5.8×10^{21} atoms/cm³ (12 at. %). They find that, for Cs^+ incident ions, use of the ion intensity ratios $\text{AsSi}^-/\text{Si}_2^-$ or As^-/Si^- as the measured intensities, with

point-by-point normalization, leads to constant *RSFs* for all doses and for angles of incidence in the range 24° to 70° . However, use of the intensity ratios $\text{AsSi}^-/\text{Si}^-$ or $\text{As}^-/\text{Si}_2^-$ led to 10% changes in the *RSF* at arsenic doses of 10^{16} ions/cm² and above and were not recommended. It is likely that these issues will be included in a future *ISO* standard.

Static SIMS

In dynamic SIMS, with the use of low energies and high incidence angles, many uncertainties are focused into the first 1 nm of depth, during which the sputtering process comes to equilibrium. In static SIMS, it has traditionally been suggested that the upper limit of fluence should be restricted to about 0.1% of this, and early work suggested that it should be less than 10^{13} ions/cm² for molecular analysis. The intensities of certain peaks may be expressed as

$$I = I_0 \exp(-N\sigma t), \quad (6.40)$$

where N is the number of ions/m² s⁻¹ arriving at the surface, t is the time and σ is a damage cross-section. For I to represent I_0 to within 10%, and for a sputtering yield in the range 1–10, one can see that elements at the surface can only be analyzed using fluences up to 10^{13} ions/cm². However, *Gilmore and Seah* [6.152] showed that the larger the fragment studied, clearly the larger the physical cross-section of the molecular fragment and the higher the value of σ , so that a 10% loss of intensity of the group $\text{C}_{10}\text{H}_9\text{O}_4$ from poly(ethylene terephthalate) occurred at an argon fluence of 10^{12} ions/cm². For the smaller C_6H_4 ion, 5×10^{12} argon ions/cm² could be tolerated.

Today, molecules of very much larger physical sizes are analyzed with concomitantly lower damage thresholds but, fortunately, modern time of flight mass spectrometers used for SIMS studies only need a total of 10^9 ions and, with a useful ion yield of 10^{-4} , the spectrum has an excellent 10^5 ions. This may be achieved in typical systems using a pulsed ion source delivering 600 ions per pulse every 100 μs for a total spectrum acquisition time of three minutes. If this dose is spread out over a raster area of 300 μm by 300 μm , the fluence is just at the 10^{12} cm⁻² static limit. However, for spatially resolved data this is no longer possible, and damage becomes an important issue. This needs consideration in order to generate reliable and repeatable data. The next important issue is to interpret that data, and we shall deal with these aspects in the next sections. At the present time, relevant *ISO* activity is just starting in TC 201 SC

6, and so no standards are available to help the analyst as yet.

Control of Damage. Two sources of damage arise in static SIMS: the primary ions and the electrons from the electron flood neutralizing system for discharging insulators for analysis. As noted earlier, most analysts keep the ion fluence below 10^{12} ions/cm² to avoid damage, although for the study of larger molecules, such as proteins, which may have a cross-sectional area of 20 nm², one may expect 20% to be damaged at this dose and 2×10^{11} ions/cm² may be a safer limit. This leads to an optimum spatial resolution of 0.7 mm for spectra with 10^5 counts.

Depending on the information required, one can, of course, work at much better spatial resolution, as shown in Fig. 6.10. In the study in Fig. 6.10, it is known that there are essentially two regions, since the sample was made to be a polymer blend of polyvinyl chloride (PVC) and polycarbonate (PC) that are phase-separated but may be partially miscible. Here one can work to lower signal levels per pixel and then sum pixels to obtain low-noise spectra. One may also use a higher dose to consume more of the material. Thus, for PVC one may use the Cl⁻ signal, and for PC the sum of the O⁻ and OH⁻ signals. In Fig. 6.10, the images comprise 256 × 256 pixels with a dose per pixel of 10^4 ions, giving a total of 6×10^8 ions into the 50 μm × 50 μm area and a fluence of 2.5×10^{13} ions/cm². For a good static SIMS spectrum at the 10^{12} ions/cm² level, we must analyze 150 μm × 150 μm using a total number of 2.25×10^8 ions, as shown in Fig. 6.11. Fortunately, here we have a useful ion yield in the negative ions of 10^{-3} to 10^{-2} , so that each pixel of the left hand image of Fig. 6.10 contains 10 to 100 Cl⁻ ions. We can see patterns of dark dots within the bright zones. These are not noise, but can be shown by AFM to be 200 nm diameter pools of PC [6.1]. The SIMS is just resolving these generally as single pixels, indicating a static SIMS resolution, in a near-static mode, of 200 nm.

Figures 6.10 and 6.11 show typical analyses of materials using a modern time of flight SIMS system. The samples are insulating and need electron flooding to remove charge. This is relatively easy, but in practice we have found that many users ensure charge neutralization by using an electron flux density that is far too high. This ensures that there is no charging, but it damages the sample at about the same rate as the ions. Low-energy electrons have a very high cross-section for bond dissociation. Gilmore and Seah [6.153] find that, at electron fluences of 6×10^{14} electrons/cm², polymers such

Fig. 6.10a,b Static SIMS negative ion images for a total fluence of 2.5×10^{13} ions/cm² of a PVC and PC polymer blend, (a) Cl⁻ for PVC and (b) OH⁻ + O⁻ for PC, field of view 50 μm × 50 μm (after Gilmore et al. [6.1])

Fig. 6.11 Static SIMS negative ion spectrum for 10^{12} ions/cm² on a fresh 150 μm × 150 μm area of material as in Fig. 6.10 (after Gilmore et al. [6.1])

as PS, PVC, PMMA and PTFE are damaged, whereas some instruments have been set well above this limit. The avoidance of electron flood damage typically limits the electron flood current to 100 nA but, as a minimum, the sample needs about 30 electrons per incident ion to stop significant charging.

Identifying Materials. In static SIMS we cannot identify materials, beyond elemental species, simply by observing the masses of the peaks. For the molecules generally studied, there are very many mass peaks of

high intensity in the 12 to 100 u range and often series of peaks at masses up to and beyond 1000 u. The peaks mainly correspond to highly degraded fragments of the original molecules or material at the surface. This degradation is such that many organic materials look broadly similar, and experts develop their own schemes of selected significant peaks in order to measure intensities. Thus, much information is rejected. In order to identify materials in this way, static SIMS libraries have been developed. The first two libraries [6.154, 155] were in a print-on-paper format, effectively using unit mass resolution since they arose from very careful data compilations using the earlier quadrupole mass spectrometers. Despite the care, contamination and damage effects are more likely in these data. These libraries contain 81 materials and 85 polymers, respectively. The more recent library by *Vickerman* et al. [6.156] extends the earlier library [6.154] by including spectra for the higher mass resolution, early time-of-flight instruments so that the combined library now covers 519 materials. The fourth library [6.157] is for consistent high-resolution data, is available digitally and is for calibrated, later generation time-of-flight instruments. This contains data for 147 compounds. These libraries form an invaluable resource to which analysts may add their own data. For quantification, analysts typically select one or two major characteristic peaks and simply use equations like (6.3). Individual research groups use much more sophisticated analyses, but these are not applicable for general analysis.

The modern time of flight mass spectrometer should be able to determine mass to better than the 10 ppm

needed to be able to associate each peak with the correct number of C, O, N, H, and so on, atoms. However, a recent interlaboratory study [6.159] shows that, even having calibrated the scale on appropriate masses, a lack of understanding of the issues involved [6.160] leads to a standard deviation of scatter of 150 ppm for the protonated irgafos peak at 647.46 u [6.159]. Thus, at the present time, the lack of an appropriate procedure means that analysts need to check a range of possibilities to identify each peak.

The spectrum measured in a laboratory may differ from that shown in a database library for one or more of several reasons. Even when using reference samples to generate a library, great care needs to be taken to avoid contaminants, for example poly(dimethyl siloxane) (PDMS). Secondly, in the first static SIMS interlaboratory study [6.161], it was shown that whilst some laboratories could repeat data at a 1% level, 10% was more typical and 70% occurred in some cases, indicating that some laboratories/instruments could not really generate repeatable data. In that work the 18 analysts used 21 instruments and their preferred ion sources ranged from Ar^+ and Ga^+ to Cs^+ and O_2^+ with primary ion beam energies from 2.5 keV to 25 keV. In a more recent study [6.153], improvements in practice and equipment have led to a general improvement in repeatability, but the issue of different sources remains.

To study larger molecules, a range of new ion sources has been developed to provide a higher yield of large fragments compared to the sources listed above. *Benninghoven* et al. [6.162] show that the yields of all fragments increase through the primary ion series

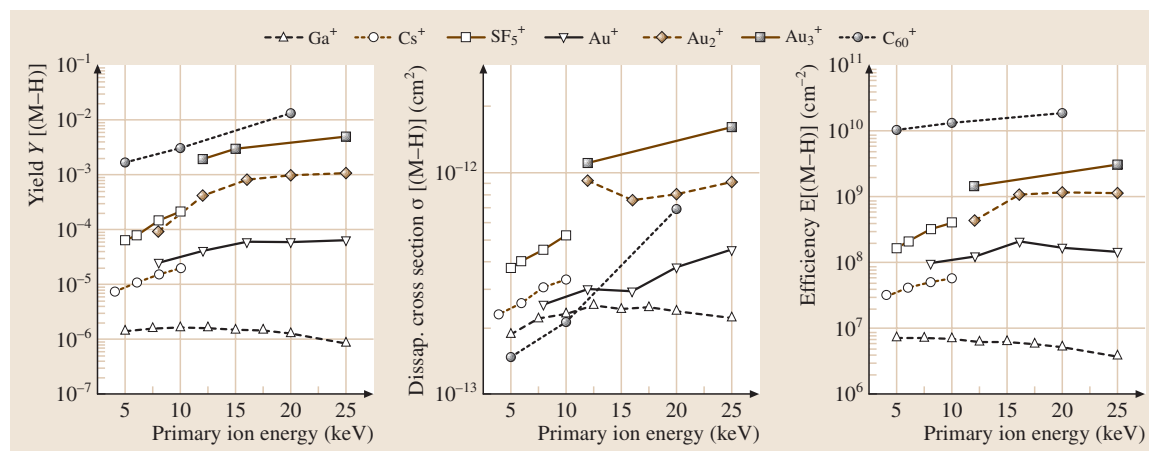

Fig. 6.12 Secondary ion yields, damage or disappearance cross-section σ and efficiency E measured for the irganox 1010 quasi-molecular ion $(\text{M-H})^-$ as a function of the primary ion energy and type (after *Kersting* et al. [6.158])

Ar^+ , Xe^+ , SF_5^+ , $\text{C}_{10}\text{H}_8^+$, C_6F_6^+ , $\text{C}_{10}\text{F}_8^+$ when analyzing irganox 1010 at the surface of polyethylene. These results, for 11 keV ions, covered the mass range 50 to 1000 u and indicated a simple increase above 100 u of 0.3, 1, 4, 6, 7 and 12, respectively, when normalized to the Xe^+ data. Below 150 u the increases were stronger. For matrix-isolated biomolecules, a change from Ar^+ to SF_5^+ led to yield increases of characteristic peaks above 1000 u of 6 to 32 times. *Schneiders et al.* [6.163] show that, for molecular overlayers of adenine and β -alanine on Ag or Si, SF_5^+ gives significantly higher yields than Xe^+ and that this is, in turn, better than Ar^+ . These overall results are nicely summarized in the studies of *Kersting et al.* [6.158, 164], who look at both the yield increase and the damage effects, as shown in Fig. 6.12, where they call σ in our (6.40) the disappearance cross-section. They define the ratio of the yield to the damage cross-section as the efficiency E . Clearly, if the yield doubled at the expense of twice the rate of damage, there would be no real improvement for the analyst and this would be reflected in an unchanged value of the efficiency E . However, in Fig. 6.12 it is clear, where data are given for C_{60}^+ , Au_3^+ , Au_2^+ , Au^+ , SF_5^+ , Cs^+ and Ga^+ , that they are 2000, 500, 200, 33, 45 and 6 times better than Ga, respectively. It seems that higher mass ions are better than low mass, and polyatomic ions are better than monatomic ions of the same beam energy.

Earlier studies of polyatomic ions identified C_{60}^+ as an interesting candidate. *Wong et al.* [6.166] have designed a suitable ion gun and show significant yield enhancements compared with Ga^+ at 15 keV. The total yield increase for the polypeptide gramicidin, spin-cast onto copper, is 41 and, in the 200 to 1000 u range, rises to 50. For the molecular ion, a strong signal is observed for C_{60}^+ but not at all for Ga^+ . The results for bulk PET were around 60 for most of the mass range for equivalent doses of both ions. The damage rates were not measured but the very strong result for the gramicidin molecular ion showed significant promise. More recently, *Weibel et al.* [6.167] extended this work and measured the Y , σ and E values to show that E for masses above 250 u would range from 60 to 15 000 times higher for C_{60}^+ than for Ga^+ when analyzing thick polymer or irganox 1010 layers.

To increase the mass of the projectile for the liquid metal ion gun structures used for high-resolution imaging, *Davies et al.* [6.168] have used a gold ion source. Using a gold–germanium eutectic alloy as the source for a liquid metal ion gun, they could generate Ge^{++} , Ge^+ , Au^{++} , Au^+ , Au_2^+ and Au_3^+ beams all at around the 1 pA needed. The results, compared with Ga^+ for

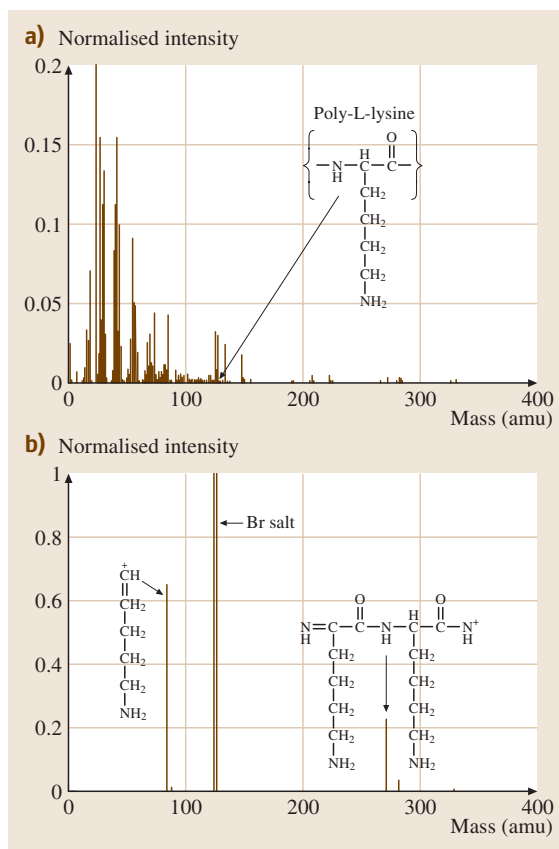

Fig. 6.13a,b Spectra for poly-L-lysine: **(a)** 10 keV Cs^+ static SIMS spectrum showing strong fragments at low mass and no peak at the repeat unit of 128 u, and **(b)** G-SIMS using the ratio of 10 keV Cs^+ to Ar^+ with strong intensity at 84.1 u for the side chain and 271.2 u for a dimer repeat with an extra NH from the backbone (after *Gilmore and Seah* [6.165])

the gramicidin and PET analyzed with the C_{60}^+ , show that Au^+ gives typically a fourfold improvement and that Au_3^+ gives a tenfold improvement, except for the gramicidin molecular ion where the improvement is 64 times. It appears that the Au_3^+ is less effective at generating the molecular ions for the gramicidin than C_{60}^+ , but no data are available for the damage rates to evaluate the efficiencies. Clearly, the liquid metal ion source approach will continue to provide better spatial resolution, and so we expect that there will be further new sources in the future. This does not help the analyst trying to use the spectral libraries, since the relative intensities of the peaks depends on the ion source. For the analyst there is an urgent need for (i) a routine to treat spectra

Fig. 6.14a-c G-SIMS-FPM for folic acid, **(a)** the molecular structure of folic acid identifying six subunits, **(b)** the change in relative intensities of G-SIMS peaks with g index showing the peak g values, g_{max} and **(c)** the reassembly plot showing fragmentation pathways (after *Gilmore and Seah* [6.169])

gorithms to extract chemical information directly from the spectra. To aid this process in static SIMS, two ISO standards, ISO 14976 and ISO 22048, as shown in Table 6.2, have been designed to allow export and import of spectral data files so that new software may be developed to do this processing.

In recent years a variant of static SIMS has been developed called G-SIMS. This spectroscopy uses the ratio of two static SIMS spectra to generate a new spectrum called the G-SIMS spectrum that contains peaks far less degraded in the fragmentation process. As a result of the characterization for the static SIMS interlaboratory study [6.161], it was shown that the ratio of the spectrum obtained for 4 keV argon to that for 10 keV argon exhibited clusters of results near unity but with fragments of the type C_xH_y having the highest ratio for the least degradation [6.170]. The G-SIMS spectrum I_x for the mass x is given by

$$I_x = F_x^g N_x M_x, \quad (6.41)$$

where the ratio of the 4 keV and 10 keV spectra is F_x , g is the G-SIMS index, N_x is the 4 keV static SIMS spectrum, and M_x is a linear mass term. In practice, for 4 keV and 10 keV argon, a useful value of g is found to be 13. Tests with other sources shows that whilst 4 and 10 keV argon is convenient and is an easy choice to be able to align the beams on the same area, SF_5^+ , Cs and Xe may be ratioed to Ar or Ga and a stronger effect obtained [6.170]. An example of G-SIMS is shown in Fig. 6.13 for poly-L-lysine [6.165]. Figure 6.13a is the static SIMS spectrum where the poly-L-lysine structure is shown. The spectrum is, as usual, dominated by the low mass fragments. In Fig. 6.13b is a G-SIMS spectrum using the ratio of 10 keV Cs to 10 keV Ar and a g index of 13 [6.165]. The intense double peak in the center arises from a separate bromide compound as the material is supplied as a salt. The G-SIMS peaks show a clear dimer with an added NH and a peak defining the amino acid side chain. A number of polymers [6.170] and organics [6.165] have been studied, and each time the information can be related to unfragmented parts of the molecule.

In a test of the capability of G-SIMS, investigations of a small brown stain on paper identified oil of

so that they may be related from one source to another, (ii) a procedure for accurate mass calibration, and (iii) a chemometrics platform to be able to apply reliable al-

bergamot from the molecular peak that was not noticeable in the static SIMS spectrum. Identifying species from the molecular weight is thus possible using G-SIMS and, possibly, Au_3^+ or C_{60}^+ . This frees the analyst from the limit of less than 800 materials defined by the spectra available in libraries of static SIMS spectra [6.155–157, 159] and opens up the method to the life sciences and other areas where the libraries would need to run to hundreds of thousands of spectra. Unfortunately, in the life sciences and similar areas, the molecular weight may not be adequate to identify a molecule and knowledge is required about its structure. An extension of G-SIMS called G-SIMS with fragmentation pathway mapping (G-SIMS-FPM) shows how this may be done [6.169]. By altering the index g in (6.41), we may view spectra that move progressively from the highly fragmented static SIMS ($g = 0$) to the unfragmented G-SIMS with $g = 40$. During this process, we can see higher mass peaks being built up and parts of the molecule being reassembled in the spectra. With accurate mass calibration, the composition of each fragment may be evaluated. Figure 6.14 shows how this works for folic acid. To the left in Fig. 6.14b we see the intensities of certain peaks. As g increases these either grow or die. Those that grow may peak at a certain g value, g_{max} , and this value is then plotted as the ordinate value in Fig. 6.14c. Molecules or large fragments to the right in Fig. 6.14b or the top in Fig. 6.14c are split into smaller

mass fragments peaking further to the left in Fig. 6.14b or down and to the left in Fig. 6.14c. Unfortunately, not all fragments are emitted as ions and so the plots are not complete, but they do add sufficient dimension to the information to permit identification where the static SIMS or G-SIMS data are insufficient.

6.1.4 Conclusions

In Sect. 6.1, we have presented the measurement status of surface chemical analysis. The three main techniques of AES, XPS and SIMS are all still rapidly developing in both instrumentation and applications. The spatial and spectral resolutions are still improving and signal levels are increasing. AES, XPS and dynamic SIMS are all relatively mature with extensive procedural standards available from ISO [6.3, 4] and ASTM [6.2]. This area is also highly active, and both these and research results also feed back into the hardware and software of the commercial instruments. Static SIMS, which has very strong development potential, is being increasingly used in industrial laboratories to obtain levels of detail and sensitivity not available with AES or XPS. The latest generation of TOF-SIMS instruments and their new ion sources make this a very fast developing and fruitful area. New standards in ISO are expected to be developed over the coming years.

6.2 Surface Topography Analysis

The topography of a surface is the set of geometrical details that can be recorded through a measurement. Most commonly, topography is either related to the mechanical nature of the surface, typically involved in contact situations, or to its electromagnetic nature, typically involved in optical effects. Topography is of paramount importance for the functional behavior of a surface, strongly interplaying with material properties and operating conditions.

Surface topography characterization is a powerful tool in connection with design, manufacture and function. As schematically illustrated in Fig. 6.15, it allows one to link the functional behavior of a surface to the microgeometry obtained from its generation. The three main phases of surface topography characterization are: measurement, visualization and quantification. These phases encompass a number of basic steps, nowadays

prevalently involving digital techniques and extensive use of computers: data acquisition, conditioning, visualization, elaboration and quantification. In particular, quantification typically concerns the geometry of single surface features at a micrometer or nanometer scale, being based on the extraction of parameters, curves, functions or basic geometrical features from a representative profile or area on the surface. Quantifying the microgeometries of surfaces after they have been measured is important in all applications of process control, quality control and design for functionality.

The principal methods of surface topography measurement are stylus profilometry, optical scanning techniques and scanning probe microscopy (SPM). These methods, based on acquisition of topography data from point-by-point scans, give quantitative information on heights with respect to position. Other

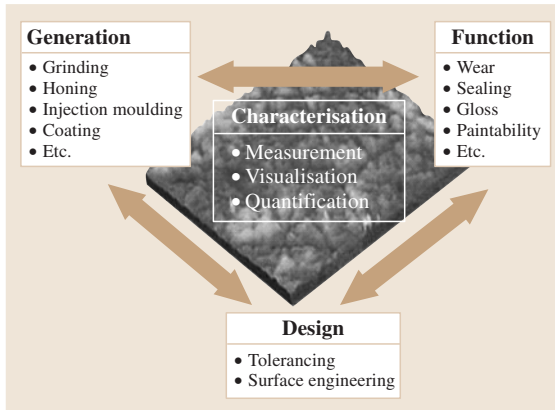

Fig. 6.15 Surface topography characterization links design, generation and function (after [6.171])

methods such as scanning electron microscopy (SEM) can also be used. Based on a different approach, the so-called integral methods produce parameters representing some average property of the surface under examination. A further classification distinguishes between contacting and noncontacting instruments. While stylus instruments are inherently contacting methods and optical instruments noncontacting methods, scanning probe microscopes can be both contacting and noncontacting. We shall describe the basics of each of the methods later, but it is useful to outline the attributes of the methods here so that the reader can focus early on their method of choice.

In a stylus profilometer, the pick-up draws a stylus over the surface at a constant speed, and an electric signal is produced by the transducer. This kind of instrument can produce very accurate measurements in the laboratory as well as in an industrial environment, covering vertical ranges up to several millimeters with resolutions as good as nanometric, with lateral scans of up to hundreds of millimeters being possible. The stylus is typically provided with a diamond tip with a cone angle (total included angle) of 60° or 90° and a tip radius in the range $1\text{--}10\text{ }\mu\text{m}$. The maximum detectable slopes using a stylus instrument are, respectively, 60° or 45° . The spatial resolution achieved by this method, generally in the range $2\text{--}20\text{ }\mu\text{m}$, is limited by the tip geometry, and depends on the actual surface slopes and heights in the neighborhood of the point of contact. Moreover, the force applied by the stylus on the surface can generate plastic deformation on the surface, making this method inapplicable to surfaces that are soft or where even light scratches cannot be accepted.

Optical scanning techniques encompass most typically optical profilometers, confocal microscopes, and interferometers. The optical methods are noncontacting, which allows measurements on soft surfaces. However, this kind of instrument is subject to measurement errors related to achieving a useful reflection signal from surfaces that are shiny or transparent to the light source. Optical styli for profilometry can be based on the auto-focusing signal of a laser beam detector. The beam has a spot diameter of about $1\text{ }\mu\text{m}$, and this kind of instrument is similar in use to conventional stylus instruments, with a vertical resolution of approximately 5 nm . The maximum detectable slope using an auto-focusing stylus instrument is approximately 15° . Laser scanning confocal microscopy is another optical technique based on the focus detection principle, where a surface picture element (pixel) is imaged at a time. Topography is reconstructed as a stack of vertical optical sections, in a fashion similar to computer tomography. Confocal microscopes allow steep surface details to be assessed, the maximum detectable slope being up to 75° . Confocal microscopes have a limited lateral resolution, and some commercially available instruments even a limited vertical resolution. Interference microscopy combines an optical microscope and an interferometer objective into a single instrument. These optical methods allow fast noncontacting measurements on essentially flat surfaces. Interferometric methods offer a subnanometer vertical resolution, being employed for surfaces with average roughnesses down to 0.1 nm and peak-to-valley heights up to several millimeters. Interferometric microscopes are all limited with respect to the surface slopes from the finite numerical apertures. Moreover, the lateral resolution is limited by diffraction. The maximum detectable slope using interferometry amounts to about 30° .

Scanning probe microscopy, including atomic force microscopes (AFMs) and scanning tunneling microscopes (STMs), describes a powerful class of tools for subnanometric acquisition of topography data on very fine surfaces. SPMs use a sharp probe scanning over the surface while maintaining a very close spacing to the surface. SPMs allow measurements on surfaces with an area up to approximately $100\text{ }\mu\text{m} \times 100\text{ }\mu\text{m}$ and that have local variations in surface height which are less than approximately $10\text{ }\mu\text{m}$. SPM is a 3-D microscopy technology in which the resolution is not limited by the diffraction of light. The vertical resolution of an SPM is about 0.1 nm , while the horizontal resolution for most AFMs is typically 2 nm to 10 nm , but it can be atomic. SPMs require minimal sample preparation.

Table 6.8 Resolutions and ranges of some techniques for surface topography analysis

focus of this technique. However, SEM photographs are still inherently 2-D, and no height information can be extracted directly from the images. The 3-D achieved by reconstructing from stereo pairs or triplets can be used to evaluate surface topography, but it is limited by a number of factors. First of all, SEM measurements require conductive sample materials, or sample preparation through deposition of a gold layer on the surface. A major limitation is that roughness parameters should be calculated over a relatively large area while, in the case of large magnifications, the area is relatively small. Another limitation is that smooth surfaces are reconstructed with high uncertainty.

Figure 6.16 [6.185] shows a diagram of the spatial resolutions of the different techniques that helps to place the more popularly used methods in context. Additional information is given in Table 6.8. Documentary standards covering surface topography are published by ISO. Updated information regarding the ISO standards for surface texture can be found at the web address www.iso.ch and by searching in the ISO catalogue under 17.040.20 *Properties of surfaces* and 17.040.30 *Measuring instruments*. Surface texture is a topic covered by the technical committee TC213 “Geometrical Product Specifications” under the ISO, the homepage of which can be found through the above mentioned website. Table 6.9 shows the titles of ISO standards published in the field of surface texture. These standards cover 2-D profiling techniques, while standards for 3-D areal measurements are currently under development by TC213. Table 6.10 contains a list of ISO working documents related to 3D surface topography (working documents are those prior to formal draft documents for voting in ISO). Essential textbooks covering the area are [6.186–188].

6.2.1 Stylus Profilometry

General Introduction
The most well-known surface profilometer in the manufacturing industry is the stylus instrument used for conventional two-dimensional roughness measurements. This kind of instrument, shown in Fig. 6.17, has existed for over 60 years, and it yields a high degree of accuracy, robustness and user-friendliness. In a typical surface tester, the pick-up draws the stylus over the surface at a constant speed, and an electric signal is produced by the transducer, which can be piezoelectric, inductive or laser interferometric. The signal is amplified and digitized for subsequent data processing such as filtering and parameter calculation. In

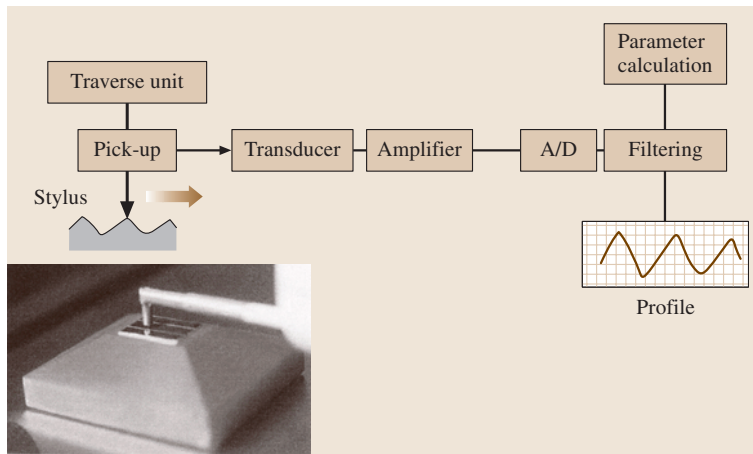

Fig. 6.17 Operational scheme for a stylus profilometer

a more comprehensive laboratory stylus system, parallel tracings can be made over the workpiece, allowing reconstruction of a whole surface area, in order to perform a so-called three-dimensional surface topography characterization. The versatility of the stylus instrument is underlined by the ability to use this instrument on all kinds of items irrespectively of orientation, and to mount the pick-up on other machines, such as a coordinate measuring machine or a form tester, to achieve measurement of the surface topography over complex workpieces. The stylus is provided with a diamond tip with a total cone angle of 60° or, more commonly, 90° . Standardized values for the tip radius are 2, 5 and $10\ \mu\text{m}$, but other values are also used. Stylus instruments feature vertical ranges of up to several millimeters, with best resolutions at nanometric level and scans of up to hundreds of millimeters possible. The standardized values for the maximum load corresponding to the above-mentioned radii are 0.7, 4 and $16\ \text{mN}$, respectively. In many cases, a tracing speed of $0.5\ \text{mm/s}$ is used.

Fig. 6.18 Transmission characteristic of roughness and waviness profiles using ISO filters [6.174]

Measurement and Filtering

When tracing a surface profile, a stylus instrument works as schematically shown in Fig. 6.17. Filters are used to separate roughness from waviness and form. ISO operates with three different types of profile that can be extracted from the acquired profile through filtering: primary P-profile; waviness W-profile; roughness R-profile. Filters are useful in that they permit the user to focus on wavelength components that are important from a functional point of view. Modern filter definitions introduced in ISO standards are based on digital Gaussian cut-off filters characterized by being phase-correct and robust to single features such as scratches. Referring to Fig. 6.18 and [6.174], ISO operates with cut-off filters with nominal wavelengths λ_s , λ_c and λ_f , where index “s” refers to sampling, “c” to cut-off, and “f” to form. An ISO filter is characterized by the wavelength at which it transmits 50% of the amplitude. As illustrated in Fig. 6.18, the three filters λ_s , λ_c and λ_f delimit the wavelength intervals for the roughness and waviness profiles by creating two filter windows. As an alternative, parameters can be calculated on the basis of the so-called primary profile, which results from eliminating the short-wave components only, by using the λ_s filter (λ_s is used to eliminate the mechanical filtering effect from the stylus tip radius). As indicated on the figure, the filters are not sharp but instead produce a progressive damping of the signal.

The data obtained from a measured surface are typically processed as follows:

1. A form fit, such as a least squares arc or line (best fit), is applied to the data in order to remove the form.

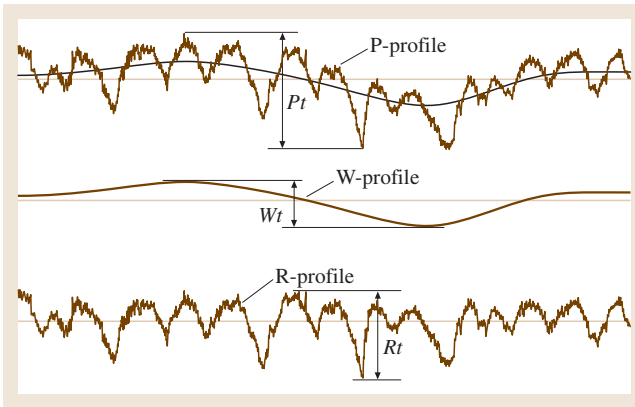

Fig. 6.19 Primary P-profile, waviness W-profile and roughness R-profile

2. The ultrashort wave components are removed using a λ_s filter. The result is the Primary profile, from which P-parameters can be calculated.
3. The Primary profile is passed through a λ_c filter with a specific cut-off value that separates waviness from roughness.
4. The resultant roughness or waviness profile is then processed to calculate the roughness or waviness parameters.

The result of filtering is illustrated in Fig. 6.19. ISO 4287 operates with a number of standardized elements used for parameter calculations: the *mean line*, which is the reference line from which the parameters are calculated, such as the *mean line for the roughness profile*, which is the line corresponding to the longwave profile component suppressed by the profile filter λ_c ; the *sampling length* l_P , respectively l_W and l_R , which is the length in the direction of the X-axis used to identify the irregularities characterizing the profile; and the *evaluation length* l_n , generally defined by ISO as five times the sampling length (P_t , W_t and R_t shown in Fig. 6.19 are calculated over the evaluation length).

Fig. 6.20 Definition of bearing curve parameters according to ISO 13565-2:1996 [6.177]. Vertically, the *bearing curve* is divided into three zones, each described by a parameter: Rpk (peaks), Rk (core), Rvk (valleys)

Visualization

The very first step in surface topography analysis consists of a visualization of the microgeometry, either as single profiles or as surface areas, to provide realistic representations of the surface. The usefulness of such an approach for a qualitative characterization is well recognised: often the image inspection, possibly aided by some enhancement techniques, can be assumed as the only aim of the analysis. Indeed, the image conveys a vast amount of information, which can be easily interpreted by an experienced observer: even a single profile contains a large amount of relevant information, and moreover in a condensed way by adopting different scales for the horizontal and vertical axes. The passage from profile two-dimensional analysis to surface three-dimensional analysis enlarges the possibilities for gaining knowledge and representing the surface texture. Many techniques have been developed to display the sampled data, with the possibility of enhancing some particular features, such as:

- Contour plots, colour plots and grayscale mapping, techniques borrowed from soil cartography to represent the surface heights.
- Isometric and dimetric (as in Fig. 6.15) projections, where the single data points are interconnected with all the neighboring points by straight or curved lines. Projections can be modified by the scales and projection angles, for enhancement of amplitudes, texture, etc.
- Inversion and truncation techniques, whereby the visual interpretation of the projections is enhanced through data manipulation. Other manipulation techniques are used, for example, to emphasize surface slopes.

Quantification of Surface Texture

Quantitative assessment of surface texture can be very useful in relation to process control, tolerance verification, and functional analysis. Nevertheless, it must

be undertaken with care, since interpretation of mere parameters can lead to wrong conclusions. Unless the topographic nature of the surface under consideration is known, it is strongly recommended that quantitative characterization should only be used in connection with a visual examination of the surface topography, as described above.

2-D Parameters Covered by ISO Standards. Conventional roughness parameters, which are those most commonly known to quantify surface texture, are often referred to as 2-D parameters, since they are computed on the basis of single profiles containing information in two dimensions (horizontal and vertical). The 2-D surface texture area has been totally revised by ISO, with the introduction of several new international standards [6.172–184]. According to current ISO terminology, as mentioned in connection with filters, the concept of surface texture encompasses roughness, waviness and the primary profile. In the following, an overview is presented of the existing ISO parameters for surface texture. Only ISO parameters are considered here, since they adequately cover what can be quantified through 2-D parameters. A more complete review of parameters can be found in the monographs [6.186–188]. Conventional 2-D parameters are described in the current ISO standard ISO 4287 [6.174], while other 2-D parameters are covered by ISO 12085 [6.175] and ISO 13565 [6.176–178]. ISO 1302 [6.173] prescribes a detailed indication of surface texture tolerances on technical drawings, with indication of the measurement specifications to follow when verifying tolerances.

Conventional 2-D Parameters. ISO 4287 defines three series of 14 parameters each: P-parameters for the unfiltered profile, R-parameters for the roughness profile and W-parameters for the waviness profile; see Table 6.11 and [6.174]. Filtering to obtain the R and W profiles is

introduced in the same standard and specified in [6.180]. Only examples of some parameters are given in this section. The reader should refer to the standard for complete definitions of each parameter. Conventional 2-D surface texture parameters are defined in ISO 4287 but their value ranges are addressed in ISO 4288 [6.179]. ISO 4288 uses five sampling lengths as default for roughness profile parameters, indicating how to recalculate their upper and lower limits based on other numbers of sampling lengths. It should be noted that the same terminology is used in ISO 4287 and ISO 4288 to indicate the parameters computed over one sampling length and over five sampling lengths, respectively. It should be also noted that wavelengths under 13 μm and amplitudes of less than 25 nm are not covered by existing ISO standards, which therefore disregard typical ranges of interest in usual AFM metrology. However, since the ranges of definition seem to be dictated by the physical possibilities of existing stylus instruments, it can be assumed that the definitions can also be extended to values below those, but this must be investigated.

- *Ra* is the most widely used quantification parameter in surface texture measurement. It has also been known in the past as the center line average (*CLA*) or, in the USA, as the arithmetic average (*AA*). *Ra* is the arithmetic average value of the profile departure from the mean line within a sampling length, which can be defined as

$$Ra = \frac{1}{L} \int_0^L |z(x)| dx \approx \frac{1}{n} \sum_{i=1}^n |z_i| \quad (6.42)$$

Here *z* is the height from the mean line defined in Fig. 6.19.

- *Rq*, corresponding to the root mean square (*RMS*), is preferred to *Ra* for modeling purposes. *Rq* is the geometric average value of the profile departure from

Table 6.11 Profile parameters defined by ISO 4287 (1997)

	Amplitude parameters									Distance parameters	Hybrid parameters	Curves and related parameters		
	Top-valley						mean value

the mean line within a sampling length, which can be defined as

$$Rq = \sqrt{\frac{1}{L} \int_0^L [z(x)]^2 dx} \approx \sqrt{\frac{1}{n} \sum_{i=1}^n (z_i)^2}$$

(6.43)

- *Rp* is the maximum height of the profile above the mean line within a sampling length.
- *Rv* is the maximum depth of the profile below the mean line within a sampling length.
- *Rz* is the maximum peak-to-valley height of the profile within the sampling length.
- *Rt* is a parameter which basically has the same definition as *Rz* but the definition of which is based on the total assessment, or evaluation, length (*ln*). The evaluation length covers by default five sampling lengths, see ISO 4288 [6.179].
- *RSm* (mean spacing) is the mean width of the profile elements at the mean line within the sampling length.

Other Parameters Defined by ISO. Other parameters defined by ISO standards are the motif parameters and

the bearing curve parameters. ISO 12085 [6.175] concerns parameters calculated through profile evaluation using the motif method, so far only used by the French motor industry. The method is based on dividing the unfiltered profile into geometrical features, characterized by peaks, that may merge or remain unaltered depending on their relative magnitudes, and thus calculating the parameters shown in Table 6.12. It should be noted that waviness and roughness in ISO 12085 do not refer to the same definitions used for the conventional parameters defined in ISO 4887. ISO 13565 describes two sets of parameters extracted from the bearing curve, and was specifically developed to characterise stratified surfaces with different functional properties at different depths. ISO 13565-1 [6.176] describes filtering. Parameters developed by the German motor industry are defined in ISO 13565-2 (Fig. 6.20 and [6.177]) while ISO 13565-3 describes the parameter set developed by the American engine manufacturer Cummins [6.178–184, 189].

3-D Parameters. Parameters calculated over an area are referred to as areal, or 3-D, parameters. Currently, 3-D surface texture measurement is the object of a number of TC213 working documents that are expected to appear as ISO standards in the near future. Based on the research carried out within the European Program [6.190], a set of seventeen 3-D parameters has been proposed [6.191, 192]. These parameters are denoted by “S” instead of “R” to indicate that they are calculated over a surface. Table 6.12 gives an overview of the so-called S-parameter set currently under consideration by ISO TC213. Most of the parameters of the set are derived from the corresponding 2-D parameters, while three are uniquely devised for surfaces. For example, the parameters *Sa* and *Sq* are calculated using equations similar to, respectively, (6.42) and (6.43). The reader should refer to the ISO documents or to the above-mentioned research reports for complete definitions of each parameter.

6.2.2 Optical Techniques

Many different measuring instruments based on optical techniques exist [6.186, 188, 193, 194]. In this section, the three most important ones are described: optical stylus profilometry, confocal microscopy and interferometry. Some issues are of importance to all optical microscopy methods [6.195]:

- **Material response:** optical probing is only possible when a signal above the detector threshold is re-

ceived: the material's reflectivity is determinant of this.

- Lateral resolution: this is limited by light diffraction. For an instrument's numerical aperture NA and a light wavelength λ , the limit d is given by [6.195]

$$d = \frac{1.22\lambda}{NA} . \quad (6.44)$$

- Maximum detectable slope: this depends on the kind of reflection (specular or diffused), which in turn depends on the surface topography and material, as well as on the objective working distance and numerical aperture.
- Wavelength of full amplitude modulation: this quantity is intended as the maximum aspect ratio of a measurable surface structure.

Optical Stylus Profilometry

Optical styli for profilometry can be based on the auto-focusing signal of a laser beam detector. A laser beam with a spot diameter of about $1\ \mu\text{m}$ is focused onto a point on the surface through a lens characterized by a high numerical aperture (NA). The scattered light is collected by the same lens on a focus detector, which operates a control system. When the detector moves horizontally the controller, normally piezoelectric, modifies the distance of the lens from the surface so as to keep the beam focused. Consequently, the movement of the lens follows the surface at a constant separation distance, and its trajectory describes the surface profile, as shown in Fig. 6.21. This kind of instrument is similar in use to conventional stylus instruments, with a vertical resolution of approximately $5\ \text{nm}$. The optical method is non-contacting, which allows measurements on soft surfaces. However, this kind of instrument is connected to some problems related to achieving a useful reflection signal from surfaces that are shiny or transparent to the laser beam. The measurements obtained with the auto-focusing method do not always correlate very well with those obtained with the stylus method [6.192, 194], as the optical method tends to overestimate the peak heights and the stylus method to underestimate the valley heights of the surface. The optical stylus method was found to be fine on very flat samples, but when measuring roughness below $1\ \mu\text{m}$ it was very prone to error. The maximum detectable slope using an auto-focusing stylus instrument is approximately 15° .

Confocal Microscopy

Confocal microscopy is an optical technique based on the focus detection principle. It is routinely applied

Fig. 6.21 Operating principle of the auto-focusing method [6.194]

in biological sciences, where relatively thick biological samples, such as cells in tissue, are investigated using fluorescence. But it is also suitable for 3-D topography assessment, when the reflected light is detected rather than the emitted fluorescence. Here the technique is presented with reference to the reflection mode of operation with a laser light source. The working principle is easily seen by referring to Fig. 6.22, where key components and optical ray diagrams are sketched (the scanner which moves the laser spot on the surface is not shown) [6.195].

Confocality consists in that both the light source pinhole P1 and the detector pinhole P2 are focused on the specimen. In laser scanning confocal microscopy one surface picture element (pixel) is imaged at a time. The final image is therefore built up sequentially. This has relevant consequences for the application of this technique to topography measurement; the measurement time is negatively affected while the maximum detectable surface slope is increased. Topography is reconstructed as a stack of vertical optical sections, in

Fig. 6.22 Confocal principle

a fashion similar to computer tomography. In other words, it is built by overlapping a number of optical slices with normal vectors aligned with the optical axis. A single optical slice contribution to the final topography is given by all of the pixels where reflection occurs. The two pinholes shown in Fig. 6.22 allow, in principle, the detection of light back from the focal plane. Stray light should be stopped here and should not reach the detector. This would be strictly true for an infinitesimally small pinhole, but the finite size always allows some amount of out-of-plane light to be collected by the photodetector. The pinhole diameter can be adjusted by the operator; practical values for the diameter in reflection mode confocal microscopy go down to the diffraction limit given by (6.44). As a consequence, optical slices have a finite thickness. As regards the designs of confocal microscopes, some systems are provided with monochromatic (laser) illumination; others are based on xenon lamps which emit white light. The latter source allows detection by means of a CCD sensor, with no scan being required in the lateral plane. As concerns laser scanners, galvanometric scanning mirrors are used to move the laser spot laterally, without physical table motion. The drive of the vertical axis determines the vertical resolution. With a piezo actuator, ranges of a few hundreds of microns are possible with a resolution of a few nanometers. When a DC motor drives the objective, a range of up to 100 mm can be covered with a resolution of about 100 nm. Confocal microscopes allow steep surface details to be assessed, the maximum detectable slope being up to 75° . Confocal microscopes have a limited lateral resolution, and some commer-

cially available instruments even have a limited vertical resolution [6.195].

Interference Microscopy

Interference microscopy combines an optical microscope and an interferometer objective into a single instrument. Interferometric methods offer subnanometer vertical resolution, and are employed for surfaces with average roughnesses down to 0.1 nm and peak-to-valley heights of up to several millimeters.

Interferometry is a well-known optical principle that is widely used in metrology, which has recently also been applied to surface metrology [6.194]. Basically, interferometric systems are derived from the Fizeau interference microscope, as shown in Fig. 6.23. A light beam is sent through a microscope objective on the sample surface. A part of the incident beam is reflected back by a semi-transparent reference surface. The beams coming from the sample surface and the reference surface are projected onto the CCD detector, where they interfere. A piezoelectric transducer moves the objective and the interferometer vertically, causing a fringe modulation. The intensity at each point of the interference pattern is proportional to:

$$I(x, y) = \cos [\varphi(x, y) + \alpha(t)] , \quad (6.45)$$

where $\varphi(x, y)$ is the initial phase and $\alpha(t)$ is the time-varying phase. The initial phase at each point is calculated from the fringe modulation and the corresponding height is obtained using

$$z(x, y) = \frac{\varphi(x, y)\lambda}{4\pi} , \quad (6.46)$$

where λ is the wavelength of the light source. Two main interferometric techniques are commonly used in connection with surface measurements [6.195]:

- Phase shift interferometry (PSI)
- Scanning white light interferometry (SWLI)

In PSI, the illumination is from a monochromatic light source (laser interferometry); this technique is characterized by the highest resolving power, while the dynamic range (maximum detectable depth difference between two neighboring pixels) is limited to $\lambda/4$, typically about 150 nm. A clear interference pattern can only be observed on smooth surfaces, while the interference fringes are corrupted by speckle effects when the roughness is larger than $\lambda/4$.

SWLI can be regarded as an extension of the PSI method, where a broadband frequency (instead

Fig. 6.23 Optical layout of an interferometric measuring system [6.194]

of a single frequency) contributes to topography measurement. With white light, the dynamic range is no longer limited to $\lambda/4$. This is explained, referring to the frequency domain analysis technique (FDA) by the fact that an interval of wavelengths, rather than a single one, is used to evaluate the slope. FDA implementation in SWLI is based on the discrete Fourier transform (DFT).

PSI is used mainly for testing optical components and silicon wafers with high accuracy and short measuring times (below 1 s), while most technical surfaces can be inspected by SWLI. Regardless of the category, the lateral resolution is always worse than $0.3\ \mu\text{m}$, due to the diffraction limit stated in (6.43). These microscopes are all limited with respect to the surface slopes from the finite numerical apertures. The maximum detectable slope using interferometry amounts to about 30° . These optical methods allow fast noncontacting measurements on essentially flat surfaces.

6.2.3 Scanning Probe Microscopy

General Introduction

Scanning probe microscopy, including atomic force microscopes (AFMs) and scanning tunneling microscopes (STMs), provides a powerful tool for subnanometric acquisition of topographical data on very fine surfaces. Since the invention in 1986 of the scanning tunneling microscope [6.196], SPM and especially AFM have developed very rapidly, from scientific instruments used for basic research to their use in quality control in manufacturing [6.186, 197].

Measurement and Data Processing

In an SPM, as illustrated in Fig. 6.24a, a sharp tip with a radius of approximately 5–20 nm (the original contact-mode tip and cantilever are made out of silicon

nitride using photolithography and preferential etching) is scanned over the surface by a xyz actuator with a resolution of much less than a nanometer and a dynamic range on the order of $10\ \mu\text{m}$ in the z direction and up to $100\ \mu\text{m}$ in the x - and y -directions. Alternatively, as shown in Fig. 6.24b, the tip is stationary while the sample is moved. The probe records a control signal; in the atomic force microscope this signal is the nondestructive force exerted by the surface on the tip; in the scanning tunneling microscope the control signal is a small current flowing from the tip into the sample. The tip is moved relative to the surface, raster-scanning over a number of nominally parallel lines; in the AFM the height of the probe as function of the x and y position is recorded as an image and the topography of the surface is built up into a three-dimensional image. The tip is mounted on a very soft cantilever with a spring constant k in the range of $1\ \text{N/m}$ – so soft that the scanning probe will not move the atoms around on the surface. At the start of a measurement, the cantilever is positioned towards the sample. When the tip touches the sample, the cantilever begins to bend proportionally to the force exerted by the tip on the surface. The tip, ideally terminated by a single atom, traces the contours of the surface and is actually touching the sample surface with a very low force – so low that the atomic structures are unaltered – both on the sample as well as on the tip. The low force between the tip and sample is kept at a constant level during scanning, being typically lower than $10\ \text{nN}$ in contact mode atomic force microscopy. The most accurate and commonly used principle of detection of the cantilever deflection is optical: a focused laser beam, typically from a laser diode, is reflected from the back of the cantilever towards a photodiode with two or four segments, as illustrated in Fig. 6.24b. When the cantilever is bent, the laser spot at the photodiode will move; in other words the relative intensity

Fig. 6.24a,b Principle of a SPM: (a) raster-scanning the tip over a surface, (b) optical force detection with the sample scanned in an AFM

Fig. 6.25 Different operating modes of an AFM

of light hitting the segments will change and produce a signal.

AFM Operation Modes

Different modes of AFM operation exist. The simplest mode of operation for an atomic force microscope is the contact mode, where the probing tip senses the small repulsive force occurring from constantly touching the sample surface. The signal from the detector is used to vertically adjust the tip position with respect to the sample surface, so as to eliminate the deflection of the cantilever. For most applications, resonant vibrating cantilever modes are preferred, although they are more complicated to understand. In the noncontact mode, the cantilever is forced to vibrate a little *above* its resonant frequency. When the vibrating tip comes so close to the surface that it begins to feel the attractive van der Waals forces, the amplitude of the vibration will become smaller. It is this (decreased) amplitude which is kept constant during scanning in noncontact. In intermittent contact mode, the cantilever is forced to vibrate a little *below* its resonant frequency, far away from the sample surface. When the vibrating tip comes so close to the surface that it begins to touch the sample surface during a fraction of the vibration cycle, the amplitude of the vibration, as in noncontact mode, becomes smaller relatively to the free amplitude. It is this (decreased) amplitude that is kept constant during scanning in the intermittent mode. Figure 6.25 summarizes the different modes of operation discussed above.

The atomic force microscope can be operated in several other modes than those described above, for example with the purpose of, at least qualitatively, differentiating material properties. During scanning, the tip can tilt, caused by friction between tip and sample surface. The tip also suffers from friction when it passes a ridge and, unfortunately, the friction and to-

pography signal often become mixed. It is possible to give the tip a permanent charge that makes it sensitive to charged areas on the sample when it scans over the surface without touching it. It is also possible to have the tip covered with a permanent magnetic material. If the sample has domains with different magnetic magnitudes, the tip can detect that. In a force modulation microscope, the tip is scanned in contact with the sample and the cantilever, or sample, is forced to swing periodically by a constant control signal. The actual amplitude of the cantilever changes according to the elastic properties of the sample. Atomic force microscopy can be performed in many environments, including ultrahigh vacuum, ambient conditions and liquids. If the atomic force microscope works in ultrahigh vacuum, it can resolve not only single atoms but also single atom defects on, say, the surface of silicon. Working in air, AFM can only resolve the unit cell structure. It is yet to be demonstrated that it can resolve single atom defects when working in ambient air.

AFM Scanners

In many commercial microscopes, the movement of the tip is performed by a scanner tube, which is a hollow cylinder made out of a piezoelectric material that will change its linear dimensions when subjected to an electric field, and wag in the x - y -plane like a dog's tail. By raising the voltage on the inner electrode, or by mounting a separate piezo element on top of the tube, one can generate movement in the z -direction. This construction has the advantage of being simple and rigid, since all three movements are performed by the same elements. The disadvantage is that the movement is not very accurate. Piezo materials have a number of undesirable properties. First of all, they are intrinsically nonlinear and, what is worse, piezoelectric materials also suffer from hysteresis. Another problem is creep, which means that when a voltage is applied, the extension or contraction of the piezo material will not reach its final state instantly. Another problem when generating the movement is the coupling between the x - and the y -motion. Generally speaking, whenever the tip or the sample is moving in one direction, it will unintentionally also move a little bit in other directions. This is particularly bad for movement in the x -direction, since the associated small movement in the z -direction will make a flat surface look curved [6.198]. For smooth surfaces, this curvature can easily dominate the roughness. Over a side length of 100 μm , the peak-to-peak values for the image bow range from a few nanometers for high-quality flexure stages to more than 100 nm for some commonly used

tube scanners. Part of the nonlinearity and the hysteresis can be corrected off-line by image processing software. In the x - and y directions, correction methods can lead to an accuracy of 1–2% under optimum conditions. For the z -direction, unfortunately, it is very difficult – if not impossible – to make a model correction, because the history is generally not known. Using the most linear piezo material, which means trading away some scan range in the z -direction, an accuracy that reaches down to one percent can also be achieved in this direction. The way to overcome the nonlinearity of the piezo material is to use linear distance sensors that independently measure the movement of either the sample or the tip, as used in so-called metrology AFMs.

Large-Range AFM

An AFM allows measurement of the surface topography with very high resolution, but over a limited range. In a specially made instrument, an AFM probe is mounted on a coordinate-measuring machine (CMM), achieving free positioning of the AFM in the space covered by the CMM [6.199, 200]. In particular, this integrated system can be used for surface mapping [6.199–204]. The CMM is used to reposition the AFM probe in-between surface roughness measurements to stitch together different areas covering continuous regions larger than the range scanned by the probe. Correct stitching independently of the positioning errors of the CMM is obtained through optimization of the cross-correlation between two adjacent overlapping surface areas. A maximum uncertainty of 0.8% was achieved for the case of surface mapping of $1.2\text{ mm} \times 1.2\text{ mm}$, consisting of 49 single AFM images, as shown in Fig. 6.26 [6.195]. Another example of large-range AFM, developed by PTB, is described in [6.205].

6.2.4 Scanning Electron Microscopy

Scanning electron microscopy (SEM) can be used for qualitative surface topography analysis, primarily based on the fact that SEM allows excellent visualization. As regards topography, SEM has some unique properties that, combined together, are not matched by any other microscopy technique. These are listed below [6.195].

- Possible magnification levels from less than 100 \times up to 100 000 \times . This means that the imaged range can either be on the order of 1 mm^2 or just $1\text{ }\mu\text{m}^2$. SEM is in fact a multi-scalar technique. There is no other microscopy method as flexible as SEM in terms of the range of scalability.

Fig. 6.26 Left: Scanning strategy; Right: 3-D plot of AFM image composed of 49 single scans stitched together [6.195]

- At high magnification, the ultimate resolution is as good as about 2 nm on conductive surfaces. SEM metrology is not limited by light diffraction. Such high resolving power can only be achieved by scanning probe microscopes that, on the other hand, are limited in terms of measurable range.
- Large depth of field. In a SEM, features lying at different depths can be kept simultaneously in focus.
- Long usable working distance. High magnification images, say at 1000 \times or more, can easily be taken with working distances of several millimeters (ten or even more). This feature allows the development of measuring strategies based on multiple positioning. Moreover, commercially available SEMs are provided with moveable sample stages, with some degrees of freedom for observing features from different viewpoints.

Although SEM images obtained by detecting secondary electrons have a striking three-dimensional appearance (due to the shadowing effects), they are still inherently 2-D. No height information can be extracted directly from the images, and measurements in the x - and y -dimensions are only correct in a single plane. In order to reconstruct the third dimension of surface features, photogrammetry methods can be used [6.206–212]. A specimen is imaged in the SEM under two different perspectives. Surface features of different heights on the specimen surface differ in their lateral displacement in the two images. The disparities between projections of the surface features in the two images are used to derive quantitative surface topography. A fundamental prerequisite for successful calculation is the correct matching of single surface features in the two images. In most SEMs, it is possible to take the two different stereo viewpoints by tilting the specimen about a horizontal axis.

3-D data achieved by reconstructing stereo pairs or triplets can be used to evaluate surface topography, but they are limited by a number of factors. First of all, SEM measurements require conductive sample materials, or sample preparation through deposition of a gold layer on the surface. A major limitation is that roughness parameters should be calculated over a relatively large area, while, in the case of large magnifications, the area is relatively small. Another limitation is that smooth surfaces are reconstructed with high uncertainty [6.195].

An investigation was carried out at DTU on the traceability of surface texture measurements using stereo-pair SEM. A positioning procedure that realizes pseudo-eucentric tilting was developed. A model for calculating accuracy of topography calculation was given, based on an existing theory adapted to comply with the hypothesis of eucentric tilting [6.213, 214]. A novel design for a calibration artefact, suited for testing the performance of a three-dimensional SEM at high magnifications, was proposed [6.195].

6.2.5 Parametric Methods

Besides the above methods, which produce height scans over the surface, a number of techniques exist that produce measurable parameters representing some averaged property of the surface topography. All of the phenomena related to the interaction between a light wave and a surface are affected by the microgeometry of the surface, and methods based upon specular or diffuse reflectance, speckle and polarization have been developed. A review by *Vorburger and Teague* [6.215] discusses these techniques, considering potentialities and limits. The so-called integral methods, by which surface roughness is measured and quantified as a whole, operate with parameters based on surface statistics, correlation and frequency analysis. The main advantage of statistical surface description is that it describes a profile or surface with a minimum number of parameters, which enables a characterization of the profile or surface [6.216]. The statistical analysis of surface topography leads to a broad variety of parameters, which are not covered by ISO standards in general. In addition to pure statistical properties, further information can be obtained from autocorrelation and autocovariance functions of a given surface $h(x)$ (ACF and ACVF), which are identical for functions with zero mean, as well as from the power spectral density function (PSDF). These are described mathematically in (6.47) and (6.48) below. A simplified theoretical treatment of light scattering from rough surfaces is based on the Huygens Fresnel

Fig. 6.27 The Huygens Fresnel principle as the basis of light scattering from rough surfaces [6.171]

principle, as shown in Fig. 6.27. Here, it may be helpful to emphasize that, irrespective of the method, data cannot be influenced by any property of the sample that is outside the sensing regime of the measuring instrument as defined in the Stedman diagram of Fig. 6.2. Thus, the data from instruments may not agree, even if they are fully calibrated according to the best procedures.

$$\text{PSDF}(k_x) = L^{-1} \left| \int_0^L h(x) \exp(-ik_x x) dx \right|^2, \quad (6.47)$$

$$\begin{aligned} \text{ACF}(\tau) &= L^{-1} \int_0^L h(x) h(x + \tau) dx \\ &= \frac{1}{2\pi} \int_{-\infty}^{\infty} \text{PSDF}(k_x) \exp(ik_x \tau) dk_x. \end{aligned} \quad (6.48)$$

Parametric methods based on capacitive and other methods exist as well, but are not relevant to the present chapter.

6.2.6 Applications and Limitations of Surface Measurement

Visualization of the surface profile, or surface area, is perhaps the most powerful tool associated with topographic surface analysis. Significant information can be drawn directly from the plots, especially when investigating surface functionality. When quantitative information is required, the adoption of parameters becomes essential. For instance, peaks are important when considering friction and wear properties, as the interaction between surfaces concentrates around them. Valleys are important for the retention of lubrication. At the same time, fracture propagation and corrosion start in valleys. The R_z parameter can be useful where components are subjected to high stresses; any large peak-to-valley value could be associated with areas which are likely

to suffer from crack propagation. For both qualitative as well as for quantitative characterization, 3-D analysis is a powerful tool which can give much more information compared to conventional 2-D methods. In [6.217], a method for identifying different wear mechanisms by measuring surface texture alterations was proposed and applied to deep drawing dies. Using a combination of the areal bearing curve parameters Spk and Svk , adhesive, abrasive and fatigue wear as well as plowing and pick-up could be recognized. An important application of areal analysis concerns the quantification of 3-D features such as dominant texture direction, shape of contact asperities, lubricant reservoirs, and valley connectability.

It cannot be emphasized strongly enough that single parameters, which are inherently synthetic, cannot completely describe the complex reality of a surface. Each parameter can only give information about some specific features of the microgeometrical texture, and it requires a sound interpretation. For example, the Ra parameter on its own does not tell us anything about the functional behavior of a component, and many existing surfaces can be characterized by the same values of Ra but are extremely different with respect to functionality, as clearly illustrated by Fig. 6.28. Ra can be

Fig. 6.28 Two profiles with the same Ra (and Rz) value but with very different functional behaviors

used as a process control parameter since changes in Ra value may indicate that some process conditions have changed, such as cutting tool geometry, cutting speed, feed or cutting fluid action. However, being an average value, Ra cannot be used to control processes involving stratified surfaces, such as plateau honing. As a general rule, it is strongly recommended that parameters should only be used in connection with a visual examination of the surface topography. An example of extracting comprehensive information using commercial software (SPIP™ [6.218]) in connection with surface topography analysis is shown in Fig. 6.29.

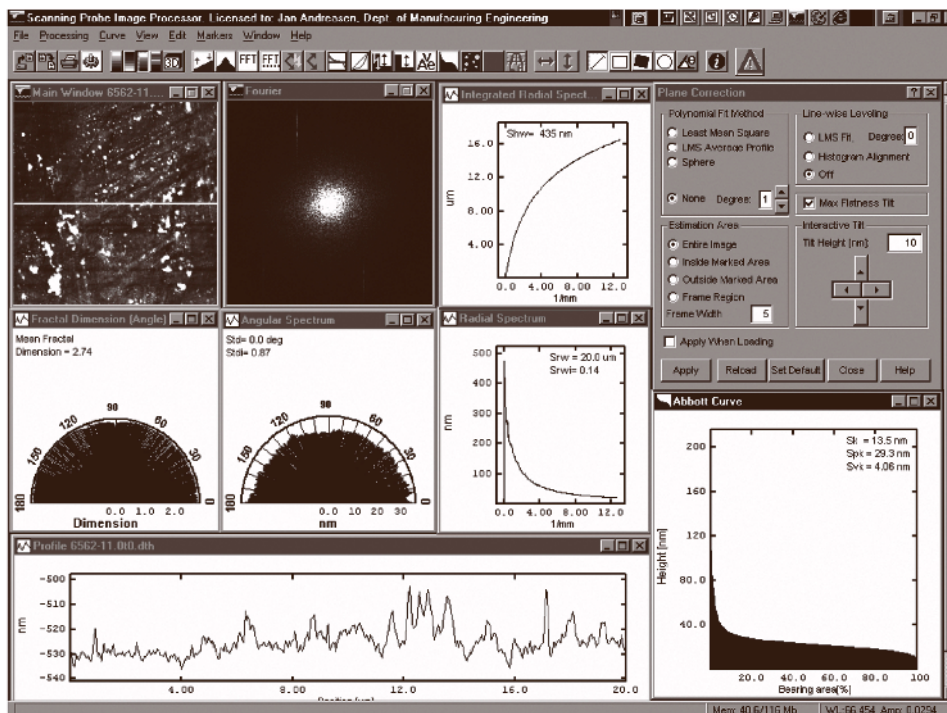

Fig. 6.29 Example of comprehensive information associated with surface analysis using SPIP [6.218]

Other limitations are related to error sources from the measurement. For instance, roughness parameters can be subject to large variations arising from their definitions and can also be unstable due to spurious features such as dust, burrs or scratches. A metrological limitation in stylus profilometry is that the geometry of the tip acts like a mechanical filter that cannot reproduce smaller details. The resolution achieved by the stylus method depends on the actual surface slopes and heights in the neighborhood of the point of contact, as illustrated in Fig. 6.16. Some parameters describing the shape of the surface are directly influenced by the geometry of the stylus, for example the tip radius R is added to the radii of peaks and subtracted from the radii of valleys. Moreover, the force applied by the stylus on the surface can generate plastic deformation of the surface and affect the measurement. Also, in AFM there are limitations on resolution imposed by the geometry of the probing tip and error sources related to instrument and measuring conditions. No existing instrument can be regarded as truly 3-D: stylus instruments, SPMs and optical instruments can be considered, at most, as $2\frac{1}{2}$. More typically, the vertical range is limited to about one-tenth of the lateral ones. No commercially available instrument is suitable for measuring deep cavities, pores, or re-entrances, not to mention hidden details. The need for true 3-D characterization of surface details has been addressed in [6.219].

6.2.7 Traceability

Traceability is defined as the property resulting from measuring to the value of a standard whereby it can

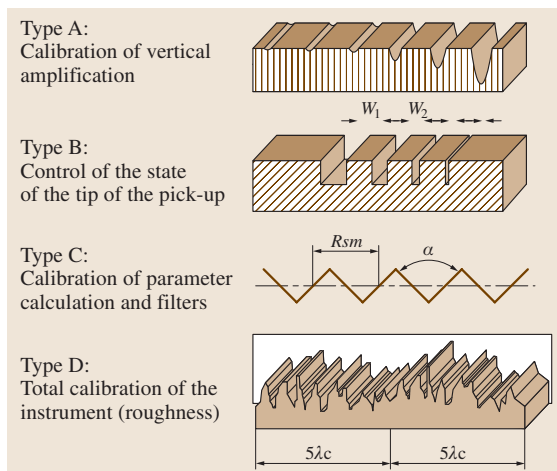

Fig. 6.30 Examples of surface texture calibration standards described by ISO 5436 [6.183, 184]

be related to stated references, usually national or international standards, through an unbroken chain of comparisons, all with stated uncertainties [6.219, 220]. In the case of surface roughness measurements, several factors influence this property, for example the measurement principle, the characteristics of the instrument, the measurement procedure and the data evaluation [6.221]. Calibration, traceability and uncertainty issues in surface texture metrology are addressed in a NPL report by *Leach* [6.222]. A recent international comparison regarding surface texture traceability is reported in [6.223].

Calibration of Instruments

Standards and procedures for the verification of the entire measurement system are described in international standards [6.183, 224]. These standards cover the most conventional uses of the instruments and the most common parameters. The verification of algorithms for the calculation of surface roughness parameters can be carried out by means of software gauges, thereby establishing traceability for the data evaluation or software. This principle is described in [6.184]. In the case of new methods for the characterization of surface texture (for example integral methods), new approaches have to be taken in order to establish traceability. Here the measurement principle, including the physical principle as well as the data evaluation method, must be taken into account, and the procedure and principle are essential to the result. An example is the on-going common effort to establish traceability for atomic force microscopy, where not only the physical principle of the instrumentation but also the data evaluation methods are being investigated [6.225–227].

Some examples of 2-D surface texture calibration standards described by ISO are shown in Fig. 6.30. These calibration standards can be purchased from roughness instrument manufacturers, and their accredited calibration is provided by a large number of laboratories. Methods and standards for 3-D instrument calibration are currently under standardization by ISO TC213 (Table 6.3).

The minimum necessary equipment for calibration of a stylus instrument for general industrial use is an optical flat to check the background noise and an ISO Type C or D standard with a known parameter value (R_a or R_z). The background noise, which originates from the electrical and mechanical parts in the instrument, results in a systematic error. As a main rule, the roughness-measuring instrument should only be used for measurements of specimens with param-

ter values higher than five times the background noise. Typical background noise levels are: i) portable roughness measuring instruments Ra : $0.02\ \mu\text{m} - -0.05\ \mu\text{m}$; ii) stationary roughness measuring instruments Ra : $0.002\ \mu\text{m} - -0.01\ \mu\text{m}$. The magnifications of instruments with external pick-up data can be calibrated using an ISO type A standard. It is customary to use calibration standards frequently, in connection with the use of the instruments.

Calibration of optical instruments is not as well-established as calibration of stylus instruments [6.193, 215, 228, 229]. A proposal for a guideline to calibrate interference microscopes using the same artifacts and procedures that are used for stylus instruments is presented in [6.229].

Calibration of SPMs, currently still under development, encompasses scaling, nonlinearity, hysteresis and orthogonality of x - y - z axes, as well as shape, size and dynamics of the probe [6.195, 225–227]. Transfer standards designed for certification are available through the instrument manufacturers, while their certification can be obtained from major national metrological institutes (PTB, NPL, NIST, and so on).

Uncertainty Budgeting

Upon calibration using a transfer standard, it is possible to produce an uncertainty budget for measurements with a stylus instrument. An example of an uncertainty budget for the calibration of an instrument using an ISO type C standard with a certified uncertainty U_n follows. The budget contains three components that can be calculated from knowledge about: 1) reference uncertainty, 2) background noise level and 3) measurement repeatability. Following a convention, “ u ” indicates the standard uncertainty at the 1σ level, while “ U ” is for the 95% confidence level at a coverage factor of 2.

- Uncertainty of the calibration standard from certificate: $u_n = \frac{U_n}{2}$
- Uncertainty in the transfer of traceability (repeatability of the instrument): $u_r = \frac{STD_r}{\sqrt{n}}$, where n is the number of measurements in the same track with the standard deviation STD_r ;
- Uncertainty caused by the background noise: $u_b = \frac{1}{2} \frac{Rx0}{\sqrt{3}}$, where $Rx0$ is the measured background noise (average $Ra0$ or $Rz0$ value measured on an optical flat, assuming rectangular noise distribution);
- Total uncertainty: $U_{\text{inst}} = 2\sqrt{u_n^2 + u_r^2 + u_b^2}$.

If the same instrument is used for measurements on a work piece, the resulting uncertainty increases with the

variation in roughness of the work piece, which is determined by taking measurements at different locations. It shall be noted that this component (estimated as u_s) depends on whether or not the measurement result is used for tolerance verification.

- u_s is the uncertainty caused by variations in the roughness of the specimen at different locations (n is the number of measurements carried out on the specimen with corresponding standard deviation STD_s)
- General (without tolerance verification): $u_s = \frac{STD_s}{\sqrt{n}}$;
- Verification after the 16% rule (ISO 4288): $u_s = \frac{1}{2} \frac{STD_s}{\sqrt{n}}$;
- Verification after the max rule (ISO 4288 [169]): $u_s = 0$ (single measurements);
- Total uncertainty: $U_{\text{tot}} = 2\sqrt{u_n^2 + u_r^2 + u_b^2 + u_s^2}$.

It may be worth reminding the reader that the uncertainties only refer to the properties of the sample within the zone defined on the Stedman plot in Fig. 6.2 – they are not necessarily the true uncertainties.

Current Situation and Future Developments

The present situation concerning surface metrology can be illustrated with respect to the traceability of surface

Fig. 6.31 Diagram of wavelength versus amplitude for different surface roughness calibration standards (courtesy of the PTB from [6.219])

Table 6.13 Merits, limitations and applications of some techniques for surface topography analysis

Technique	Merits	Limitations	Applications
Stylus profilometry	Large vertical and lateral range Slopes up to 60° Robust Universally applicable externally as well as for internal measurements	Micrometer resolution Scratches soft surfaces	All kinds of industrial surfaces
Auto-focus profilometry	Non contact	Max slope 15° Signal problems on shiny or transparent materials	Soft as well as hard surfaces
White light interferometry	Fast method High vertical resolving power (down to 0.1 nm)	Limited lateral resolution Maximum detectable slope up to about 30°	Roughness of flat surfaces Films thickness Small aspect ratio MST components
Confocal microscopy	High aspect ratio structures Maximum detectable slope up to 75°	Limited lateral resolution Limited vertical resolution in some commercially available instruments	Dimensions of high aspect ratio MST components
Scanning electron microscopy	Wide range of operation, from less than 100× up to 100000× Nanometre resolution Large depth of field Large working distance	Requires conductive sample material or preparation. Small area for calculation of roughness parameters	Nanotechnology All kinds of material
Scanning probe microscopy	Nanometre/sub nanometre resolution	Slow method Limited lateral and vertical range	Nanotechnology Nano-roughness

topography measurements. Figure 6.31 shows the range of different calibration standards currently available. Comparing the present possibilities with the measurement ranges covered by existing instruments, Fig. 6.16, and with the requirements from production [6.219], the need for developments in the nanometer range is clear. Traceable calibration of optical surface roughness instruments is also challenging [6.228–230]. Another clear challenge is the true three-dimensional characterization of surface details involving re-entrances, as discussed in [6.197, 219, 230].

6.2.8 Summary

Surface topography characterization encompasses measurement, visualization and quantification. The principal

methods of surface topography measurement are stylus profilometry, optical scanning techniques, and scanning probe microscopy (SPM). These methods, based on the acquisition of topography data from point-by-point scans, give quantitative information on heights with respect to position. Based on a different approach, the so-called integral methods produce parameters representing some average property of the surface under examination. Measurement methods, as well as their application and limitations, have been briefly reviewed, including standardization and traceability issues. Table 6.13, adapted from [6.195], gives an overview of the merits, limitations and typical applications of different techniques for surface topography measurements.

Mechanical

7. Mechanical Properties

Materials used in engineering applications as structural components are subject to *loads*, defined by the application purpose. The mechanical properties of materials characterize the *response* of a material to loading.

The mechanical loading action on materials in engineering applications may be static or dynamic and can basically be categorized as tension, compression, bending, shear, and torsion. In addition, thermomechanical loading effects can occur, (see Chap. 8 Thermal Properties). There may also be *gas loads* from the environment, leading to gas/materials interactions (see Chap. 6 Surface and Interface Characterization) and to *transport phenomena* such as permeation and diffusion.

The mechanical loading action and the corresponding response of materials can be illustrated by the well-known *stress–strain curve* (for definition see Sect. 7.1.2). Its different regimes and characteristic data points characterize the mechanical behavior of materials treated in this chapter in terms of *elasticity* (Sect. 7.1), *plasticity* (Sect. 7.2), *hardness* (Sect. 7.3), *strength* (Sect. 7.4), and *fracture* (Sect. 7.5). Methods for the determination of permeation and diffusion are compiled in Sect. 7.6.

7.1 Elasticity

Elastic properties of materials must be obtained by experiment methods. Materials are too complicated and theories of solids insufficiently sophisticated to obtain accurate theoretic determinations of elastic constants. Usually, simple static mechanical tests are used to evaluate the elastic constants. Specimens are either pulled in tension, squeezed in compression, bent in flexure or twisted in torsion and the strains measured by a variety of techniques. The elastic constants are then calculated from the elasticity equation relating stress to strain. From these measurements, Young's modulus, Poisson's ratio and the shear modulus are determined. These are the moduli commonly used for the calculation of stresses or strains in structural applications. More accurate than the static method of determining the elastic constants are the dynamic techniques that have been developed for this purpose. In these techniques a bar is set into vibration and the resonant frequencies of the bar are measured. A solution of the elastic equations for the vibration of a bar yields a relationship between the elastic constants, the resonant frequencies and the dimensions of the bar. These techniques are about five times as accurate as the static techniques for determining the elastic constants. Elastic constants can also be measured by determining the time of flight of an elastic wave through a plate of given thickness. Because there are two kinds of waves that can traverse the plate (longitudinal waves and shear waves), the two elastic constants required for structural calculations can be determined independently. Finally, the newest advances in techniques for measuring the elastic constants of materials have their origins in the need to measure these constants in thin films, or parts too small to be determined independently. The development of nanoindentation devices proves to be ideal for the measurement of elastic constants in these kinds of materials. Each of these techniques is discussed in terms of standard American Society for Testing and Materials (ASTM) and international test methods that were developed to assure repeatability and reliability of testing. This discussion serves as a primer for engineers and scientists wanting to determine the elastic constants of materials.

7.1.1 Development of Elasticity Theory

The design of new components for structural applications usually includes an analysis of stress and strain to assure structural reliability. Two general kinds of practical problems are encountered: the first in which all of

the forces on the surface of a body and the body forces are known; the second in which the surface displacements on the body are prescribed and the body forces are known [7.1]. In both cases, calculation of the stresses and displacements throughout the body and at the body surface is the objective. Within the limits of an elastic material, i. e., a material in which the displacements and stresses completely disappear once all of the constraints are removed, the theory for solving such problems was completely developed by the end of the 19th century. There are many methods of solving such problems, especially with the development of finite element analysis. All such problems require the elastic constants of the material of interest as an input in order to obtain a solution. The description of experimental techniques of measuring the elastic constants of engineering materials are the main subject of this chapter, but before describing the experimental techniques, we first give a brief history of the development of the theory of elasticity. We then go on to describe the theory of elasticity in order to put our later discussion of experimental techniques into context. There are several good books or chapters in books that give a history of the theory of elasticity [7.1–3], and there are many excellent texts that describe the theory [7.1,4]. The discussion given below rests heavily on references [7.1–4].

The first scientist to consider the strength of materials was *Galileo* in 1638 with his investigation of the strength of a rigid cantilever beam under its own weight, the beam being imbedded in a wall at one end [7.5]. He treated the beam as a rigid solid and tried to determine the condition of failure for such a beam. The concepts of stress and strain were not yet developed, nor was it known that the neutral axis should be in the middle of the beam. The solution he obtained was not correct; nevertheless, his work stimulated other scientists to work on the same problem.

The next important contributor to the theory of elasticity was *Hooke* in 1678, when he discovered the law that has been subsequently named after him [7.6]. He found that the extension of a wide variety of springs and spring-like materials was proportional to the forces applied to the springs. This finding forms the basis of the theory of elasticity, but Hooke did not apply the discovery to material problems. A few years later (1680), *Mariotte* announced the same law and used it to understand the deformation of the cantilever beam [7.7]. He argued that the resistance of a beam to flexural forces should result from some of the *filaments* of the beam be-

ing put into tension, the rest being put into compression. He assigned the neutral axis to one-half the height of the beam and used this assumption to correctly solve the force distribution in the cantilever beam. *Young* further developed Hooke's law in 1807 by introducing the idea of a modulus of elasticity [7.8,9]. Young's modulus was not expressed simply as a proportionality constant between tensile stress and tensile strain. Instead, he defined the modulus as the relative diminution of the length of a solid at the base of a long column of the solid. Nevertheless, his contribution was used in the development of general equations of the theory of elasticity.

The first attempt to develop general equations of elastic equilibrium was by *Navier*, whose model was based on central-force interactions between molecules of a solid [7.10]. He developed a set of differential equations that could be used to calculate internal displacements in an isotropic body. The form of the equations was correct, but because of an oversimplification of the force law, the equations contained only one elastic constant.

Stimulated by the work of Navier, Cauchy in 1822 developed a theory of elasticity that contained two elastic constants and is essentially the one we use today for isotropic solids (presented to the French Academy of Sciences on Sept. 30, 1822; Cauchy published the work in his *Exercices de mathématique*, 1827 and 1828. See footnote 32 in the first chapter of [7.3]). For non-isotropic solids, many more elastic constants are needed, and for a long time an argument raged over whether the number of constants for the most general type of anisotropic material should be 15 or 21. The controversy was settled by experiments that were carried out on single crystals with pronounced anisotropy, which showed that 21 is the correct number of constants in the most anisotropic elastic case. This number is also supported by crystal symmetry theory.

Once the theory of elasticity was completely developed, equations could then be derived for experimental measurement of the elastic constants. This has now been done quite generally so that the techniques that have been developed have a good scientific basis in the theory of elasticity. Elastic constants can be measured statically (tension, compression, torsion or flexure), or dynamically through the study of vibrating bars, or by measuring the velocity of sound through the material. Most of these measurements are made on materials that are isotropic, so that only two constants are determined; however, with the development of composite materials for structural members, isotropy is lost and other constants have to be considered.

7.1.2 Definition of Stress and Strain, and Relationships Between Them

The theory of linear elasticity begins by defining stress and strain [7.1,3,4]. Stress gives the intensity of the mechanical forces that pass through the body, whereas strain gives the relative displacement of points within the body. In the theory of linear elasticity, stress and strain are related by the elastic constants, which are material properties. In this section we define and discuss stress and strain and show how they are related through the elastic constants. It is these elastic constants that must be determined in order to evaluate stress distributions in structural components.

Stresses

When a body is under load by external forces, internal forces are set up between different parts of the body. The intensities of these forces are usually described by the force per unit area on the test surface through which they act. One can imagine cutting a small test surface within a material and replacing the material on one side of the surface by forces that would maintain the position of the surface in exactly the same position as it was before the cut was made. As the size of the test surface is diminished to zero, the sum of the forces on the surface divided by the area of the surface is defined as the magnitude of the stress on the surface. The direction of the stress is given by the direction of the force on the surface and need not be normal to the surface.

From the definition of stress, it is clear that the stress on a surface will vary with orientation and position of the surface within the solid. It is also usual to break down the components of stress into stresses normal and parallel to the surface. The stresses parallel to the surface are called shear stresses. Because stress depends on both the orientation of the surface, and the direction of the forces on the surface, the symbol indicating stress will have two subscripts attached to it, the first indicating the surface normal, the second indicating the direction of the forces on the surface. Consider a Cartesian coordinate system with three mutually perpendicular axes, x_1 , x_2 , and x_3 . A test surface normal to the x_1 -axis will have stresses, σ_{11} , σ_{12} , and σ_{13} , where σ is the symbol for stress. The force indicated by the stress σ_{11} is on the x_1 -surface, and its orientation is parallel to the x_1 -axis. The stress σ_{11} is either a tensile stress (positive sign by convention), or a compressive stress (negative sign). The stresses, σ_{12} and σ_{13} , are shear stresses: σ_{12} being on the x_1 -surface and oriented in the x_2 -direction; σ_{13} being on the x_1 -surface and oriented in the x_3 -direction.

Fig. 7.1 Illustration of the two-index notation of stress. Stresses on the negative side of the cube have the opposite direction to those on the front side. Stresses in the figure are all positive

An example of the stresses oriented around a small cube is shown in Fig. 7.1. From the fact that the cube is in equilibrium, the equation of equilibrium can be determined. Summing up the forces in the x_1 -direction, the following equation is obtained:

$$\frac{\partial \sigma_{11}}{\partial x_1} + \frac{\partial \sigma_{12}}{\partial x_2} + \frac{\partial \sigma_{13}}{\partial x_3} + F_1 = 0, \quad (7.1)$$

where F_1 are the body forces in the x_1 -direction. Similar equations are found for the x_2 - and x_3 -axes.

A convenient shorthand representation has been developed for equations similar to (7.1). The subscripts of (7.1) are indicated by lower-case letters, usually i , j , and k . A partial derivative is indicated by a comma; a repeated index indicates a summation. Thus, (7.1) can be

represented by:

$$\sigma_{ij,j} + F_i = 0. \quad (7.2)$$

Assignment of the value of 1, 2 and 3 for i yields three independent equations for equilibrium. The body forces F_i may be constant, or a function of space and time.

The state of equilibrium for the cube in Fig. 7.1 can also be used to prove that $\sigma_{ij} = \sigma_{ji}$. Taking the moment of the forces about a cube corner parallel to the x_1 -axis, $\sigma_{23} \sigma dx_2(dx_1 dx_3) = \sigma_{32} \sigma dx_3(dx_2 dx_1)$, which yields $\sigma_{23} = \sigma_{32}$. Similar equations are obtained around the x_2 - and x_3 -axis, proving the assertion that $\sigma_{ij} = \sigma_{ji}$. Therefore, of the nine possible stress components at any point within a body that is subjected to external forces, only six of them are independent.

Strains

Strains are determined by the relative displacements of points within a body that has been subjected to external forces. Imagine a volume within the body that was a cube prior to deformation, but has now been deformed into a general hexahedron, the axes of which may not be of equal length, or the angles between them right angles (Fig. 7.2). Two types of strain can be defined from this figure: tensile strain, in which the length of the axes of the cube have been changed by deformation, and a shear strain, in which the angle between the axes of the cube have been changed by the deformation. If u represents the displacement in the x_1 -direction of any point within the body due to the application of a set of forces, then the displacement of an adjacent point a distance dx_1 away from the first in a direction defined by the x_1 -axis is given by $u + (\partial u / \partial x_1) dx_1$. The relative change between the two points in the x_1 -direction is $\partial u / \partial x_1$, which is defined as the tensile strain in the x_1 -direction, ϵ_{11} . Similar definitions are used for the tensile strain in the x_2 - and x_3 -directions: ϵ_{22} and ϵ_{33} . In this case, v and w are the displacements in the y - and z -directions, respectively.

The shear strains are defined by the change in angle of the cube corners. Projecting the cube onto an x_2 - x_3 plane (Fig. 7.3), the change in the angle of the cube is given by $\partial v / \partial x_3 + \partial w / \partial x_2$, where v and w are the displacements in the x_2 - and x_3 -direction, respectively. The strain ϵ_{23} is defined by $\epsilon_{23} = (\partial v / \partial x_3 + \partial w / \partial x_2) / 2$. Similar equations are obtained for ϵ_{12} and ϵ_{13} . As with the shear components of the stress tensor $\epsilon_{ij} = \epsilon_{ji}$, as can be seen from the definition of shear strain.

Some other properties of stress and strain are commented on without proof. Both stress and strain are tensor quantities and transform as tensors with the rota-

Fig. 7.2 On deformation, the size of the box has increased and the angles between the sides are no longer right angles, indicating both a tensile and a shear strain

tion of system axes. Consider a transformation of axes from x_i, x_j, x_k to $x_\alpha, x_\beta, x_\gamma$, then the stresses will transform according to the following equation:

$$\sigma_{\alpha\beta} = l_{\alpha i} l_{\beta j} \sigma_{ij}, \quad (7.3)$$

where $l_{\alpha i}$ and $l_{\beta j}$ are the cosines of the angles between x_α and x_i , and x_β and x_j , respectively. Once the σ_{ij} are obtained at a point for a given set of axes, they can be obtained for any other set of axes using this simple transformation.

Stress–Strain Relations

Finally we arrive at the set of equations that relate stress and strain. Since there are six independent components to the stress tensor and six independent components to the strain tensor, there will be 36 constants of proportionality connecting the two

$$\sigma_{ij} = C_{ijkl} \varepsilon_{kl}. \quad (7.4)$$

The coefficients C_{ijkl} are the elastic stiffness constants. The repeat of the index kl in the subscripts on the right-hand side of this equation indicate by convention a summation over these subscripts for $k = 1, 2$ and 3 and similarly for l . Thus, for each of the six stress components on the left-hand side of the equation, there are six terms on the right-hand side and six coefficients C_{ijkl} . Of the 36 constants, it can be shown by strain-energy considerations that only 21 are independent. This number is reduced further by the symmetry of the solid. For a cubic material, the number of elastic constants is reduced from 21 to three. For an isotropic material, the

number of elastic constants is two. Equation (7.4) may be rewritten so that strain is expressed as a function of stress, in which case the two tensors are related by a set of constants S_{ijkl} known as the elastic compliances. The stiffness C_{ijkl} and the compliance S_{ijkl} are both fourth-order tensors that depend on the axis orientation for their values. They both transform as fourth-order tensors

$$C_{\alpha\beta\gamma\delta} = l_{\alpha i} l_{\beta j} l_{\gamma k} l_{\delta l} C_{ijkl} \quad (7.5)$$

with a similar equation for the compliances.

Since most engineering materials are isotropic, it is worth expanding the stress–strain equation (7.4) into a form that has more practical significance. The elastic constants that are most commonly used are the Young’s modulus E (the ratio of the tensile stress to the tensile strain), the shear modulus μ (the ratio of the shear stress to the shear strain), and the Poisson’s ratio ν (the ratio of the strain parallel to the tensile axis to the strain normal to the tensile axis). Since only two of these are independent for an isotropic material, it can be shown that the following relationship between the three exists

$$\mu = \frac{E}{2(1+\nu)}. \quad (7.6)$$

Strain can be expressed in terms of stress for an isotropic material, by the following equation

$$\varepsilon_{ij} = \frac{1+\nu}{E} \sigma_{ij} - \frac{\nu}{E} \delta_{ij} \Theta, \quad (7.7)$$

where δ_{ij} is the Kronecker delta; it equals one for $i = j$ and zero otherwise. The term Θ is equal to σ_{ii} , which indicates the sum over the subscript ($\sigma_{ii} = \sigma_{11} + \sigma_{22} + \sigma_{33}$). When expanded (7.7) yields six equations, one for each of the strain terms.

A similar equation can be written for stresses in terms of strains; in which case, the most appropriate elastic constants are the shear modulus μ and the Lamé constant λ

$$\sigma_{ij} = \lambda \varepsilon_{kk} \delta_{ij} + 2\mu \varepsilon_{ij}. \quad (7.8)$$

The Lamé constant can be expressed in terms of the other elastic constants by

$$\lambda = \frac{E\nu}{(1+\nu)(1-2\nu)}. \quad (7.9)$$

Most of this article deals with the evaluation of Young’s modulus, the shear modulus, and Poisson’s ratio, since these are the ones most often used in practical applications, and hence, are the ones for which the standards are written.

Fig. 7.3 As can be seen from the figure, the angle between the x_2 - and the x'_2 -axes is $1/2(dw/dx_2 + dv/dx_3)$, as for the x_3 - and x'_3 -axes. This angle is defined as the shear strain $\varepsilon_{23} = \varepsilon_{32}$. (After [7.2])

Linear elastic solutions of boundary problems can be obtained using the relationships between stress and strain (7.7) or its inverse (7.8) and the equations of equilibrium (7.2) subject to the conditions at the boundary. The solutions must satisfy a set of six equations known as the compatibility relations. These equations assure that solutions obtained yield valid displacement fields, i.e. fields in which the body contains no voids or overlapping regions after deformation.

The experimental configurations normally used to determine the elastic constants are cylinders of circular or rectangular cross sections, which are loaded in tension, flexure or torsion. Under static loading, elastic moduli are calculated from the load on the specimen, a measurement of specimen displacement and an elastic solution for the particular specimen. Measurements can also be made by dynamic techniques that involve resonance, or the time of flight of an elastic pulse through the material. In general, the static technique yielded results that are not as accurate as those obtained dynamically, differing by about -5% to $+7\%$ of the mean value of the dynamic technique [7.11]. The difference may be due to a combination of effects (adiabatic versus isotropic conditions, dislocation bowing, other sources of inelasticity, and different levels of accuracy and precision). This is discussed in Sect. 7.1.4.

In the remainder of this chapter, the techniques for determining the elastic constants for isotropic materials are discussed. The most recent **ASTM** recommended tests will form the basis of the discussion. The standards that are currently in use will be described and their application to a given material will be discussed. Since materials have a wide range of values for their elastic properties, given standards are not suitable for all materials. So, in the course of the discussion, the standards will be discussed with reference to the different classes of materials (polymers, ceramics, and metals) and recommendations will be made as to which technique is preferred for a given material. The relative error of each standard measurement will also be discussed with reference to the various materials.

Although **ASTM** tests are used in our discussions, we recognize that these standards are not universal. Other countries use different sets of standards. Nevertheless, the standards for elastic constants are all based on the same set of elastic equations and the same physical principals. So, regardless of which standard is used, the investigator should obtain identical results within experimental scatter. Furthermore, the same material considerations have to be taken into account in establishing a standard measurement technique. So here too,

the standard tests will have to be similar to obtain a given accuracy. A list of European standards is given in the appendix for those readers who prefer to use standards other than **ASTM**.

Five general tests are used to determine the elastic constants of materials. Tensile testing employing a static load is used to measure Young's modulus, and Poisson's ratio. Torsion testing of tubes or rods is used to determine the shear modulus. Flexural testing under a static load is used to determine Young's modulus. Various geometries are used for the flexural tests. Finally, resonant vibration of long thin plates and the time of flight of sonic pulses are both used to measure Young's modulus and the shear modulus.

7.1.3 Measurement of Elastic Constants in Static Experiments

In principal the simplest test geometry for determining elastic constants is the tensile test. A fixed load is placed on the ends of the specimen and the displacement over a fixed portion of gage section is measured. The load divided by the cross-sectional area gives the stress and the displacement divided by the length over which displacement was measured gives the strain. The Young's modulus is then given by the stress divided by the strain. Often, the Young's modulus is measured as part of a test carried out to determine the plastic properties of the metal. In such a test, a stress-strain curve is obtained on the metal, and the linear portion of the curve at the beginning of the test is used to calculate the Young's modulus. At the same time, if the lateral dimensions of the specimen are measured during the test, the test results can be used to determine Poisson's ratio as a function of strain.

Test Specimens

Tensile tests are generally carried out on a universal test machine. The precautions needed to achieve high measurement accuracy include alignment of the test machine, calibration of the load cell, firm attachment of the extensometers used to measure strain, and accurate measurement of the dimensions of the specimen cross section. Examples of specimen types and shapes, and methods of gripping used in these machines are shown in Fig. 7.4 [7.12]. The type of specimen depends on the stock from which the specimen is taken. Sheet materials are usually tested in the form of flat specimens that are clamped with wedge grips on their ends. The flat specimens may also be pinned as well as being clamped. Round stock is tested with threaded-end or shoulder-

end specimens that have matching shoulders or threads on the gripping device. Wires are tested using special snubbing devices in which the wire is wound around a mandrel to add the load gradually to the wire and thus prevent stress concentrations that will reduce the measured strength (in a strength test). In all specimens but the wires, the gage section is reduced to decrease the stress at the gripping points. Finally, the grips are usually attached to the testing machine through universal joints that prevent bending of the specimen during loading. Specific criteria for specimen dimensions and shapes are given in *ASTM E 8* [7.12].

Test Forces

Forces are determined by electronic load cells that attach to the testing machine and these can be calibrated through dead-weight testing through the use of elastic proving rings, or by the use of calibration strain-gage load cells following the recommendations of *ASTM E 74* (Standard Practice of Calibration of Force-Measuring Instruments for Verifying the Force Indication of Testing Machines) [7.13]. To assure that the load cell is operating correctly calibrations should be done periodically. Proving rings and load cells are both portable, however the latter tend to be smaller, es-

Fig. 7.4 Specimen types and shapes, and methods of gripping specimens in a universal testing machine. After *ASTM E8-01: Standard Test Methods for Tension Testing of Metallic Materials* [7.12]

pecially for large-scale loads and so are often preferred. Regardless which device is used, they in turn should be calibrated according to the procedures in [ASTM E 74](#). The calibration of load cells on universal test machines should be checked each time the machine is run, and periodic verifications of the load system should be carried out using [ASTM E 4](#) (Standard Practices for Force Verification of Testing Machines) [7.14]. The required practice is to verify the test system one year after the first calibration and after that a minimum of once every 18 months.

Strain Measurement

Strain on tensile specimens can be measured by the use of extensometers that attach directly to the gage section of the test specimen, by the use of strain gages that are mounted directly to the specimen, or by the use of optical systems, which directly sense the motion of marks on the gage section or flags attached to the gage section of the tensile specimen. Clip-on extensometers have knife-edges that press into the specimen surface and clearly define the length of the gage section. They are inherently more accurate than other techniques and hence are used in standard methods for determining the elastic constants [7.18].

Two basic kinds of clip-on extensometers are used to detect strain. One contains a linear variable differential transformer (LVDT) that moves as a consequence of specimen deformation and produces an electrical signal that is proportional to the motion. These are small, lightweight instruments that have knife-edges to define the exact points of contact. They can be used over a wide range of gage lengths (10–2500 mm) and can be modified to operate over a wide range of temperatures, –75 °C to 1205 °C [7.18].

The second type of extensometer uses strain gages to measure the deformation. The strain gage is usually mounted on a beam within the extensometer that deforms elastically as the tensile specimen is deformed. The strain gage is a wire grid that changes its resistance as the beam is deformed elastically. To detect the

strain, the gage is connected to a bridge that measures the resistance of the gage. The signal from the bridge is conditioned and amplified before going to a digital read out device. Using strain-gage extensometers, the amplification of the original displacement can be as high as 10 000 to 1 [7.18]. Strain gage extensometers are also light and are easily attached onto the gage sections with knife-edge clips.

Strain gages may be attached directly to the gage section of the test specimen, in which case the strain measured over a nominal gage length rather than the more precise length typical of extensometers. Since the calibration of individual strain gages and the integrity of their attachment are often deduced by measuring a material with a known elastic modulus, strain gages cannot be used to certify a measurement of elastic modulus. For noncritical applications, however, they are often the simplest approach to acquiring elastic properties and usually provide satisfactory results.

In [ASTM E 83](#) [7.19], strain extensometers are classified into six classes according to their accuracy. Only the three most accurate classes, class A, class B1 and sometimes class B2, can be used for evaluation of the Young’s modulus of materials. To evaluate the performance of a strain extensometer, verification procedures have been put forth by various standards organizations [7.18]. Class A extensometers show the highest accuracy for strain measurements, but are generally not available commercially [7.18]. Class B1 extensometers are available commercially and are the ones most commonly used for elastic constant measurement. Class B2 can also be used for elastic constant determination on plastics, which are high-compliance materials.

Test Procedures

Quasistatic tests to evaluate the elastic constants should be carried out according to the procedures outlined in the standard shown in [Table 7.1](#).

These tests vary according to the materials tested and the constant being determined. For metals the Young’s modulus is determined by applying a tensile load to the specimen following the procedure given in [ASTM E 111](#). The specimen is loaded uniaxially and strain is obtained as a function of load. Stress is calculated from the load; the linear portion of a plot of stress versus strain is used to determine the Young’s modulus. The linear section of the plot is fitted by the method of least squares and the Young’s modulus is given by the slope of the plot. The coefficient of determination r^2 and the coefficient of variation V_1 are reported to give a measure of the

Table 7.1 Standard quasistatic tests for elastic constants

Specification number	Specification title
ASTM E 111-04 [7.15]	Standard Test Method for Young’s Modulus, Tangent Modulus, and Chord Modulus
ASTM E 132-04 [7.16]	Standard Test Method for Poisson’s Ratio at Room Temperature
ASTM E 143-02 [7.17]	Standard Test Method for Shear Modulus at Room Temperature

goodness of the fit. The test can be carried out either with calibrated dead weights or, more often, by using a universal test machine. Class B1 extensometers are specified for the test, and an averaging extensometer, or the average of at least two extensometers arranged at equal angles around the test specimen are recommended. The standard points out that for many materials, Young's modulus determined in tension and compression are not the same, so that separate determinations for each mode of loading are recommended. Finally, the standard notes that some materials loaded in the elastic range exhibit some curvature and so should not be fitted by a straight line. For these materials, a tangent modulus or a chord modulus are recommended for practical applications.

The determination of Poisson's ratio at room temperature is described in [ASTM E 132](#). Tests are carried out on a universal test machine using the same sort of specimens described in [ASTM E 111](#). Average longitudinal and transverse strains ε_l and ε_t are measured as a function of applied load P . Two plots of strain versus load are obtained. The data are fitted to a linear equation by the method of least squares and the slopes of the data are determined. Poisson's ratio ν is calculated from the ratio of the two slopes

$$\nu = -(d\varepsilon_t/dP)/(d\varepsilon_l/dP). \quad (7.10)$$

As with the standard for determining Young's modulus, class B1 extensometers are specified for this test.

The determination of Young's modulus and Poisson's ratio on polymeric materials differs somewhat from the same tests carried out on metals. Because the Young's modulus of polymers is only one hundredth that of metals, strains are much higher than those for metals. Hence, class B2 extensometers are adequate for the determination of elastic constants of polymers. Also, because of the high degree of sensitivity of many plastics to the rate of straining and to environment conditions these parameters must be controlled and specified for each test. Furthermore, according to statements in [ASTM D 638](#) (Standard Test Method for Tensile Properties of Plastics) [7.21], the standard test method for tensile properties of plastics, "data obtained by this test method cannot be considered valid for applications involving load time scales or environments widely different from those of this test method." In [ASTM D 638](#), tests are carried out on dumbbell-shaped specimens or on tubes specified. The test speeds and the test conditions are specified and the specimen is loaded in a universal test machine. For polymers that exhibit an elastic region of behavior, calculations for determining Young's modulus and Poisson's ratio are the same as for metals. In case

the material exhibits no elastic behavior, a secant modulus is suggested to approximate the elastic behavior of the polymer.

Polymeric sheets are tested in tension according to the procedures given in [ASTM D 882](#) (Standard Test Method for Tensile Properties of Thin Plastic Sheet) [7.22]. The modulus of elasticity determined by this test is an index of stiffness of the plastic sheet. Specimens are sheets of polymers at least 5 mm wide, but no greater than 25.4 mm wide. A length of 250 mm is considered standard. Because of the sensitivity of polymeric sheets to environment, the sheets have to be conditioned to the laboratory test environment prior to testing. Strain rates are specified within the test procedure. The elastic modulus is determined from the linear portion of the stress-strain curve, or where the curve is nonlinear, a secant modulus is determined as in [ASTM D 638](#).

The Young's moduli of ceramic materials, concretes or stones are not determined in tension. Because of the high value of the elastic constants and the weakness of these materials in tension, the kinds of loads needed for accurate strain measurements cannot be applied without rupture of these materials. The exception to this statement is the testing of high-strength glass or ceramic fibers, which tend to be very strong and so, can be subjected to sufficiently high loads for accurate measurement of displacements. The tensile strength and Young's modulus of the fiber are calculated from load-elongation and cross-sectional-area measurements on the fiber. [ASTM D 3379-75](#) (Standard Test Method for Tensile Strength and Young's Modulus for High-Modulus Single-Filament Materials) [7.20] gives a procedure that

Fig. 7.5 Method of mounting high-strength ceramic fibers onto a universal testing machine. The fibers are glued onto a mounting tab that is gripped by the test machine. After the specimen has been mounted in the test machine, a section of the tab is cut or burned away, leaving the specimen free to be tested. Fig. 7.6 Examples of fully articulating bearing in test fixtures in test fixtures designed to test advanced ceramic composite materials. After ASTM C 1341-00 Standard Test Method for Flexural Properties of Continuous Fiber-Reinforced Advanced Ceramic Composites [7.23]

Table 7.2 Relation between strain rate and displacement rate for flexure testing in ASTM C 1341-00 [7.23]

Test geometry I (3-point)	$\dot{D} = 0.167 \hat{\epsilon} L^2 / d$
Test geometry IIA (4-point; 1/4 point)	$\dot{D} = 0.167 \hat{\epsilon} L^2 / d$
Test geometry IIB (4-point; 1/3 point)	$\dot{D} = 0.185 \hat{\epsilon} L^2 / d$

can be followed to test ceramic fibers. Fibers are glued onto a mounting tab that is gripped by the test machine (Fig. 7.5). As shown in the figure, the gage length is set by the tab. After the specimen has been mounted in the test machine, a section of the tab is cut or burned away, leaving the specimen free to be tested. Strains are estimated by the machine displacement, or are measured optically from the edges of the mounting tab.

For bulk-size ceramics, or for other materials such as stones or concretes, the Young's modulus can be measured from the displacement of a beam tested in three- or four-point bending. To assure that the specimen is loaded evenly, *ASTM C 1341-00* (Standard Test Method for Flexural Properties of Continuous Fiber-Reinforced Advanced Ceramic Composites) [7.23] recommends the use of fully articulating bearing in the test fixtures (Fig. 7.6). In these test fixtures, one of the bearings is fixed to stabilize the test specimen. The other bearings can both roll and rock to keep in full contact with the specimen cross section. Using a constant displacement rate, load is measured as a function of displacement. The Young's modulus E is obtained from the linear portion of the stressing rate – straining rate equation

$$\dot{\varepsilon} = \mathrm{d}\varepsilon/\mathrm{d}t = \dot{\sigma}/E. \quad (7.11)$$

In this test configuration, the strain rate is directly proportional to the rate of cross-head displacement. For the geometries shown in Fig. 7.7, Table 7.2 gives the relation between the strain rate and the displacement rate.

Here \dot{D} is the rate of crosshead motion in mm/s, L is the outer support span in mm d is the specimen thickness in mm. A similar technique is described in ASTM C 674-88 (1999), (Standard Test Methods for Flexural Properties of Ceramic Whiterware Materials) [7,24].

In addition to tension or compression tests to determine Young's modulus and Poisson's ratio, the shear modulus μ can be determined directly through tor-

Fig. 7.7 Specimen geometries for flexure testing. The figure is after ASTM C 1341-00 Standard Test Method for Flexural Properties of Continuous Fiber-Reinforced Advanced Ceramic Composites [7.23]

sion tests on tubes or solid round bars, [ASTM E 143](#) (Standard Test Method for Shear Modulus at Room Temperature) [7.17]. The angle of twist in radians θ is measured as a function of applied torque T and a shear stress is calculated from the appropriate equation. The shear modulus μ is given by

$$\mu = TL/J\theta, \quad (7.12)$$

where L is the gage length and J is the polar moment of inertia of the section about its center. For a cylinder

$$J = \pi(D_o^4 - D_i^4)/32, \quad (7.13)$$

where D_o is the external diameter of the cylinder and D_i is the internal diameter. For a solid cylinder, D_i equals zero.

7.1.4 Dynamic Methods of Determining Elastic Constants

Dynamic methods of measuring the elastic constants of materials are the most commonly used for all kinds of materials. They were first introduced in the mid 1930s [7.33, 34]. These techniques have the advantage that the stresses used to measure the moduli are far below those at the elastic limit. They therefore do not give rise to complex creep effects or elastic hysteresis. Because the stresses are infinitesimal, the specimens are not altered by the stresses so that repeated measurements can be made on the same sample. A single specimen can, therefore, be used to obtain the elastic moduli as a function of temperature, or pressure. Specimens are small and simple compared to those used to determine elastic constants in static tests.

Ultrasonic Pulse Technique

Two types of dynamic tests are commonly conducted to measure the elastic constants. In one an ultrasonic pulse is sent through the specimen and its time of flight measured. The elastic constant determined by this technique depends on the kind of pulse used for the measurement. If a longitudinal pulse is used, then the Young's modulus is defined by the density of the specimen ρ and the longitudinal velocity of the pulse v_l [7.2]:

$$E = \rho v_l^2. \quad (7.14)$$

The velocity of the pulse is measured directly from the time to transit a fixed distance in the specimen. For a specimen of a well-defined thickness L the distance traveled by the wave is usually $2L$, when the pulse-echo techniques is used to measure the velocity.

If an ultrasonic shear pulse v_s is used for the measurement then the shear modulus μ can be obtained from the density and the velocity measurement [7.2]

$$\mu = \rho v_s^2 \quad (7.15)$$

where v_s is the velocity of the shear pulse.

The accuracy of these measurement techniques depends on the dimensions of the specimen and on the end-face parallelism, the coupling technique and the signal-to-noise ratio. The accuracy of these techniques is typically $\pm 0.1\%$ of the mean measurement. Despite its accuracy and simplicity, the material test community has not adapted this technique. It is used, however, in [ASTM C 1419-99a](#) (Standard Test Method for Sonic Velocity in Refractory Materials at Room Temperature and Its Use in Obtaining an Approximate Young's Modulus) [7.35]

Table 7.3 [ASTM](#) Standard Test Methods employed to determine elastic constants by the resonance technique

as a standard method of obtaining approximate values of Young's modulus in refractory materials at room temperature.

Free-Vibration Techniques

The second type of dynamic test employs freely vibrating rods to determine the elastic constants. The rods can have a rectilinear or circular cross section. Specimens are excited mechanically, either by an impulse or continuously through the rod supports. Then, the resonant frequency for the rod is measured and the density ρ or mass m and the specimen dimensions are used to determine the elastic constants. The bars can be excited in such a way as to favor measurement of the shear modulus or the Young's modulus; equations have been developed to calculate both these quantities. The derivations of these equations are complex, especially the equation for standing flexural vibrations, and so are

not addressed in this review. A discussion of the equations used in the resonance techniques and references to the earlier work in this field can be found in the article by Tefft [7.36]. The impulse technique and the continuous resonance technique have both been adapted by a number of ASTM committees for the purpose of measuring elastic constants (Table 7.3). The techniques proposed by these committees are very similar to one another.

Free Resonance by Impulse Excitation

A full description of this technique is given in ASTM designation E 1876-01. The following brief description has been abstracted from the designation. A schematic diagram of the kind of specimen used to measure elastic moduli by free resonance is shown in Fig. 7.8. The ratio of the specimen length to the minimum cross-section dimension should be 20–25 for ease of calculation. For shear modulus measurement on rectangular bars, a width-to-thickness ratio of five or greater is recommended. The specimen supports should be located at the fundamental nodal points $0.224L$ from each end. The specimen is then impacted with a small impuler, such as that shown in Fig. 7.9. The vibration is then picked up by a microphone sensor located at the antinode. Alternatively, a contact sensor located near the node lines can also be used to pick up the vibration. The impact sites and the location of the sensors are indicated in Fig. 7.8.

The Young's modulus is calculated from the fundamental vibrational frequency f_t , the specimen mass m , width b , length L , and thickness t , and a correction factor T_1 [7.32]:

$$E = 0.9465(m f_t^2 / b)(L^3 / t^3) T_1. \quad (7.16)$$

Fig. 7.8 A schematic diagram of the kind of specimen used to measure elastic moduli by the free-resonance technique (flexure testing). After ASTM E 1876-01 Standard Test Method for Dynamic Young's Modulus, Shear Modulus, and Poisson's Ratio by Impulse Excitation of Vibration [7.32]

Fig. 7.9 A typical impuler for small specimens. After ASTM E 1876-01 Standard Test Method for Dynamic Young's Modulus, Shear Modulus, and Poisson's Ratio by Impulse Excitation of Vibration [7.32]

The correction factor is a complex algebraic term that depends on the Poisson's ratio, the thickness and length of the test specimen. For specimen lengths 20 times greater than the thickness, T_1 is independent of the Poisson's ratio to a good approximation. In this limit, the following equation may be used for T_1 [7.32]:

$$T_1 = 1.000 + 6.585(t/L)^2. \quad (7.17)$$

The procedure for determining the Young's modulus from rods with circular cross sections is similar to those for rectangular cross sections, but the equations used are different. These may be found in [ASTM E 1876](#) [7.32]. Young's modulus can also be obtained from rectangular specimens subjected to longitudinal vibrations. Here the specimen is impacted on one end and the vibrations are picked up from the other. The equations for the calculation and the details of the procedure are given in [ASTM E 1876](#).

The dynamic shear modulus can be obtained from rectangular specimens of a similar geometry to that used to obtain the Young's modulus. As with the flexural specimens, the specimen supports are placed along the node lines, but the location of these lines, Fig. 7.10, differ substantially from those of the flexural tests. The location of the support lines, the impulse point and the sensor points are shown in Fig. 7.10. Once the fundamental torsional resonant frequency f_t is determined, the dynamic shear modulus can be determined from the following equation [7.32]:

$$G = \frac{4Lm f_t^2}{bt} [B/(1+A)], \quad (7.18)$$

where B and A are correction factors that can be found in [ASTM E 1876](#).

Free Resonance by Continuous Excitation

The continuous resonance technique differs from the impulse technique only in the way the resonant frequencies are excited. Therefore, the equations used to calculate the shear modulus and Young's modulus are identical to those used for the impulse technique. One configuration of test specimen is shown in Fig. 7.11. A rectangular specimen is suspended with two loops of thread or fine wire. The exciting transducer sends a sonic vibration down one of the supports and the signal is detected through the other support. The resonant vibration is detected as an enhancement of the signal as the frequency of the input signal is varied. Care has to be taken to separate the flexural resonant modes from the torsional resonant modes and the various resonant harmonics from each other. Suggestions as to how this can

Fig. 7.10 A schematic diagram of the kind of specimen used to measure elastic moduli by the free resonance technique (torsion testing). After [ASTM E 1876-01](#) Standard Test Method for Dynamic Young's Modulus, Shear Modulus, and Poisson's Ratio by Impulse Excitation of Vibration [7.32]

Fig. 7.11 A schematic diagram of the kind of experimental set up used to determine elastic moduli by the continuous resonance technique. After [ASTM E 1875](#) Standard Test Method for Dynamic Young's Modulus, Shear Modulus, and Poisson's Ratio by Sonic Resonance [7.31]

be achieved are given in [ASTM E 1875](#). A second configuration for specimen support is shown in Fig. 7.12. Locating the supports at the flexural or torsional nodes tends to favor the primary harmonic for each of these modes. Nevertheless, a proper identification of the resonant frequencies requires movement of the transducers along the total specimen length to identify the nodes and antinodes. The suspension method has been used to de-

Fig. 7.12 An alternate configuration for determining the elastic moduli by the continuous resonance technique. Here the supports are directly under the resonance nodes. After ASTM E 1875 Standard Test Method for Dynamic Young's Modulus, Shear Modulus, and Poisson's Ratio by Sonic Resonance [7.31]

termine the elastic moduli as a function of temperature, from cryogenic [7.37] to high temperatures [7.38].

Comparing the Static and Dynamic Methods

From a historical perspective, the static methods of determining elastic constants were the first to be developed. Dynamic methods were only discovered in the 1930s [7.33, 34] and required some time to become known and then popular. Standards for the static methods of determining elastic constants were developed in the 1950s. For example, ASTM E 111 was first issued in 1955. The dynamic techniques required a rather complex theoretical analysis and a numerical evaluation in order to know the resonant frequencies as a function of specimen shape, density and dimensions. Also, modern electronics had to have been developed before the measurements could be made to determine resonant frequencies. It was not until the late 1950s that progress was sufficient that the dynamic techniques could be developed in such a way as to be easy to use and useful. The first ASTM designation for measurement of elastic constants by resonance was C 623 in 1969, i.e., about 10 years after the technique was developed.

Ide [7.33] recognized the advantages of dynamic techniques over static techniques of determining elastic constants as early as 1935. He stated, "Dynamic methods for measuring Young's modulus of elasticity possess advantages over the usual static methods. The dynamic modulus is obtained for minute alternating stresses far below the elastic limit, which do not give rise to complex 'creep' effects or to elastic hysteresis. This accurately fulfills the assumptions of the mathematical theory." This opinion about the inherent superiority is still held today. In a study by Smith et al. [7.11], the authors used dynamic test techniques to determine the Young's modu-

lus of an Inconel alloy to an accuracy of better than 1% of the mean value. The static techniques could only achieve an accuracy of between 5% and 7% on the same alloy. These authors recommend one of the dynamic techniques (impulse excitation) for routine quality-control work because of their accuracy and simplicity. The continuous excitation method was recommended for more complete elastic characterization studies of materials. A major advantage of the impulse technique is that a nodal analysis is not required to determine the resonance frequencies. They feel that the static method is not desirable for quality-control work, because it is a labor-intensive technique that is time-consuming.

There are fundamental reasons for differences between the dynamic and static techniques [7.39]. Static tests are isothermal because there is plenty of time for heat conduction during the test. Ultrasonic tests take place so fast that the conditions are adiabatic and the sample's temperature actually changes during the test. Resonant tests are usually adiabatic, but this depends on the resonant frequency and the size of the specimen. Dislocation bowing and other sources of internal friction always take place during static tests and never during ultrasonic tests. Again, resonant tests may or may not be affected by these phenomena. In fact, tests in which the frequency is changed are used to characterize these effects. Static tests tend to explore higher stresses than dynamic tests. Therefore, higher-order elastic behavior is implicitly included in static measurements.

If the application is highly loaded and static in nature, such as in a building, ship, or bridge, the static methods for measuring modulus are more appropriate despite the uncertainty levels mentioned above. If the application is dynamic in nature, such as ballistic penetration or elastic wave propagation, one should use dynamic methods to evaluate the elastic constants.

7.1.5 Instrumented Indentation as a Method of Determining Elastic Constants

Up to this point, the discussion has involved what may be regarded as standard test methods. The methods are standard in the sense that they were developed to evaluate the elastic constants of materials that are of a macroscopic size. The materials are uniform and can be considered to behave as a continuum. Chemically and microstructurally the materials are uniform throughout. Most standard materials are first manufactured and then are machined to the size and shape of the part. The elastic constants of the materials are the same in the part as

in the bulk. In the case of materials that are manufactured directly into parts (H-beams, motor castings, etc.), the parts are large enough that pieces can be removed to measure their property, and the property measured in this way is assumed to be identical to the property in the part. For certain applications, however, removal of pieces from the part is not an easy option; the parts may be too small to have pieces removed from them in such a way as to be representative of the part on the whole. Also, the piece removed may be too small to be tested by standard means. Materials that fit this category include multilayers, and interlayers in electronic components, component parts of micro-electromechanical systems (MEMS), and thermal barrier coatings in the stators and blades of gas turbines. For these components, the elastic constants of the materials that make up the part have to be measured by techniques that are not the standard techniques discussed earlier in this paper. Often, the properties of the materials have to be measured in situ, that is, while the material is still in place in the part. (Materials scientists are currently developing small test

fixtures and methods of testing specimens μm in size. The specimens are obtained directly from components, so that the properties measured will be representative of those components.) Instrumented indentation testing is a technique that offers the possibility of determining the elastic constants in situ and currently is being used extensively for this purpose. In the rest of this section, this technique is briefly reviewed and the advantages and disadvantages of the technique are discussed. A good review article for the instrumented indentation apparatus may be found in [7.40]. The technique is discussed in greater detail in [7.41] and in Sect. 7.3.4 of this volume.

Instrumented Indentation Test Apparatus

A schematic diagram of an instrumented indentation apparatus is shown in Fig. 7.13. The apparatus consists of three parts: a force actuator to apply the load, a displacement sensor to measure the depth of penetration and an indenter to penetrate the solid. Forces for these instruments have been generated electromagnetically, electrostatically or piezoelectrically [7.40] and the level of force is often determined by the voltage or current used to generate the force. Displacements are measured by a variety of gages: capacitive sensors, linear variable differential transformers and laser interferometers.

The indenters are generally made of diamond, having several geometries. In general, four-sided pyramid indenters are not used for nanoindenters, because they usually end in a flat-ended chisel edge that interferes with the method at very light loads. Three-sided indenters are used since they can be sharpened to a point. The most common three-sided indenter is the Berkovich indenter, which has the same depth to area as the commonly used Vickers hardness indenter. The centerline to face angle for the Berkovich indenter is 65.3° . A cube-corner pyramidal indenter, so called because the three faces of the indenter are at 90° to one another, is also commonly used for nanoindentation studies – see Sect. 7.3.4. The centerline to face angle for the cube-corner indenter is 35.3° . This indenter angle is more acute than that for the Berkovich indenter. Hence, the stresses at the tip of the indenter are much higher than the stresses at the tip of the Berkovich indenter and the tendency for crack formation is greater. The third type of indenter used for instrument indentation studies is the spherical indenter. This has the advantage over the others that the initial contact of the indenter to the solid is elastic, which would make it ideal for the determination of elastic constants. Unfortunately, small spherical indenters – a micron or less in diameter – are difficult

Fig. 7.13 A schematic diagram illustrating the parts to an instrumented indentation tester. (After [7.40])

Fig. 7.14 An illustration of a load displacement curve for a single loading cycle on an instrumented indentation tester. (After [7.40])

to make, which is why the Berkovich indenter is the indenter of choice for most small-scale testing [7.40].

Determining the Elastic Modulus by Indentation

A schematic representation of the indentation load P as a function of displacement h is shown in Fig. 7.14. The loading of the indenter is due to a mixture of elastic and plastic deformation. The initial portion of the loading is primarily due to elastic deformation in the vicinity of the indentation [7.41]. As the penetration increases, so does the plastic contribution to the deformation. An estimate for the Young's modulus is obtained from the slope of the unloading curve S , at the point of maximum load using the following formula, which is founded in elastic contact theory [7.40, 42, 43]

$$E_r = \frac{\sqrt{\pi}}{2\beta} \frac{S}{\sqrt{A}}, \quad (7.19)$$

where A is the area of contact β is a constant that depends on the geometry of the indenter [7.44], and E_r is the reduced elastic modulus. The reduced elastic modulus is used to take account of the fact that deformation occurs in both the target material and the indenter. To calculate the Young's modulus of the target material, an estimate of the Poisson's ratio of the material must be made. This estimate results in an error of only 5% in the determination of E . The value of β for the Berkovich and the cube-corner indenters is 1.034 [7.40].

The slope of the unloading curve S is known as the contact stiffness, and can be obtained by using

Fig. 7.15 A schematic representation of a section through a conical indentation illustrating the various parameters used to obtain (7.18) through (7.21). (After [7.40])

a power relation of the load P to the penetration depth h developed by *Oliver and Pharr* [7.45]

$$P = BA(h - h_f)^m. \quad (7.20)$$

Where B and m are empirical fitting parameters and h_f is the final displacement after complete unloading. The contact stiffness is determined by differentiating (7.20) with regard to h and evaluating the result at $h = h_{\max}$

$$S = Bm(h_{\max} - h_f)^{m-1}. \quad (7.21)$$

Equation (7.21) does not always provide an adequate description of the unloading curve in which case a fit is usually applied just to the upper 25% to 50% of the data [7.40].

All that is needed to characterize Young's modulus by (7.19) is the contact area A at maximum load P_{\max} . The contact area is usually expressed in terms of the depth of the circle of contact h_c which defines the depth of contact for a conical indentation (Fig. 7.15). The geometry of the area of contact is discussed in [7.41] with regard to the penetration depth h_c and the area of contact A . For a Berkovich indenter, the two are related by the following equation

$$A = 24.5h_c^2. \quad (7.22)$$

The parameter h_c is given by the following formula

$$h_c = h - \varepsilon \frac{P}{S}. \quad (7.23)$$

The parameter ε is a constant that depends on the indenter geometry. Its value can be obtained through elastic or elastic-plastic analyses of the indentation process. For the Berkovich indenter, the parameter ε has a value of about 0.75 [7.45].

Table 7.4 International Organization for Standardization ISO 14577, metallic materials – instrumented indentation test for hardness and materials parameters. Work is also underway in the ASTM on similar standards

Standard	Current stage	Purpose
ISO 14 577-1:2002 Ed. 1	Published	Test method
ISO 14 577-2:2002 Ed. 1	Published	Verification and calibration of testing machines
ISO 14 577-3:2002 Ed. 1	Published	Calibration of reference blocks
ISO 14 577-4 Ed. 1	Under development	Test methods for coatings
ISO 14 577-5 Ed. 1	Under development	Indentation tensile properties

With the determination of the area of contact, all of the parameters in (7.17) are known and the Young's modulus can in principle be calculated. In 2002, the technique was issued as a test standard by the International Organization for Standardization (ISO): ISO

14577-1 through ISO 14577-3 (Metallic materials – Instrumented indentation test for hardness and materials parameters). Two additional parts to the standard are still under consideration. The parts of this standard and their purpose are listed in Table 7.4.

7.2 Plasticity

Plasticity, or permanent deformation, is one of the most useful mechanical properties of materials. It permits forming of parts, and provides a significant degree of safety in use. The ability to specify plastic properties measured by the standard methods described in this chapter provides industry with a valuable means of controlling the manufacture of materials. These measures also provide the analyst with data for prediction and modeling. However, the current phenomenological basis for plasticity requires a large number of measurements and the development of a more physical basis is badly needed. In this chapter, we briefly discuss the physical basis for plasticity and then describe at length standard methods for measuring plastic properties. Although most industrial needs are being met by existing standards, the appearance of new materials and extreme applications of traditional materials are driving the development of new standard measurement methods.

In the context of this section, plasticity refers to the permanent strain that occurs after the elastic limit and before the onset of localization that determines a material's ultimate strength. Plasticity in materials is known to be due to the creation, movement, and annihilation of defects (dislocations, vacancies, etc.) while the forces between atoms remain elastic in nature. It is also well known that these defects often move at stresses below the elastic limit, a process called microplasticity, and that the ultimate strength can be determined by purely plastic processes. Nevertheless, from an engineering point of view, it is entirely appropriate to consider elasticity

(Sect. 7.1), plasticity (Sect. 7.2), and ultimate strength (Sect. 7.4) as separate phenomena.

7.2.1 Fundamentals of Plasticity

The onset of plasticity at the yield strength signals an end to purely elastic deformation, i.e., the elastic limit. Many designs are elastic and the maximum working (or allowable) load may be chosen as the load when the yield strength is reached in some part of the design. Plasticity may also be viewed as a margin of safety before the ultimate strength has been reached. For this reason, the maximum plastic strain or ductility may assure the user of a certain level of safety if the yield strength is exceeded by accident. Ductility also permits the manufacturer to form materials without failure, and workhardening (the increase in stress with plastic strain needed to continue plastic deformation) assures that the part will be even stronger when it is finished. The standards that exist today were created in an effort to standardize the meaning and measurement of these important plastic properties.

These standards now also serve the analytical community that seeks to predict plastic behavior under conditions of use, forming, accidents, etc. This community uses the theory of plasticity to make its predictions. While there is elastic strain proportional to applied pressure (through the bulk modulus) and the fracture strength depends on the applied pressure, plastic deformation is practically independent of the applied pressure. There is

Fig. 7.16 Model of an edge dislocation oriented so that the atoms are viewed parallel to the dislocation line (CD) in Fig. 7.18. (Model courtesy of R. deWit [7.48])

also little or no volume change associated with plasticity. The plastic behavior depends strongly on the deviatoric or shear components of the stress tensor and results in a shape change rather than a volume change. These observations have led to the development of the mathematical or phenomenological theory of plasticity. In this theory, plastic yielding begins at a critical value of the second invariant of the stress tensor (von Mises criterion) or at the maximum shear stress (Tresca criterion). If the von Mises criterion is plotted in a space of principal stresses, it appears as a cylinder whose axis lies along the $\sigma_1 = \sigma_2 = \sigma_3$ locus. In the σ_1/σ_2 plane, per-

Fig. 7.17 Model of a screw dislocation viewed perpendicular to the dislocation line CD in Fig. 7.19. (Model courtesy of R. deWit [7.48])

pendicular to the σ_3 -axis, the cut through the cylinder appears as an ellipse and is known as the von Mises ellipse. Inside the ellipse, all strain is assumed to be elastic. When the combination of stresses touches the ellipse, plastic deformation begins to take place. Plastic strain usually results in strain hardening and this may change the size, shape, or position of the von Mises ellipse. After yielding, it may no longer be elliptical. The description of this theory in any more detail is beyond the scope of this article. The reader is directed to one of the earliest and most important treatise on this subject [7.46] and to one of the most recent texts [7.47]. The theory of plasticity has had great success in the prediction of plastic deformation of materials. However, because of its phenomenological basis, it requires an

extensive number of measurements and assumptions to accurately describe the behavior of real materials undergoing complex deformation paths.

There are several physical phenomena that result in plasticity: movement of dislocations [7.49], movement of atoms (Nabarro–Herring creep or Coble creep) [7.50], phase transformations (TRIP) [7.51], twinning (TWIP) [7.52], or clay plasticity [7.53]. The predominant mechanism is movement of dislocations and a brief description of how this results in plastic behavior is appropriate here.

Dislocations as a source of plastic deformation in crystals were postulated in the 1930s independently by Taylor, Orowan, and Polanyi [7.54]. Quantum mechanics was being developed at that time and at least one of these three was searching for a *quantum* of plastic deformation [7.55]. They sought something that could explain the low yield strength as compared to the high theoretical stress to slide a whole atomic plane over another. It also had to be consistent with the behavior of slip steps and etch pits with increasing plastic strain. They proposed new kinds of crystal defects in the crystal lattice, edge and screw dislocations (Figs. 7.16 and 7.17) [7.48], that could concentrate the applied stress on a row of atoms.

Under the action of a stress much less than the theoretical shear stress, dislocations could move (Figs. 7.18 and 7.19), resulting in plastic deformation of a crystal and the formation of slip steps.

The evidence supporting this at the time was etch pits which resulted from stress-enhanced dissolution around the dislocation. Transmission electron microscopy has

now well established dislocations as the primary source of plasticity (Fig. 7.20).

For significant plasticity to occur in a crystal, the movement and interaction of 10^1 – 10^4 km of dislocation length must take place in every cubic millimeter of material [7.56]. Furthermore, most materials of commercial importance are polycrystalline and contain enormous numbers of crystals that may be randomly or nonrandomly oriented. Thus, the quantitative prediction of plastic behavior in commercial materials based on an understanding of dislocation mechanics is a difficult problem and has not yet been successful enough to replace the phenomenological approach described previously and embodied in current analytical schemes. This situation is beginning to change [7.57–60] and may ultimately lead to great simplifications in what actually must be measured.

7.2.2 Mechanical Loading Modes Causing Plastic Deformation

As noted in the previous section, plasticity is extremely insensitive to the mean stress (hydrostatic tension or pressure). Thus, there is no test using purely hydrostatic tension or pressure to measure plasticity. That is not to say there is no interest in the effect of superimposed hydrostatic tension or pressure. This invariant of the stress tensor will greatly affect the fracture behavior of most materials. *Bridgman* used superimposed hydrostatic pressure to suppress fracture in tensile bars and achieve much larger elongations to fracture and reductions in area [7.61]. He noted that plastic yielding in tension occurred at roughly the same value of shear stress as yielding in compression. Furthermore, workhardening behavior was unaffected by pressure. Since the effect of hydrostatic tension or pressure is mainly on the factors that determine strength, it will not be discussed in this section on plasticity.

Due to the fact that plasticity responds to the deviatoric components of the stress tensor, most tests are designed to develop significant levels of shear stress. In Fig. 7.21, commonly used mechanical modes of loading are shown that may be used to measure the plastic properties of materials. There are standard test methods for plastic behavior that employ each of these loading modes and are the subject of this section on plasticity.

In uniaxial *tension*, a bar or sheet is pulled along its long axis. The stress in the bar is calculated by dividing the applied force by the cross-sectional area of the bar. The strain is determined from the change in length of an initial, fiducial length. In uniaxial *compression*,

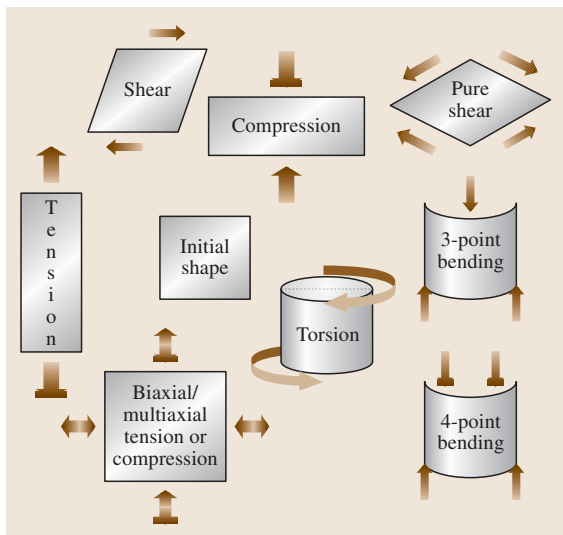

Fig. 7.21 Modes of mechanical loading used to measure plastic properties of materials

sion a bar is subject to compressive loading along one axis and the stress and strain are determined in much the same way as for tension. Both tension and compression have components of hydrostatic tension or pressure which may affect the ultimate behavior, but not the yielding or workhardening behavior. One of the great values of tension and compression testing arises from the fact that the stress and strain are uniform and simply calculated from applied forces, displacements, and specimen dimensions.

In practice, *shear* results in some bending and *bending* results in some shear loading. The shear stress is the tangential surface force divided by the surface area. The shear strain is defined as the change in angle that results. Bending develops additional tensile and compressive loading away from the neutral axis resulting in mean stress effects. *Pure shear* and *torsion* (which generates pure shear) do not develop any significant level of mean stress.

Lastly, combinations of loading modes are used to assess the effect of complex stress or strain states on plasticity and ultimate behavior. Bulge testing or cup testing is largely a *biaxial tension* test for sheet material with a small component of bending. The ratio of the stress or strain in the two orthogonal directions can be adjusted by cut outs or specimen shape. One of the most popular tests for plasticity, the hardness test, is a complex *multiaxial compression* test with a high, superimposed pressure (Sect. 7.3).

7.2.3 Standard Methods of Measuring Plastic Properties

This section lists and briefly describes standard tests used to measure plastic behavior. Some of the most critical features of each method and their limitations are discussed. As noted above, plasticity is highly sensitive to the stress and strain state. Thus, the methods are classified according to loading mode and listed in order of importance or frequency of performance.

Hardness Tests

Whereas hardness is treated in detail in the next section, Sect. 7.3, a glimpse of plasticity in hardness is also made here. The hardness of a material as measured by the indentation test methods quantifies a material's resistance to plastic flow. By definition, a soft material deforms plastically more easily than a hard material. Indentation tests are used industrially for quality control. They are the most frequently performed mechanical tests because of their simplicity, rapidity, low cost, and usually nondestructive nature. In the indentation test, a spherical or pointed indenter is pressed into the surface of a material by a predetermined force. The depth of the resulting indentation or the force divided by the area of the resulting indentation is a measure of the hardness. However, these tests measure the resistance to plastic deformation in complex, multiaxial, and nonuniform stress and strain fields at varying strain rates. Thus, the interpretation of these tests in terms of more common concepts is difficult. The yield strength, workhardening, or ultimate tensile strength can only be estimated by empirical correlation. The ductility cannot be estimated by any means. It is extremely difficult to use the results from these tests analytically to accurately describe plastic deformation in other applications. This drawback is being addressed by instrumented indentation test standards (ISO 14577 (Metallic materials – Instrumented indentation test for hardness and materials parameters) [7.62] and efforts underway at ASTM). The commercial importance of hardness testing cannot be underestimated and justifies an entire Sect. 7.3 devoted entirely to hardness.

Tension Tests

The uniaxial tension test is the most important test for measuring the plastic properties of materials for specification and analytical purposes. It provides well-defined measures of yielding, workhardening, ultimate tensile strength, and ductility. It is also used to measure the temperature dependence and strain rate sensitivity of these

Fig. 7.22 Examples of tensile test specimens used to measure plastic behavior of metals

quantities. Versions of the tension test provide important parameters for predicting forming behavior. The tension test is carried out on a bar, plate, or strip of material that has a region of reduced cross-sectional area, the gage section (Fig. 7.22). The reduced area causes all plastic deformation to occur in the gage section. The unreduced ends are held in grips (see Fig. 7.4 of Sect. 7.1) and the specimen is elongated parallel to its long axis. Initially, the sample deforms elastically, as described in Sect. 7.1, and in linear proportion to the applied stress as shown schematically in Fig. 7.23. At some applied force, non-linear and unrecoverable deformation, i.e., plasticity begins. The proportional limit is the force at the onset of plasticity divided by the initial cross-sectional area of the sample.

Various definitions of yielding are used. In the figure, the 0.2% offset (plastic) yield stress is shown. As the sample continues to elongate, it workhardens. At the ultimate tensile strength (UTS), it breaks or becomes unstable to continued uniform deformation. A region of localized thinning or necking characterizes the latter instability (Fig. 7.24). This ultimate behavior is covered in Sect. 7.4 on strength.

There are many standards for performing uniaxial tensile tests. Some standards are widely used: [ASTM E 8](#) (Standard Test Methods of Tension Testing Metallic Materials) [7.63], [ISO 6892](#) (Metallic Materials – Tensile Testing at Ambient Temperatures) [7.64], [DIN EN 10002-1](#) (Metallic materials – Tensile testing – Part 1: Method of testing at ambient temperature) [7.65], [JIS Z 2241](#) (Method of tensile test for metallic materials) [7.66], and [BS 18](#) [Methods for tensile testing of metals (including aerospace materials)] [7.67]. Other standards are modeled after these or are based in some way on them. For example, [ASTM E 8M](#) (Standard

Fig. 7.23 Uniaxial engineering stress versus engineering strain curves at two strain rates, showing elastic region, onset of plasticity (proportional limit), offset yield stress, workhardening, ultimate tensile strength, and fracture

Test Methods for Tension Testing of Metallic Materials) [7.68] is a metric version of [ASTM E 8](#) [7.53], [SAE J416](#) (Tensile Test Specimens) [7.69] provides some guidance in sample geometry for testing according to [ASTM E 8](#) [7.63], [ASTM A 370](#) (Standard Test Methods and Definitions for Mechanical Testing of Steel Products) [7.70] describes tensile testing of steel products, and [ASTM B 557](#) (Standard Test Methods of Tension Testing Wrought and Cast Aluminum- and Magnesium-Alloy Products) [7.71] provides for tensile testing lightweight metals, but all reference [ASTM E 8](#) [7.63]. [ASTM E 345](#) (Standard Test Methods of Tension Testing of Metallic Foil) [7.72] also refers to [ASTM E 8](#) [7.63] when testing metallic foils. [ASTM E 646](#) (Standard Test Method for Tensile Strain-Hardening Exponents (n -Values) of Metallic Sheet) [7.73], [ISO 10275](#) (Metallic materials – Sheet and strip – Determination of tensile strain hardening exponent) [7.74], and [NF A03-659](#) (Method of determination of the coefficient of work hardening N of sheet steels) [7.75] refer to [ASTM E 8](#) [7.63] or [ISO 6892](#) [7.64] compliant ten-

Fig. 7.24 Broken tensile specimen showing necking prior to fracture

sile tests to measure workhardening behavior. [ASTM E 517](#) (Standard Test Method for Plastic Strain Ratio r for Sheet) [7.76] and [NF A03-658](#) (Method of determination of the plastic anisotropic coefficient R of sheet steels) [7.77] also require adherence to one of the standard tensile test methods to measure the r -ratio. Frequently used fastener test standards (e.g., [SAE J429](#) (Mechanical and Material Requirements for Externally Threaded Fasteners) [7.78], [ASTM F 606](#) (Standard Test Methods for Determining the Mechanical Properties of Externally and Internally Threaded Fasteners, Washers, and Rivets) [7.79], and [ISO 898](#) (Mechanical properties of fasteners) [7.80]) refer to [ASTM E 8](#) [7.63] or [ISO 6892](#) [7.64] for details of tensile testing fasteners and fastener materials. While the [ASTM](#) tensile tests for plastics [[ASTM D 638](#) (Standard Test Method for Tensile Properties of Plastics) [7.81], [ASTM D 882](#) (Standard Test Method for Tensile Properties of Thin Plastic Sheet) [7.82], and [ASTM D 1708](#) (Standard Test Method for Tensile Properties of Plastics By Use of Microtensile Specimens) [7.83]] do not reference [ASTM E 8](#) [7.63]; the actual performance of the test is very similar to that in [ASTM E 8](#) [7.63]. The interpretation of results is somewhat different.

In principle, all standards for tensile testing are fairly similar, so only [ASTM E 8](#) [7.63] will be described in detail here. This standard first discusses the following acceptable testing apparatus: testing machines and by reference [ASTM E 4](#) (Standard Practices for Force Verification of Testing Machines) [7.84], gripping devices, dimension-measuring devices, and extensometers, which measure sample displacement for monitoring strain within the gage section, by reference to [ASTM E 83](#) (Standard Practice for Verification and Classification of Extensometers) [7.85]. Acceptable test specimen details are then presented. These cover size, shape, location from product, and machining. Testing procedure is described in detail: (1) preparation of test machine, (2) measurement of specimen dimensions, (3) gage length marking of specimens, (4) zeroing of the test machine, (5) gripping of the test specimen, (6) speed of testing, (7) determination of yield strength, (8) yield point elongation, (9) uniform elongation, (10) tensile strength, (11) elongation, (12) reduction of area, (13) rounding reported test data, and (14) replacement criteria for unsatisfactory specimens or tests.

Of these, (6) speed of testing and (7) method of determining yield strength have the most significant effect on the actual measurement of plastic properties. Speed of testing is defined in terms of: (a) rate of straining of the specimen, (b) rate of stressing of the specimen,

(c) rate of separation of the two crossheads of the testing machine during the test, (d) the elapsed time for completing part or all of the test, or (e) free-running crosshead speed. Speed of testing can affect all test values because of the strain-rate sensitivity of materials. Ideally, the actual strain rate experienced by the gage section should be known and reported. All other speed of testing measures are relevant only so far as they affect this strain rate. Unless the strain rate is controlled, two laboratories may get significantly different results even when following the standard method.

According to [ASTM E 8](#) [7.63], the yield strength can be determined by: (a) the offset method, (b) the extension under load method, (c) the autographic diagram method, or (d) the half-of-the-beam method. These methods may produce different results with different uncertainties, yet all are equally valid at this time.

In general, the quantities reported from this test are yield point or yield strength, ultimate tensile strength (UTS), elongation to fracture (total elongation divided by initial gage length), and reduction in area (area decrease in the fracture plane divided by initial gage area). It is not uncommon to find data with no record of testing speed or initial gage length. This is unfortunate since the speed of testing (as noted above) can significantly affect the yield strength and the other properties to a lesser extent. The initial gage length can affect the elongation due to the nonuniform deformation that occurs in the necked region.

Other important quantities, such as workhardening, strain-rate sensitivity, and temperature effects, can also be determined in a tensile test. The measurement of these is left to other standards that will be discussed next.

Workhardening Behavior. After yielding, the stress-strain curves of many materials exhibit workhardening, that is, an increased stress to achieve additional plastic strain. This is usually due to the increased concentration of dislocations and their complex interactions. Various standards address the measurement of workhardening:

- [ASTM E 646](#) [Standard Test Method for Tensile Strain-Hardening Exponents (n -Values) of Metallic Sheet] [7.73],
- [ISO 10275](#) (Metallic Materials – Sheet and Strip – Determination of Tensile Strain Hardening Exponent) [7.74],
- [NF A03-659](#) (Method of determination of the coefficient of work hardening N of sheet steels) [7.75]

to mention a few. In general, a uniaxial tensile test is performed according to [ASTM E 8](#) [7.63] with some added

constraints with regard to rate of testing and collection of data. The true stress/true strain (that is, the applied force or elongation divided by the current, instead of the initial, area or gage length) curve is determined from the raw data. In [ASTM E 646 \[7.73\]](#), the curve is fit by the equation

$$\sigma = N\varepsilon^n$$

to find n , the strain hardening exponent, where σ is the true stress, ε is the true strain, and n is a constant. The method is appropriate for materials whose stress/strain curve can be reasonably fit by the equation above. For the most important exception, i.e., steel, which may have a discontinuous stress-strain curve, it is recommended that only the region that can be fit reasonably be used. In general, n is probably a function of strain. This possibility is not covered in [ASTM E 646 \[7.73\]](#).

Strain-Rate Sensitivity. The only standard addressing the measurement of this property is European Structural Integrity Society (ESIS) designation P7-00.2000, Procedure for Dynamic Tensile Tests. (European Structural Integrity Society documents may be obtained from Professor K.-H. Schwalbe, GKSS-Forschungszentrum Geesthacht, 21502 Geesthacht, Germany.) Here the tensile test data (σ and true strain rate, $d\varepsilon/dt$, both measured at the same strain ε) are fit to an equation of the form

$$\sigma = M(d\varepsilon/dt)^m$$

to find m , the strain-rate sensitivity. This procedure is relatively new. In time, this approach may be accepted by other standards development organizations (SDOs). The only issue may be that the form of the equation has little physical basis. There are other fits to strain-rate-dependent plastic properties, e.g., the Johnson-Cook model [\[7.86\]](#) or the Bodner-Partom model [\[7.87\]](#).

Temperature Effects on Plasticity. The movement of dislocations and vacancies is strongly temperature-dependent and, thus, so is plasticity [\[7.88\]](#). It is important to characterize this behavior for any application that occurs at low or high temperatures. Examples of such applications are cryogenic tanks, pipelines operating in the arctic, steam plant components, nuclear power generators, jet engines, structures that might be exposed to fires – the list is a long one. Some standards addressing tensile tests at low and high temperatures are:

- [ASTM E 1450](#) (Standard Test Method for Tensile Testing of Structural Alloys in Liquid Helium) [\[7.89\]](#),

- [ISO/DIN 19819](#) (Metallic materials - Tensile testing in liquid helium) [\[7.90\]](#),
- [ISO 15579](#) (Metallic materials – Tensile testing at low temperatures) [\[7.91\]](#),
- [ASTM E 21](#) (Elevated Temperature Tension Testing of Metallic Materials) [\[7.92\]](#),
- [DIN EN 10002-5](#) (Tensile testing of metallic materials, method of testing at elevated temperature) [\[7.93\]](#),
- [JIS G 0567](#) (Method of elevated temperature tensile test for steels and heat-resisting alloys) [\[7.94\]](#).

These standard tests are essentially the same as the room-temperature ones, but have or refer to extensive requirements related to controlling and/or determining the temperature at which the test is performed (see, for example, [ASTM E 633](#) [Standard Guide for the Use of Thermocouples in Creep and Stress Rupture Testing to 1800 °F (1000 °C)] [\[7.95\]](#)). Additionally, in elevated-temperature tests, the speed of testing is more tightly controlled than in room-temperature tests. This additional control is necessary because the plastic behavior becomes strongly time- or rate-dependent at high temperatures due to the significant amount of creep strain that can accrue even in a short-term tensile test.

Time-Dependent Plasticity. Time-dependent plasticity is called creep. This mode of plasticity is important in any part or structure that is exposed to temperatures above about 1/3 of its melting temperature, especially if it must resist permanent deformation for significant lengths of time. Creep may also be noticed at room temperature in very long, highly stressed components such as bridge cables. The loosening of bolts is also due to creep, but under a decreasing stress. This effect is called stress relaxation.

The importance of time dependent plasticity, i.e., creep and stress relaxation, has necessitated the development of many standard tests for metals:

- [ASTM E 139](#) (Conducting Creep, Creep Rupture, and Stress Rupture Tests of Metallic Materials) [\[7.96\]](#),
- [ASTM E 328](#) (Stress Relaxation for Materials and Structures) [\[7.97\]](#),
- [DIN EN 10291](#) (Metallic materials – Uniaxial creep testing in tension – Method of test) [\[7.98\]](#),
- [DIN EN 10319](#) (Metallic materials – Tensile stress relaxation testing) [\[7.99\]](#),
- [ISO 204](#) (Metallic materials – Uninterrupted uniaxial creep testing in tension – Method of test) [\[7.100\]](#),

- **JIS Z 2271** (Method of creep and creep rupture testing for metallic materials) [7.101].

At elevated temperatures, brittle materials that normally exhibit extremely limited or no plasticity at room temperature, begin to deform plastically by creep. For this reason, there are tensile creep standards, similar to those for metallic materials that apply to ceramics, composites, and plastics:

- **ASTM C 1337** (Standard Test Method for Creep and Creep Rupture of Continuous Fiber-Reinforced Ceramic Composites under Tensile Loading at Elevated Temperatures) [7.102],
- **ASTM C 1291** (Standard Test Method for Elevated Temperature Tensile Creep Strain, Creep Strain Rate, and Creep Time-to-Failure for Advanced Monolithic Ceramics) [7.103],
- **ISO 899-1** (Plastics – Determination of creep behavior – Part 1. Tensile creep) [7.104],
- **JIS K 7115** (Plastics – Determination of creep behavior – Part 1. Tensile creep) [7.105].

Creep tests are performed by loading a standard uniaxial tensile sample with a constant force or stress and measuring the tensile strain that occurs with time. Stress-relaxation tests apply a constant strain and measure the relaxation of stress with time. Both tests are measures of time-dependent plasticity.

These tests are usually done at an elevated temperature, but the term elevated is quite relative to the material being tested. Significant time-dependent plasticity is usually observed at or above one-third of the melting temperature of most materials. For solder alloys, this is below room temperature. For structural ceramics, industrially relevant creep and stress relaxation rates require temperatures in excess of 1000 °C.

For metals and alloys, it is usually found that creep rates increase exponentially with temperature. They are often modeled using an Arrhenius (or other thermal activation) law [7.88]. Therefore, it is important to know and tightly control the temperature to about ± 1 °C if 1% accuracy is desired. Furthermore, this temperature must be applied uniformly to the gage section of the test piece. The various standard methods require accurate and uniform temperature environments for the test.

Another important parameter is the load. Since a constant force, that may be greater than 10^4 N, is generally required for a long time (up to 100 000 h or more), it is customary to use dead or static loads. These are most frequently applied by a complicated system of

levers, knife-edges, and weights. It is essential to confirm that the applied load is correct. This is dealt with in the standards, see for example **ISO 7500-2** (Metallic materials – verification of static uniaxial testing machines – Part 2: Tension creep testing machines – Verification of the applied load) [7.106] or **ASTM E 4** [7.84].

As the creep sample elongates under load, its cross-sectional area usually decreases. Thus, a constant applied force leads to an increasing stress on the sample. Loading systems have been designed that reduce the load as the sample creeps to maintain a constant stress [7.107, 108]. These are not covered by any standard. While this might seem to be an oversight, most applications of creep-resistant materials can only tolerate a few percent strain. For these, the difference between constant load and constant stress is negligible. However, if one is interested in creep forming or superplastic forming (SPF) where large plastic strains are required, the differences between the two loading systems can be quite large [7.109].

Superplasticity. Superplasticity in metals is characterized by extraordinarily large ductilities. It is not uncommon to observe strains of 1000% to 3000%. While at first a laboratory curiosity, superplasticity is now used to form complex and highly deformed shapes like small boat hulls, fuel tanks, spare tire wells, aircraft doors, to mention a few. Superplastic behavior is exhibited by a number of alloys under particular conditions of microstructure, temperature, and strain rate. Any test for superplasticity is chiefly for the purpose of characterizing this processing window. An **ASTM** standard method of characterizing superplastic behavior in uniaxial tension has been recently approved. A draft **ISO** tensile test has also been proposed based on **JIS H 7501** (Method for evaluation of tensile properties of metallic superplastic materials) [7.110]. This Japanese standard specifies the test specimen geometry, the apparatus, and the procedure for the evaluation of tensile properties of metallic superplastic materials. In particular, it specifies how the stress/strain curves and the strain rate sensitivity are to be determined. It has been noticed for some time that superplastic materials have a strain rate sensitivity m near unity. Some researchers have claimed that an “ m ” near unity implies superplastic behavior despite limited ductility in the actual test. Superplasticity, by definition, requires very large ductilities, so these claims would seem incorrect.

The main feature of any standard for measuring superplasticity would be specifications to perform the test over a range of temperatures, perform the test over

a range of commercially useful strain rates, and apply and measure the large strains that will necessarily occur.

Plastic Strain Ratio r for Sheet Metal. Another important plastic property that can be obtained from the tension test is the plastic strain ratio r . It is defined as the ratio of the true plastic width strain to the true plastic thickness strain at some level of plastic tensile strain in the length direction (usually 15% to 20%). The plastic strain ratio quantifies the ability of a sheet metal to resist plastic thinning when subjected to tensile strains in the plane of the sheet. It is a consequence of plastic anisotropy and is related to the preferred crystallographic orientations within a polycrystalline metal. This resistance to thinning contributes to the forming of shapes, such as cylindrical flat-bottomed cups, by the deep-drawing process. The r -value, therefore, may be considered an indicator of sheet metal drawability. Three standards for measuring the plastic strain ratio are:

- **ASTM E 517** (Standard Test Method for Plastic Strain Ratio r for Sheet Metal) [7.76],
- **ISO 10113** (Metallic materials – Sheet and strip – Determination of plastic strain ratio) [7.111],
- **NF A03-658** (Iron and steel – Method of determination of the plastic anisotropic coefficient R of steel sheet steels) [7.77].

Basically, a tensile test is run according to one of the tensile test standards mentioned previously. In addition to measuring the gage length, the width of the gage is measured. While the thickness can be measured directly, the changes in thickness are very small, especially in thin sheets. The standard permits calculating the thickness from the width and length assuming constant volume. These measurements should be done in the unloaded condition as the definition of r is in terms of true plastic strains, not total strains. Otherwise, some adjustment for the elastic strains must be made.

Since r is strongly dependent on the crystallographic texture, it may depend on the direction within the sheet the tensile sample was taken. The standards have procedures for assessing this effect.

Compression Tests

Compression testing, like tension testing, is uniaxial. It provides similar data on plasticity of materials: initial plastic behavior, such as yield strength and workhardening. It is sensitive to alignment and buckling can be a problem. Friction between the sample and compression platens may also affect the results. Barreling, i. e.,

nonuniform changes in the cross sectional area along the length also causes deviations from uniaxiality and ambiguities in the measurement of stress and strain. If not for these effects, the compression test could be carried out to very high strains in a plastic material. Instead, it is usually limited to about the same amount of strain as the tensile test, or less. Standard methods for performing compression tests are

- **ASTM E 9** (Standard Test Methods for Compression Testing of Metallic Materials at Room Temperature) [7.112],
- **ASTM E 209** (Standard Practice for Compression Tests of Metallic Materials at Elevated Temperatures with Conventional or Rapid Heating Rates and Strain Rates) [7.113],
- **DIN 50106** (Testing of Metallic Materials – Compression Test) [7.114],
- **DIN EN 12290** (Advanced Technology Ceramics – Mechanical Properties of Ceramic Composites at High Temperature in Air at Atmospheric Pressure – Determination of Compressive Properties) [7.115],
- **ISO 604** (Plastics – Determination of Compressive Properties) [7.116],
- **JIS K 7132** (Cellular plastics, rigid – Determination of Compressive Creep under Specified Load and Temperature Conditions) [7.117],
- **JIS K 7135** (Cellular plastics, rigid – Determination of Compressive Creep) [7.118].

The samples are typically short cylinders (height-to-diameter ratios between 2 and 3) or plates. If the plates are thin, anti-buckling guides are required. An increasing axial compressive force loads the specimen and the mechanical properties (mainly yield strength and workhardening) in compression are determined. There is much more attention paid to axial alignment issues in these standards compared to those for tension. This is because load alignment will only get worse as compression increases whereas it usually improves with tensile strain. If one wishes to achieve as large a strain as possible in these tests, it is essential to provide lubrication throughout the test. Some experimentalists machine shallow, concentric grooves in the top and bottom of the sample and fill them with lubricant. This provides a reservoir of lubricant throughout the test and has met with a fair degree of success.

ASTM E 209 [7.113] is interesting because it provides guidance for performing compression tests under a wide range of temperatures, strain rates, and heating rates. This provides the basic data for determining, for example, the strain-rate sensitivity or the temperature-

dependence of workhardening, but the standard does not favor any one model for interpreting the results. This approach permits one to use or compare any of the many constitutive laws that might apply.

Standard Tests Employing Other Loading Modes

As we shall see, standard tests for plasticity employing modes of loading other than tension and compression have been used chiefly as measures of ultimate strength or ductility. This may be due to stress concentrations obscuring the early yield behavior, poorly defined gage section to calculate the strain, difficulty determining the stress directly from the applied load, or a combination of these. The fact that these tests do provide certain important plastic properties and are easy to perform often outweighs their other limitations.

Shear. Shear loading is applied as single shear or double shear as shown in Fig. 7.25. In single shear, pulling the ends of the sheet specimen in tension generates a state of shear between the two slot tips. The slots are at 45° to the tensile axis and the radius of the slot tips are tightly controlled. Yielding is very sensitive to the details of the slot tip curvatures and the gage length for shear is not well defined.

In double shear, a bar of material is inserted in a clevis grip and pull (or push) rod having close-tolerance holes. The pull or push rod and clevis may be pulled in tension or compressed to generate two regions of shear (i.e., double shear) in the specimen. Again, the gage length for the shear is poorly defined. The onset of yielding is also sensitive to the radius of curvature of the edges of the holes in the pull/push rod and the clevis.

Fig. 7.25a,b Shear loading modes. (a) single shear, in tension only for sheet and plates, and (b) double shear, in tension or compression, for bars

Standards for measuring plastic properties in shear are:

- **ASTM B831** – (Standard Test Method for Shear Testing of Thin Aluminum Alloy Products) [7.119],
- **ASTM B769** – (Standard Test Method for Shear Testing of Aluminum Alloys) [7.120],
- **ASTM B565** – (Standard Test Method for Shear Testing of Aluminum and Aluminum-Alloy Rivets and Cold-Heading Wire and Rod) [7.121],
- **DIN 50141** – (Testing of Metals: Shear Test) [7.122],
- **DIN EN 4525** – (Aerospace series – Aluminium and aluminium alloys – Test method; shear testing) [7.123],
- **DIN EN 28749** – (Determination of shear strength of pins) [7.124],
- **ISO 7961** – (Aerospace – Bolts – Test methods) [7.125],
- **ISO 84749** – (Pins and Grooved Pins – Shear Test) [7.126].

ASTM B 831 [7.119] is carried out in the single-shear mode (Fig. 7.25a), while **ASTM B 565** [7.121] is in double-shear tension, and **ASTM B 769** [7.120], **DIN 50141** [7.122], and **ISO 7961** [7.125] are in double-shear compression. All of the standard shear tests are used mainly to measure the ultimate shear strength. This is due to the fact that load fixture or specimen stress concentrations limit their usefulness in accurately measuring the early yield behavior and the poorly defined gage section over which the shear acts means that the shear strain is not well defined. These tests provide a shear stress that can be used to assure that a component does not fail plastically in shear even if the yield stress in shear is exceeded.

Torsion. Torsion loading is generated by twisting a bar that is usually round in cross section around its long axis (Fig. 7.21). Torsion provides a pure shear loading with principal stresses $\sigma_1 = -\sigma_2$ and $\sigma_3 = 0$. Therefore, the hydrostatic tension is zero throughout the test and does not increase as it does in a tension test. Consequently, the processes responsible for ductile fracture are greatly reduced. When a solid bar is tested in torsion, very large ductilities are possible if the material is inherently ductile. No instabilities will intervene as occur in tension and compression testing. If a tube is tested in torsion, however, buckling will occur and end the test prematurely.

There are standards for torsion testing to measure the shear modulus and standards to measure the ductility of wires in pure shear:

- **ASTM E 143** (Standard Test Method for Shear Modulus at Room Temperature) [7.127],
- **ASTM A 938** (Standard Test Method for Torsion Testing of Wires) [7.128],
- **ISO 7800** (Metallic Materials – Wire – Simple Torsion Test) [7.129],
- **ISO 9649:1990** (Metallic Materials – Wire – Reverse Torsion Test) [7.130].

There are published procedures used by individual researchers, notably *Nadai* [7.131], who developed an analysis to obtain the shear stress/shear strain curve from torsion tests on bars. Without such an analysis, the stress in a solid bar cannot be determined. For this reason, some researchers use tubes. As noted above, tubes have a limited strain before buckling occurs.

At this time, the only standard torsion test that provides shear stress/shear strain data in the plastic region is **ASTM F 1622** – Standard Test Method for Measuring the Torsional Properties of Metallic Bone Screws [7.132]. This standard is not only limited to a narrow range of materials and components, but it only determines the torsional yield strength. Nevertheless, since the entire plot of torque versus angle of rotation is recorded, the data obtained by this method could be analyzed to give the shear stress/shear strain curve.

Bending. Bending, like torsion, requires an analysis to convert the load–displacement or moment–curvature data to stress–strain curves when more than a few tenths of 1% plastic strain has accrued. The standards that use bending to characterize room-temperature plasticity are only for determining the ductility or resistance to cracking under this mode of loading. No other data are obtained. Room-temperature bend test standards include

- **ASTM E 290** (Standard Test Method for Bend Testing of Materials for Ductility) [7.133],
- **ASTM E 190** (Standard Test Method for Guided Bend Test for Ductility of Welds) [7.134],
- **ASTM E 796** (Standard Test Method for Ductility Testing of Metallic Foils) [7.135],
- **ISO 7438** (Metallic Materials – Bend Test) [7.136],
- **ISO 7799** (Metallic Materials – Sheet and Strip 3 mm thick or less – Reverse Bend Test) [7.137],
- **ISO 7801** (Metallic Materials – Wire – Reverse Bend Test) [7.138],
- **ISO 7802** (Metallic Materials – Wire – Wrapping Test) [7.139],
- **ISO 8491** (Metallic Materials – Tube (in full section) – Bend Test) [7.140].

There are more international standards that refer to these and many more national standards that use bending as a means of determining plastic ductility of a variety of materials and welds in various shapes. They are all variations on the above methods. In **ASTM E 290** [7.133], **ISO 7438** [7.136], and **ISO 8491** [7.140], the sample is bent monotonically either in three- or four-point bending, or as a cantilever. In **ASTM E 796** [7.135], **ISO 7799** [7.137], and **ISO 7801** [7.138], the bending is carried out by cumulative cyclic, reversed bending. If the sample cracks, the amount of cumulative cyclic strain in bending to achieve cracking is reported. Other requirements might be that the sample be bent to a certain level without cracking, such as in **ASTM E 190** [7.134] and **ISO 7802** [7.139]. In this case, the method is a pass or fail test.

Bending is a favorite testing mode for brittle materials because of the simplicity of sample fabrication and not having to grip the sample in any way. For this reason, ceramics are often tested in bending. Bending is also one of the customary ways to test ceramics and brittle plastics at temperatures where they do exhibit creep. As long as the creep strain is small, the elastic stress analysis is approximately correct and there are standards for these tests:

- **DIN V ENV 820-4** (Advanced Technical Ceramics – Monolithic Ceramics; Thermo-mechanical Properties – Part 4: Determination of Flexural Creep Deformation at Elevated Temperatures) [7.141],
- **ISO 899-2** (Plastics – Determination of Creep Behaviour – Part 2: Flexural Creep by Three-Point Loading) [7.142],
- **JIS K 7116** (Plastics – Determination of Creep Behaviour – Part 2: Flexural Creep by Three-Point Loading) [7.143].

It is important to note here that ceramics are well known to have different creep behavior in tension and compression. An added complication of using bending to characterize creep in ceramics is the fact that it convolutes compression and tension behavior. Thus, bending obscures some important features in the plastic behavior of ceramics at high temperature.

Ball Punch Deformation of Sheet Materials. These tests are used to determine the ductility of materials under a particular biaxial strain state. In this test, a spherical punch is pressed into a sheet of material that is held in a hold-down assembly. The ball is pressed into the sheet forming a cup until the sheet fails in some way. Ball punch tests tend to be equi-biaxial, that is $\varepsilon_1 = \varepsilon_2$ in

the plane of the sheet. Due to conservation of volume, $\varepsilon_3 = -(\varepsilon_1 + \varepsilon_2)$. Exhaustion of ductility is defined at the onset of severe localization, cracking, or drop in load on the punch. Standard methods for this test are

- ASTM E 643 (Standard Test Method for Ball Punch Deformation of Metallic Sheet Materials) [7.144],
- ASTM E 2218 (Standard Test Method for Determination of Forming Limit Diagrams) [7.145],
- ISO 20482 (Metallic Materials – Sheet and Strip – Erichsen Cupping Test) [7.146],
- ISO 12004 (Metallic Materials – Guidelines for the Determination of Forming-Limit Diagrams) [7.147].

ASTM E 2218 [7.145] and ISO 12004 [7.147] provide directions for achieving other states of plastic strain by testing strips of different widths instead of square or round sheets. The state of strain is determined from the distortion of an array of squares, circles, or both printed onto the surface of the sheet specimens. While the load on the punch or the hold-down force may be measured in these tests, the stress in the sheet is unknown. Furthermore, only the endpoint condition is reported. In the case of ASTM E 643 [7.144] and ISO 20482 [7.146], it is the limiting dome height. In the case of ASTM E 2218 [7.145] and ISO 12004 [7.147], it is the principal in-plane strains ε_1 and ε_2 at failure.

Other Loading Modes. There are applications in which highly complex plastic straining is required to make important parts or assure safe performance. The ability of a material to sustain these modes of loading is so important that standards have been developed just for them. The following standard test methods are mainly to determine the ductility of various materials under a particular complex strain history which is usually indicated by the name of the test:

- ISO 8492 (Metallic Materials – Tube – Flattening Test) [7.148],
- ISO 8493 (Metallic Materials – Tube – Drift-expanding Test) [7.149],
- ISO 8494 (Metallic Materials – Tube – Flanging Test) [7.150],
- ISO 8495 (Metallic Materials – Tube – Ring-expanding Test) [7.151],
- ISO 8496 (Metallic Materials – Tube – Ring Tensile Test) [7.152],
- ISO 11531 (Metallic Materials – Earing Test) [7.153],
- ISO 15363 (Metallic Materials – Tube Ring Hydraulic Pressure Test) [7.154],
- ISO/TS 16630 (Metallic Materials – Method of Hole Expanding Test) [7.155].

These tests are in some ways like the hardness test: they are so specific and involve such a complex strain path that no extended meaning in terms of more fundamental quantities can be easily deduced from them. Nevertheless, they have significant industrial and commercial importance. The reader is referred to the standards themselves for more information.

7.2.4 Novel Test Developments for Plasticity

Motivation for the development of new standards for measuring plasticity may be better appreciated after a brief discussion of the industrial needs in this area that are not being met by existing standards.

Now, one can specify the yield strength in tension or compression, the ultimate tensile strength, the elongation at fracture, and the reduction in area at fracture. The workhardening exponent and the r -ratio can be specified. The creep rate and stress relaxation behavior can be specified. The critical plastic strain for localization or fracture can be specified under a variety of strain states. All these specifications can be checked by standardized tests. Are there material properties associated with plasticity that industry needs to specify that are *not* covered by standard tests? As will be shown below, there are unsatisfied needs for standards to measure plastic properties.

Data for New Forming Processes

New forming methods drive a need for specification of materials with particular properties. An example mentioned previously was superplastic forming (SPF). Currently, industry cannot specify the material for an SPF operation by some standard means of testing to determine whether it is superplastic enough for a particular application. User and supplier can easily end up at odds. That is what is driving the development of standards in this area.

Another issue stems from the desire to reduce the weight of automobiles and other products. This has driven industry to use high-strength steel and aluminum alloys. An impediment to the wider use of these materials is that they do not form like the traditional automotive alloys. One particular problem is that, during certain forming operations, they spring back so much that conventional die-design methods do not work. This problem, known as springback, arises from a complex interaction of the elastic and plastic strain, the residual stress, and the complicated shape of the workpiece. Two standards for characterizing the tendency for materials to springback are currently under consideration – one

by ISO, and another by ASTM. The ISO document is based on JIS H 7702 (Method for Springback Evaluation in Stretch Bending of Aluminium Alloy Sheets for Automotive Use) [7.156] while the ASTM standard is based on extensive industrial experience [7.157] has just been approved.

Data for Crashworthiness and Fire-Resistive Steel

Another driving force for the development of standards for characterizing plastic behavior arises when materials are used under extreme conditions that can be reasonably expected to occur. Two examples are: (1) automotive materials involved in high-speed collisions, and (2) structural steel exposed to a fire.

In case (1), an extensive topic called crashworthiness has grown up in the last decade. Automobiles are now designed to remain as safe as possible under accident conditions. Their materials of manufacture are expected to behave reproducibly in a certain way at the high rates encountered under such conditions. A review of existing standards for acquiring data needed to predict structural behavior in an accident [7.158] identified the need for tests to measure high-rate plastic-deformation properties. This need has motivated the European Structural Integrity Society (ESIS) to develop its procedure for high-rate tensile tests mentioned previously. (European Structural Integrity Society documents may be obtained from Professor K.-H. Schwalbe, GKSS-Forschungszentrum Geesthacht, 21502 Geesthacht, Germany.) Recently, Japan has developed methods based on the Kolsky bar to provide this sort of rate-dependent plastic data [7.159]. It will not be long before these methods are proposed to standards development organizations (SDOs).

In the case of steel used in buildings, bridges, or other structures subject to fires, the reduction in yield strength with increasing temperature and the onset of creep result in large plastic strains that endanger the load-carrying capacity of the structure. Japanese and German steel-makers have begun making and selling steel claimed to be fire-resistive [7.160]. By this they mean that the yield strength retains 2/3 of its room temperature value at 600 °C. ASTM has now convened a working group

to decide what is meant by fire-resistive: is the arbitrary definition above satisfactory, or should some combination of standard or modified hot tensile and creep tests be used to define fire resistive, or, lastly, should a new type of standard test, such as a tensile creep test conducted with a temperature ramp, be developed? Other possibilities are also being considered.

Finite Element Analysis

The impact of complex computer codes and powerful computers has made the accurate prediction of forming and performance possible if the needed inputs of material properties are available. These programs accept plastic properties in a variety of forms from raw stress-strain curves in tabular form to evaluated constitutive laws such as the Voce equation [7.161]. The traditional data provided by existing standards is barely adequate for these analyses. One real problem that frequently arises is the need for true stress/true strain data well beyond the onset of necking and fracture in tension tests, or beyond buckling and barreling instabilities in compression tests. The current solution to the lack of data is to make some simplistic assumptions, such as arbitrarily extending the stress-strain curve as required. This need could be better filled by data obtained in the torsion test [7.162], which can probe these high strains easily. As mentioned earlier in this chapter, torsion standards have been developed for shear modulus measurements, fatigue testing, and ductility testing. It should not be difficult to go this next step.

The other area that is left to assumption in these advanced analyses is the multiaxial workhardening behavior. Most often, the yield surface is assumed to expand in a self-similar way with strain (isotropic hardening) [7.47]. However, it is known that, in many cases, it is better to assume that the origin of the yield surface moves in stress space (kinematic hardening) [7.47]. Improved prediction would be possible if there were a standard method for measuring exactly what does happen. There have been developments recently in measuring the stress during cup deformation tests that would permit this to happen [7.163]. It may take a decade or more for these developments to reach the standards development organizations (SDOs).

7.3 Hardness

Hardness may be defined as the resistance of a material to permanent penetration by another material. A hardness test is generally conducted to determine the suitability

of a material to fulfill a certain purpose [7.164]. Conventional types of static indentation hardness tests, such as the Brinell, Vickers, Rockwell, and Knoop hardness,

Table 7.5 First publications of hardness testing standards in different countries

Test method	Germany	UK	USA	France	ISO	Europe
Brinell (1900)	1942	1937	1924	1946	1981	1955
Rockwell (1919)	1942	1940	1932	1946	1986	1955
Vickers (1925)	1940	1931	1952	1946	1982	1955
Knoop (1939)			1969		1993	

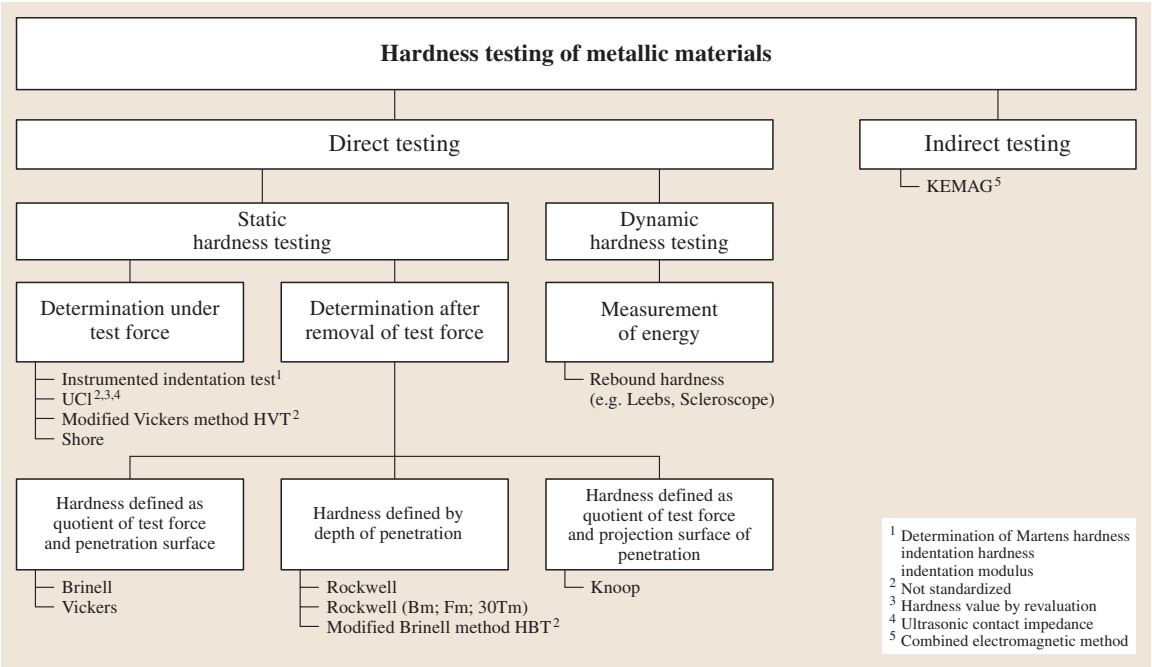

Fig. 7.26 Overview of the hardness testing methods. (see [7.165])

provide a single hardness number as the result, which is most useful as it correlates to other properties of the material, such as strength, wear resistance, and ductility. The correlation of hardness to other physical properties has made it a common tool for industrial quality control, acceptance testing, and selection of materials.

With the rising interest in the testing of thin coatings and in order to obtain more information from an indentation test, the instrumented indentation tests have been developed and standardized. In addition to obtaining conventional hardness values, the instrumented indentation tests can also determine other material parameters such as Martens hardness, indentation hardness, indentation modulus, indentation creep and indentation relaxation.

Hardness testing is one of the longest used and well-known test methods not only for metallic materials, but for other types of material as well. It has special

importance in the field of mechanical test methods, because it is a relative inexpensive, easy to use and nearly nondestructive method for the characterization of materials and products. In order to work with comparable measured values, standards of hardness testing methods have been developed. This work started in the 1920s (see Table 7.5). In some cases, national, regional and international standards specify different requirements; however, it is generally accepted to aim at the complete alignment of hardness standards at all standardization levels [7.166, 167].

Hardness data are test-system dependent and not fundamental metrological values. For this reason, hardness testing needs a combination of certified reference materials (reference blocks) and certified calibration machines to establish and maintain national and worldwide uniform hardness scales. Therefore, all hardness testing standards related to a specific hardness test

include different parts specifying requirements for the:

1. Test method,
2. Verification and calibration of testing machines, and
3. Calibration of reference blocks.

An overview of the different well-known conventional methods of hardness testing is given in Fig. 7.26.

7.3.1 Conventional Hardness Test Methods (Brinell, Rockwell, Vickers and Knoop)

The most commonly used indentation hardness tests used today are the Brinell, Rockwell, Vickers, and Knoop methods. Beginning with the introduction of the Brinell hardness test in 1900, these methods were developed over the next four decades, each bringing an improvement to testing applications. The Rockwell method greatly increased the speed of testing for industry, the Vickers method provided a continuous hardness scale from the softest to hardest metals, and the Knoop method provided greater measurement sensitivity at the lowest test forces. Since their development, these methods have been improved and their applications expanded, particularly in the cases of the Brinell and Rockwell methods.

Fig. 7.27 Principle of the Brinell hardness test

Many manufactured products are made of different types of materials, varying in hardness, strength, size and thickness. To accommodate the testing of these diverse products, each conventional hardness method has defined a range of standard force levels to be used in conjunction with several different types of indenters. Each combination of indenter type and applied force level has been designated as a distinct hardness scale of the specific hardness test method.

Brinell Hardness Test (HBW)

Principle of the Brinell Hardness Test [7.168, 169]. An indenter (hardmetal ball with diameter D) is forced into the surface of a test piece and the diameter of the indentation d left in the surface after removal of the force F is measured (Fig. 7.27). The Brinell hardness is proportional to the quotient obtained by dividing the test force by the curved surface area of the indentation. The indentation is assumed to be spherical with a radius corresponding to half of the diameter of the ball

$$\begin{aligned} \text{Brinell hardness HBW} \\ &= \text{Constant} \times \frac{\text{Test force}}{\text{Surface area of indentation}} \\ &= 0.102 \times \frac{2F}{\pi D(D - \sqrt{D^2 - d^2})}, \end{aligned} \quad (7.24)$$

where F is in N and D and d are in mm.

Designation of the Brinell Hardness Test. The Brinell hardness is denoted by HBW followed by numbers representing the ball diameter, applied test force, and the duration time of the test force. Note that, in former standards, in cases when a steel ball had been used, the Brinell hardness was denoted by HB or HBS.

Example. 600 HBW 1/30/20:

600	Brinell hardness value
HBW	Brinell hardness symbol
1/	Ball diameter in mm
30	Applied test force (294.2 N \cong 30 kgf)
/20	Duration time of test force (20 s) if not indicated in the designation (10–15 s)

Application of the Brinell Hardness Test. For the application of the Brinell hardness test, the most commonly used Brinell scales for different testing conditions are given in Table 7.6. Other combinations of test forces and ball sizes are allowed, usually by special agreement.

Table 7.6 Standard test forces for the different testing conditions

Hardness symbol	Ball diameter D (mm)	Force:diameter ratio $0.102F/D^2$ (N/mm ²)	Nominal value of test force F (kN)
HBW 10/3000	10	30	29.42
HBW 10/1500	10	15	14.71
HBW 10/1000	10	10	9.807
HBW 10/500	10	5	4.903
HBW 10/250	10	2.5	2.452
HBW 10/100	10	1	0.9807
HBW 5/750	5	30	7.355
HBW 5/250	5	10	2.452
HBW 5/125	5	5	1.226
HBW 5/62.5	5	2.5	0.6129
HBW 5/25	5	1	0.2452
HBW 2.5/187.5	2.5	30	1.839
HBW 2.5/62.5	2.5	10	0.6129
HBW 2.5/31.25	2.5	5	0.3065
HBW 2.5/15.62	2.5	2.5	0.1532
HBW 2.5/6.25	2.5	1	0.06129
HBW 1/30	1	30	0.2942
HBW 1/10	1	10	0.09807
HBW 1/5	1	5	0.04903
HBW 1/2, 5	1	2.5	0.02452
HBW 1/1	1	1	0.009807

Advantages of the Brinell Hardness Test.

- Suitable for hardness tests even under rough workshop conditions if large ball indenters and high test forces are used.
- Suitable for hardness tests on inhomogeneous materials because of the large test indentations, provided that the extent of the inhomogeneity is small in comparison to the test indentation.
- Suitable for hardness tests on large blanks such as forged pieces, castings, hot-rolled or hot-pressed and heat-treated components.
- Relatively little surface preparation is required if large ball indenters and high test forces are used.
- Measurement is usually not affected by movement of the specimen in the direction in which the test force is acting.
- Simple, robust and low-cost indenters.

Disadvantages of the Brinell Hardness Test.

- Restriction of application range to a maximum Brinell hardness of 650 HBW.
- Restriction when testing small and thin-walled specimens.

- Relatively long test time due to the measurement of the indentation diameter.
- Relatively serious damage to the specimen due to the large test indentation.
- Measurement of many indentations can lead to operator fatigue and increased measurement error.

Rockwell Hardness Test (HR)

Principle of the Rockwell Hardness Test [7.170, 171]. The general Rockwell test procedure is the same regardless of the Rockwell scale or indenter being used. The indenter is brought into contact with the material to be tested and a preliminary force is applied to the indenter. The preliminary force is held constant for a specified time duration, after which the depth of indentation is measured. An additional force is then applied at a specified rate to increase the applied force to the total force level. The total force is held constant for a specified time duration, after which the additional force is removed, returning to the preliminary force level. After holding the preliminary force constant for a specified time duration, the depth of indentation is measured for a second time, followed by removal of the indenter from the test material (Fig. 7.28). The difference in the two depth measure-

Fig. 7.28 Rockwell principle diagram (Key: 1 – Indentation depth by preliminary force F_0 ; 2 – Indentation depth by additional test force F_1 ; 3 – Elastic recovery just after removal of additional test force F_1 ; 4 – Permanent indentation depth h ; 5 – Surface of test piece; 6 – Reference plane for measurement; 7 – Position of indenter)

ments is calculated as h in mm. From the value of h and the two constant numbers N and S (Table 7.7), the Rockwell hardness is calculated following the formula:

$$\text{Rockwell hardness} = N - \frac{h}{S} \quad (7.25)$$

Designation of the Rockwell Hardness Test. The Rockwell hardness is denoted by the symbol HR, followed by a letter indicating the scale, and either an S or W to indicate the type of ball used (S = steel; W = hardmetal, tungsten carbide alloy) (Table 7.7).

Example. 70 HR 30N W:

70 Rockwell hardness value
 HR Rockwell hardness symbol
 30N Rockwell scale symbol (Table 7.7)
 W Indication of type of ball used, S = steel, W = hardmetal

Application of the Rockwell Hardness Test. For the application of the Rockwell hardness test, the indenter types and specified test forces, as well as, typical applications for the different scales are given in Table 7.7. ASTM International defines thirty different Rockwell scales [7.170] while the ISO [7.171] defines a subset of these scales (Table 7.7).

Advantages of the Rockwell Hardness Test.

- Relatively short test time because the hardness value is automatically displayed immediately following the indentation process.
- The test may be automated.
- Relatively low procurement costs for the testing machine because no optical measuring device is necessary.
- No operator influence of evaluation because the hardness value is displayed directly.
- Relatively short time needed to train operator.

Disadvantages of the Rockwell Hardness Test.

- Possibility of measurement errors due to movement of the test piece and poorly seated or worn machine components during the application of the test forces.
- Less possibility of testing materials with surface layer hardening as a consequence of relatively high test forces.
- Sensitivity of the diamond indenter to damage, thus producing a risk of incorrect measurements
- Relatively low sensitivity on the difference in hardness.
- Significant influence of the shape of the conical diamond indenter on the test result (especially of the tip).

Vickers Hardness Test (HV)

Principle of the Vickers Hardness Test [7.172–174]. A diamond indenter in the form of a right pyramid with a square base and with a specified angle between opposite faces at the vertex is forced into the surface of a test piece followed by measurement of the diagonal length of the indentation left in the surface after removal of the test force F (Fig. 7.29).

Designation of the Vickers Hardness Test. The Vickers hardness is denoted by the symbol HV followed by numbers representing the applied test force, and the duration time of the test force.

Example. 640 HV 30/20:

640 Vickers hardness value
 HV Hardness symbol
 30 Applied test force (294.2 N \cong 30 kgf)
 /20 Duration time of test force (20 s) if not indicated in the designation (10–15 s)

Table 7.7 Rockwell hardness scales and typical applications [7.175]

Scale symbol	Indenter type (ball dimensions indicate diameter)	Preliminary force (N)	Total force (N)	Typical applications	HR calculation	
					N	S
HRA	Spheroconical diamond	98.07	588.4	Cemented carbides, thin steel, and shallow case hardened steel	100	0.002
HRB	Ball – 1.588 mm	98.07	980.7	Copper alloys, soft steels, aluminum alloys, malleable iron, etc.	130	0.002
HRC	Spheroconical diamond	98.07	1471	Steel, hard cast irons, pearlitic malleable iron, titanium, deep case hardened steel, and other materials harder than HRB 100	100	0.002
HRD	Spheroconical diamond	98.07	980.7	Thin steel and medium case hardened steel, and pearlitic malleable iron	100	0.002
HRE	Ball – 3.175 mm	98.07	980.7	Cast iron, aluminum and magnesium alloys, and bearing metals	130	0.002
HRF	Ball – 1.588 mm	98.07	588.4	Annealed copper alloys, and thin soft sheet metals	130	0.002
HRG	Ball – 1.588 mm	98.07	1471	Malleable irons, copper–nickel–zinc and cupro–nickel alloys	130	0.002

^a These scales are defined by ASTM International, but are not included in the ISO standards

Application of the Vickers Hardness Test. ISO [7.174] specifies the method of Vickers hardness test for the three different ranges of test force for metal-

lic materials, whereas ASTM International [7.172, 173] divides the Vickers test into two ranges (Table 7.8).

Table 7.8 Ranges of Vickers hardness tests

ISO		
Vickers range (ISO 6507-1)	Nominal ranges of test force, F (N)	Hardness range
Vickers hardness	$F \geq 49.03$	$\geq \text{HV } 5$
Low force Vickers hardness	$1.961 \leq F < 49.03$	HV 0.2 to HV 5
Vickers microhardness	$0.09807 \leq F < 1.961$	HV 0.01 to HV 0.2

ASTM International		
Vickers range	Nominal ranges of test force F (N)	Hardness range
Vickers hardness (ASTM E 92)	$9.807 \leq F < 1177$	HV 1 to HV 120
Vickers micro-indentation hardness (ASTM E 384)	$0.0098 \leq F < 9.807$	HV 0.001 to HV 1

The Vickers hardness test is specified in ISO to apply to lengths of indentation diagonals of 0.020–1.400 mm, whereas ASTM International [7.173] allows indentation diagonals below 0.020 mm.

Although, for the application of the Vickers hardness test, any force level is allowed between the specified limits, traditionally used and recommended test forces for different testing conditions are given in Table 7.9.

Advantages of the Vickers Hardness Test.

- Practically no limit to the use of the method due to the hardness of the test piece.
- Testing thin sheets, small test pieces or test surfaces, thin-walled tubes, thin, hard and plated coatings is possible.

Table 7.9 Recommended test forces

Hardness test ^a		Low-force hardness test		Microhardness test	
Hardness symbol	Nominal value of the test force F (N)	Hardness symbol	Nominal value of the test force F (N)	Hardness symbol	Nominal value of the test force F (N)
HV 5	49.03	HV 0.2	1.961	HV 0.01	0.09807
HV 10	98.07	HV 0.3	2.942	HV 0.015	0.147
HV 20	196.1	HV 0.5	4.903	HV 0.02	0.1961
HV 30	294.2	HV 1	9.807	HV 0.025	0.2452
HV 50	490.3	HV 2	19.61	HV 0.05	0.4903
HV 100	980.7	HV 3	29.42	HV 0.1	0.9807

^a Nominal test forces greater than 980.7 N may be applied

**Fig. 7.29** Principle of the Vickers hardness test

- In most cases, the small indentation has no influence on the function or appearance of tested materials or products.
- The hardness value is usually independent of the test force in the range of HV 0.2 and above.
- No incorrect measurement if the test piece yields to a limited extent in the direction of the test force.
- Can be reported in terms of stress values.

Disadvantages of the Vickers Hardness Test.

- High effort in preparing a suitable test surface.
- Relatively long test time due to the measurement of the diagonal lengths.
- Sensitivity of the diamond indenter to damage.
- If the test indentations are small, dependence of the hardness on the shape deviations of the indenter and the preparation of the test surfaces.
- Very sensitive to effects of vibration, especially in the microhardness range.
- Relatively large variation in measurement depending on the operator of microscope. Especially for low force hardness testing

Table 7.10 Symbols and designations for the Knoop hardness test

Symbol	Designation
F	Test force (N)
d	Length of the long diagonal (mm)
c	Indenter constant, relating projected area of the indentation to the square of the length of the long diagonal Indenter constant, $c = \frac{\tan \frac{\beta}{2}}{2 \tan \frac{\alpha}{2}}$, ideally $c = 0.07028$, where α and β are the angles between the opposite edges at the vertex of the diamond pyramid (Fig. 7.30)
HK	Knoop hardness = Gravitational constant ^a $\times \frac{\text{Test force}}{\text{Projected area of indentation}}$ $= 0.102 \times \frac{F}{cd^2} = 1.451 \frac{F}{d^2}$
^a : gravitational constant = $\frac{1}{g_n} = \frac{1}{9.80665} \approx 0.102$, where g_n is the acceleration of gravity	

For the application of the Vickers hardness test for the different ranges of test force see [7.176–179].

Knoop Hardness Test (HK)

Principle of the Knoop Hardness Test [7.173,180]. A diamond indenter, in the form of a rhombic-based pyramid with specified angles between opposite faces at the vertex, is forced into the surface of a test piece followed by measurement of the long diagonal of the indentation remaining in the surface after removal of the test force F (Figs. 7.30, 7.31, Table 7.10).

The Knoop hardness is proportional to the quotient obtained by dividing the test force by the projected area of the indentation, which is assumed to be a rhombic-based pyramid, and having at the vertex the same angles as the indenter.

Designation of the Knoop Hardness. The Knoop hardness is denoted by the symbol HK followed by numbers representing the applied test force, and the duration time of the test force.

Example. 640 HK 0.1/20:

- 640 Knoop hardness value
- HK Hardness symbol
- 0.1 Applied test force (0.9807 N \cong 0.1 kgf)
- /20 Duration time of test force (20 s) if not indicated in the designation (10–15 s)

Application of the Knoop Hardness Test. For the application of the Knoop hardness test, traditionally used and recommended test forces for different testing conditions are given in Table 7.11.

Advantages of the Knoop Hardness Test.

- Particularly suitable for narrow test pieces, such as wire, due to the large diagonal length ratio of approximately 7 : 1.

Fig. 7.30 Symbols and designations for the Knoop hardness test

Fig. 7.31 Symbols and designations for the Knoop hardness test

Table 7.11 Recommended test forces

Hardness Symbol	Nominal value of the test force F (N)
HK 0.01	0.09807
HK 0.02	0.1961
HK 0.025	0.2452
HK 0.05	0.4903
HK 0.1	0.9807
HK 0.2	1.961
HK 0.3	2.942
HK 0.5	4.903
HK 1	9.807

- Better suited to thin test pieces or platings than the Vickers test method because the indentation depth is smaller by a factor of four for the same diagonal length.
- Particularly suitable for brittle materials because of lower tendency to cracking.
- Particularly suited to investigating the anisotropy of a material because the Knoop test is dependent on the direction selected for the long diagonal in such cases.
- In most cases, the small indentation has no influence on the function or appearance of tested materials or products.
- Practically no limit on the application of the method from the hardness of the material tested.

Disadvantages of the Knoop Hardness Test.

- Time effort to achieve a sufficiently fine test surface.
- Considerable dependency of the hardness on the test force, with an especially strong influence of the preparation of the test surface.
- Sensitivity to damage of the diamond indenter.
- Expensive alignment of the test surface to achieve symmetrical test indentations.
- Relatively long test time due to the measurement of the diagonal length.
- Measurement of the diagonal length is more difficult than in the Vickers test method as a consequence of the indenter geometry.

7.3.2 Selecting a Conventional Hardness Test Method and Hardness Scale

The selection of a specific hardness testing method is substantially influenced by many factors as discussed below. Unfortunately, there is no one hardness

test that meets the optimum conditions for all applications. Although the Brinell, Rockwell, Vickers and Knoop hardness testing methods have been developed to be capable of testing most materials, in many testing circumstances the size or depth of the indentation is generally the primary consideration when choosing the appropriate test forces and type of indenter to be utilized by the hardness test method. The combinations of test forces and indenter types are known as a hardness method's specific hardness scales. The hardness scales have been defined to provide suitable measurement sensitivity and indentation depths that are appropriate for different materials, strengths and dimensions of test pieces. The largest and deepest indentations are generally obtained from the heavy-force Brinell scales, followed by the commonly used heavy-force Rockwell and Vickers scales, while small to extremely small indentations can be obtained from the commonly used lower-force Rockwell, Vickers and Knoop scales.

Strength of the Test Piece

A material's resistance to penetration or its strength is of primary importance when selecting a hardness method or hardness scale. An appropriate test force and indenter must be chosen to produce a large enough indentation in the test material to enable the hardness testing machine's measuring system to resolve and measure the depth or size of the indentation with sufficient sensitivity to produce a meaningful hardness result, but at the same time to not penetrate too deeply beyond the indenter's useful depth. On the other hand, a suitable indenter of the appropriate material, size and shape must be chosen to prevent the indenter from being damaged when testing high-strength materials. For example, hardened and tempered steel material generally requires hardness methods that employ higher test forces and a pointed or conical diamond indenter, whereas testing cemented carbides with high forces could lead to the diamond being fractured.

Test-Piece Size, Shape, Weight, Accessibility, Dimensions, and Thickness

The choice of a hardness test method may be influenced by the size, shape or weight of the test piece. The designs of some typical standard hardness testing machines may prevent the testing of very large and heavy test pieces or unusually shaped test pieces, and may require special machine designs, special designs of indenters or additional test piece support fixtures. These types of designs are usually limited to the Brinell, Rockwell and heavy-force Vickers machines. In contrast, small sample sizes

may require mounting in a support material which is generally only suitable for the Knoop and low-force Vickers hardness methods.

The dimensions of the test piece may also have to be considered for another reason. As a hardness measurement is being made, the material surrounding the indentation is plastically deformed, with the deformation extending well to the sides and below the indentation. If a hardness measurement is made too near the edge of the test material, the deformation surrounding the indentation may extend to the edge and push out the material, thus affecting the measured hardness value. Similarly, if the deformation extends completely through the thickness of thin test material, then the deformed material may flow at the interface with the supporting anvil, or the anvil material may contribute to the hardness measurement. These problems can influence the deformation process likely causing the test to give erroneous hardness results. Consequently, in cases where a hardness test is to be made on narrow-width or thin material or material having a small area, an appropriate hardness test and scale must be chosen that produces indentations small enough to prevent this edge interaction. Also keep in mind that the area surrounding a previously made indentation may also affect a new hardness test due to induced residual stress and areas of workhardening surrounding the indentation. Therefore, the number of indentations that will be made must be taken into consideration when small test areas are involved.

Material Composition and Homogeneity

The size and location of metallurgical features within the test material should be considered when choosing the hardness test method and hardness scale. For materials that are not homogeneous, an appropriate hardness test and scale should be chosen that will produce a sufficiently large indentation representative of the material as a whole. For example, forgings and cast iron are typically tested using the Brinell method. If the subject of interest is a material artifact, such as a decarburization zone or a thin material layer, then a hardness test and scale should be chosen that produces a small or shallow indentation. In an analogous way to the issues of test-piece size, the closeness to adjacent regions of a differing hardness, such as the heat-affected zone of a weld, should also be considered. If the deformation zone surrounding an indentation extends into these regions, the test measurement may be influenced. In such cases, an appropriate hardness test and scale should be chosen that uses test forces and indenter that produce a small enough indentation to avoid the influence of these areas.

Permissible Damage

One of the greatest attributes of a hardness test is that it is essentially a nondestructive test, leaving only a small indentation which usually does not detract from a product's function or appearance. However, there are some applications for which a hardness indentation of a certain size could be detrimental to a product's service or appearance. For example, it is possible that an indentation could act as an initiation point for a fracture in a part subjected to cyclic loading, or a large visible indentation could affect the appearance of a product. In these cases, smaller indentations may be the solution.

Test Surface Preparation

When the ability to prepare the testing surface is not possible or practical or is limited, a hardness method and hardness scale must be chosen that is less sensitive to the level of surface preparation. The degree of surface roughness that can be tolerated by the different hardness testing methods is generally dependent on the force levels to be applied, indenter size and resultant indentation size. In general, the larger the indentation size and depth, the less sensitive is the hardness test to the level of surface roughness and imperfections, and the more likely the measurement will represent the true hardness value of a material. This is particularly true for the Brinell, Vickers and Knoop methods because of the need to accurately resolve and measure the resultant indentation. The larger the sizes of surface anomalies with respect to the indentation size, the more likely it becomes that errors in the indentation measurement and the hardness result will increase.

An important feature of the Rockwell test method, which bases the hardness result on depth measurement rather than indentation size, is the use of the preliminary force as part of the testing cycle. Application of the preliminary force acts to push the indenter through minor surface imperfections and to crush residual foreign particles present on the test surface. By establishing a reference beneath the surface prior to making the first depth measurement, it allows testing of materials with slight surface flaws while maintaining much of the test accuracy.

As a general guide, the high-force scales of the Brinell test method requires the least surface preparation, such as a surface that has been filed, ground, machined or polished with no. 000 emery paper. Material tested by the Rockwell test method usually does not need to be polished, but should be smooth, clean and free of scale. The Brinell test method and the heavy-force Vickers scales producing small indentations are likely to

require polished surfaces to allow accurate measurement of the indentation sizes.

Permissible Measurement Uncertainty

The measurement uncertainty of a hardness test is influenced by many factors, including, among others, the operator, the machine's repeatability and reproducibility, and the testing environment (see Sect. 7.3.3). With respect to choosing a hardness test method, the number of different operators that would potentially use the hardness machine should be considered. Two of the larger sources of hardness measurement error are related to the operator's measurement of an indentation, such as is the case for Brinell, Vickers and Knoop methods, and the operation of manually controlled hardness testers. The variability between operators contributes to the measurement uncertainty by increasing the lack of repeatability and reproducibility in the measurement system. If a low measurement uncertainty is of high concern, then it may be beneficial to use automatically controlled hardness machines or automated indentation measuring systems, or to use the Rockwell hardness method, which lessens the influence of the operator by basing the hardness result on indentation depth as measured by the machine.

Speed of Testing Desired

For many industrial processes, time is one of the most important parameters. In circumstances where hardness testing is an integral part of a process and many tests must be performed, the time required to complete each test becomes an extremely important consideration. For a hardness test, the time required for each step of a measurement must be considered from the preparation of the test piece, to the indentation process, to the measurements needed to determine the hardness result, and finally to the calculation of the hardness value. The Brinell, Vickers and Knoop methods are two-step processes: (1) the indentation process, followed by (2) measurement of the indentation. The Rockwell hardness method was specifically designed to reduce the time needed for a hardness test by eliminating the second step of having to measure the size of the indent after the indentation process. The Rockwell hardness method quickly and automatically calculates and displays the hardness result based on the machine's measurement of indentation depth. Instrumented indentation testing is likely to take the longest time to complete due to the care and time required for preparing the test sample, running the indentation cycle, and analyzing the data.

Economic Viability and the Availability of Machines and Equipment

Other nontechnical but nevertheless important considerations in choosing a hardness method are the economics and practicality of the selection. Economic limitations often drive the choice of which hardness method is chosen for use. It may be a difficult choice in weighing the benefits of the best hardness method for an application against its cost. This may be particularly true when existing hardness equipment currently exists in-house. Finally, the volume of testing and the necessary training of operators should be taken into account when selecting a test.

Guidance on selecting hardness test methods is given in international hardness test method standards, such as those published by ISO and ASTM International. When several hardness methods are acceptable for testing a material, generally, the most commonly used method for the type of material or product should be chosen. In circumstances where the user wants to compare measurements with previously obtained hardness data, the same hardness test method and scale should be chosen as was used for the previous testing as long as a valid test can be obtained. This is preferred to testing with one hardness test method and scale and then converting the data to another hardness scale by way of published conversion tables. Converted data is never as accurate as the original measurement. This also holds true when the hardness method and scale is specified in a product specification or contract. The specified hardness method or scale should be used whenever possible as long as a valid test can be obtained.

7.3.3 Measurement Uncertainty in Hardness Testing (HR, HBW, HV, HK)

The concept of measurement uncertainty is relatively new to users of hardness testing, particularly as applied to the conventional hardness tests, Rockwell, Brinell, Vickers and Knoop. Historically, industry has relied on limiting hardness measurement error by adhering to error tolerances specified by national and international hardness test method standards. Test method standards specify tolerances for components of the hardness machine, such as the allowed error when applying the test forces and the error in measuring the indentation size or penetration depth. Tolerances are also specified for the performance of the hardness machine limiting the machine's measurement error with respect to the certified values of hardness block reference standards.

Hardness measurement uncertainty is very different from the tolerances specified by test method standards. Uncertainty does not limit measurement error. It provides an estimation of the error in a hardness measurement value with respect to the true hardness of the tested material. In recent years, with the advent of accreditation programs for testing and calibration laboratories, measurement uncertainty has gained increasing importance for hardness laboratories since most accreditation programs require a laboratory to determine their own measurement uncertainty.

Estimating Hardness Uncertainty – Direct Approach

The Guide to the Expression of Uncertainty in Measurement (GUM) [7.181] provides guidance for estimating the uncertainty in a measurement value. One procedure is a direct approach to quantify the significant influence quantities of the test (for example: force error, test speed, indenter shape, etc.), determine the biases and uncertainties of each influence quantity, correct for the biases, determine and evaluate sensitivity coefficients to convert from the units of the input quantity to the units of the measurand, and finally combine the uncertainties to provide an overall uncertainty in the resultant measurement value.

A hardness test involves the time-dependent application of forces to specifically shaped indenters, and, for some types of harness tests, simultaneously measuring the resultant indentation depths. This is done using machines that can range from entirely mechanical to various combinations of electronic and mechanical components. As a result, it is often difficult to identify all of the significant influence quantities that contribute to the measurement uncertainty. For example, error sources may exist due to the internal workings of the mechanical components of the hardness machine or the indenter, which are not easily measurable. Complicating this, the determination of some sensitivity coefficients is a lengthy and difficult undertaking since these conversion factors may be dependent on the hardness scale and the material being tested which can only be determined by experimental testing. An additional complication is that the accepted practice for calibrating a hardness machine is to not correct for biases in the operational components of the machine as long as they are within the specified tolerance limits.

Although this technique of assessing the separate parameters of the hardness testing machine for their individual error contributions is an effective method for determining hardness measurement uncertainty, it

may be best applied at the highest calibration levels, such as by National Metrology Institutes, which have the time and resources to assess each of the sources of error. However, it may present an overwhelming challenge to many industrial hardness laboratories using the conventional hardness tests. Detailed procedures for calculating uncertainty by this method are too involved to be described here; however, recommended procedures have been published as a document of the European Cooperation for Accreditation of Laboratories (EAL) [7.182].

Estimating Hardness Uncertainty – Indirect Approach

A second procedure for determining hardness uncertainty is an indirect approach based on familiar procedures and practices of hardness testing facilities and laboratories. Most of the contributions of uncertainty can be estimated from the results of hardness tests on reference materials and the material under test. Hardness reference materials provide traceability to the national hardness standards maintained by the world's National Metrology Institutes (NMIs) and are necessary to establish a starting point for the uncertainty analysis as per the GUM. In some cases, where reference materials are not available from a NMI, suitable reference materials may be obtained from a secondary reference source.

This indirect approach views the hardness machine and indenter as a single measuring device, and considers uncertainties associated with the overall measurement performance of the hardness machine. It may be more applicable for industrial laboratories in determining the measurement uncertainty for the conventional types of hardness tests. It is important to understand that this procedure is appropriate only when a hardness machine is operating within all operational and performance tolerances to ensure that a large error in one machine component is not being offset by another large, but opposite, error in a second component. These opposite errors could then combine to produce satisfactory hardness results when testing reference blocks even when the machine is not operating properly.

This approach considers uncertainties due to the lack of repeatability of the hardness machine, the reproducibility of the hardness measurement over time, the resolution of the hardness machine display or indentation measuring instrument, the nonuniformity of the material under test, the uncertainty of the certified value of the reference standards, and the measurement bias as compared to reference standards.

- The repeatability of the hardness machine is its ability to continually produce the same hardness value each time a measurement is made over a short time period and under constant testing conditions, including the same operator. All testing instruments, including hardness machines, exhibit some degree of a lack of repeatability.
- The reproducibility of a hardness machine can be thought of as how well the hardness values agree under changing testing conditions. Influences such as different machine operators and changes in the test environment often affect the performance of a hardness machine.
- The finite resolution of devices that display the hardness value or that measure the size of indentations prevents the determination of an absolutely accurate hardness value. Devices such as a dial display on a Rockwell hardness machine or a portable handscope for measuring Brinell hardness indents may have a low resolution which can contribute a significant level of uncertainty to the hardness value.
- When reported measurement values are based on the average of multiple hardness tests, the nonuniformity of the material under test contributes a component of uncertainty in the hardness value, such as would occur in the calibration of a reference block.
- Reference test blocks provide the link to the hardness standard to which traceability is claimed. All reference hardness blocks should have a reported uncertainty in the certified hardness value. This uncertainty contributes to the measurement uncertainty of hardness machines calibrated or verified with the reference test blocks.

The general approach of this procedure is to calculate a combined standard uncertainty u_c by combining the contributing components of uncertainty u_1, u_2, \dots, u_n , for the applicable sources of error discussed above, such that

$$u_c = \sqrt{u_1^2 + u_2^2 + \dots + u_n^2}. \quad (7.26)$$

The appropriate contributing components of uncertainty to combine for this calculation are dependent on what the uncertainty value represents. For example, a combined uncertainty may be calculated for a single hardness value, an average of multiple hardness values, a hardness machine's error determined as part of an indirect verification, or the certified value resulting from a reference block calibration.

Measurement uncertainty is usually expressed and reported as a combined expanded uncertainty U_c , which is calculated by multiplying the combined standard uncertainty u_c by a numerical coverage factor k , such that

$$U_c = k u_c. \quad (7.27)$$

A coverage factor is chosen that depends on how well the standard uncertainty was estimated (number of measurements), and the level of uncertainty that is desired. The measurement bias b of the hardness machine is the difference between the expected hardness measurement results and the true hardness of a material. When test systems are not corrected for measurement bias, the bias then contributes to the overall uncertainty in a measurement. Ideally, measurement biases should be corrected; however, in practice, this is commonly not done for traditional types of hardness tests. There are a number of possible methods for incorporating uncorrected biases into an uncertainty calculation, each of which has both advantages and disadvantages. A simple and conservative method is to combine the bias with the expanded uncertainty as

$$U = k u_c + |b|, \quad (7.28)$$

where $|b|$ is the absolute value of the bias.

Discussions of the calculations for each of the uncertainty components, which uncertainty components should be combined, and how they should be combined for all types of hardness measurements are too involved to be described in detail here. Guidance on this approach can be found in newly developed recommended procedures recently added to the international hardness test method standards of [ISO](#) and [ASTM](#) for the specific conventional hardness tests.

Reporting Uncertainty

Ideally, an individual measurement uncertainty should be determined for each hardness scale and hardness level of interest since the contributing components of uncertainty may vary depending on the scale and hardness level. In practice, this may not be practical. In many cases, a single uncertainty value may be applied to a range of hardness levels based on the laboratory's experience and knowledge of the operation of the hardness machine. Also, because several approaches may be used to evaluate and express measurement uncertainty, a brief description of what the reported uncertainty value represents should be included with the reported uncertainty value.

7.3.4 Instrumented Indentation Test (IIT)

Principle of the Instrumented Indentation Test [7.183]

The continuous monitoring of the force and the depth of indentation can allow the determination of hardness values equivalent to traditional hardness values. More significantly, additional properties of the material, such as its indentation modulus and elasto-plastic hardness, can also be determined. All these values can be calculated without the need to measure the indent optically (Fig. 7.32, Fig. 7.33). An indenter consisting of a material harder than the material tested with the following shapes can be used:

1. diamond indenter shaped as an orthogonal pyramid with a square base and with an angle $\alpha = 136^\circ$

Fig. 7.32 Schematic representation of test procedure (Key: 1 – Application of the test force; 2 – Removal of the test force; 3 – Tangent to curve 2 at F_{\max})

Fig. 7.33 Schematic representation of a cross section through indentation (Key: 1 – Indenter; 2 – Surface of residual plastic indentation in test piece; 3 – Surface of test piece at maximum indentation depth and test force)

2. diamond pyramid with triangular base (e.g., Berkovich pyramid),
3. hardmetal ball (especially for the determination of the elastic behavior of materials),
4. diamond spherical indenter.

For tests at indentation depths of less than $1\ \mu\text{m}$, the mechanical deformation strongly depends on the real shape of indenter tip and the calculated materials parameters are significantly influenced by the contact area function of the indenter used in the testing machine. Therefore careful calibration of both instrument and indenter shape is required in order to achieve an acceptable reproducibility of the material parameters determined with different machines.

At high contact pressures, damage to the indenter is possible. For this reason in the force range higher than $2\ \text{N}$, hardmetal indenters are often used. For test pieces with very high hardness and modulus of elasticity the influence of indenter deformation on test result should be taken into account.

The test procedure can either be force-controlled or displacement-controlled. The test force F , the corresponding indentation depth h and time are recorded during the whole test procedure. The result of the test is the data set of the test force and the relevant indentation depth as a function of time (Fig. 7.32). For a reproducible determination of the force and corresponding indentation depth, the zero point for the force/indentation depth measurement must be assigned individually for each test.

Where time-dependent effects are being measured:

1. Using the force-controlled method, the test force is kept constant over a specified period and the change of the indentation depth is measured as a function of the holding time of the test force,
2. Using the indentation-depth-controlled method the indentation depth is kept constant over a specified period and the change of the test force is measured as a function of the holding time of the indentation depth.

For references for the application of the instrumented indentation test, see [7.184–202].

Table 7.12 gives the symbols and designations used for the instrumented indentation test.

Table 7.13 gives an overview about the parameters of the instrumented indentation test and additional influence factors on the test result.

Table 7.12 Symbols and designations

Symbol	Designation	Unit ^{a,b}
α	Angle, specific to the shape of the pyramidal indenter	degrees
r	Radius of spherical indenter	mm
F	Test force	N
F_{\max}	Maximum test force	N
h	Indentation depth under applied test force	mm
h_{\max}	Maximum indentation depth at F_{\max}	mm
h_r	Point of intersection of the tangent to curve 2 at F_{\max} with the indentation depth axis (see Fig. 7.32)	mm
h_p	Permanent indentation depth after removal of the test force	mm
h_c	Depth of the contact of the indenter with the test piece at F_{\max}	mm
$A_s(h)$	Surface area of the indenter at distance h from the tip	mm ²
$A_p(h_c)$	Projected area of contact of the indenter at distance h_c from the tip	mm ²
HM	Martens hardness	N/mm ²
HM _s	Martens hardness, determined from the slope of the increasing force/indentation depth curve	N/mm ²
H_{IT}	Indentation hardness	N/mm ²
E_{IT}	Indentation modulus	N/mm ²
C_{IT}	Indentation creep	%
R_{IT}	Indentation relaxation	%
W_{total}	Total mechanical work of indentation	Nm
W_{elast}	Elastic reverse deformation work of indentation	Nm
η_{IT}	Relation $W_{\text{elast}}/W_{\text{total}}$	%

^a To avoid very long numbers multiples or sub-multiples of the units may be used^b 1 N/mm² = 1 MPa

Martens Hardness (HM)

Determination of Martens Hardness. Martens hardness is measured under an applied test force. Martens hardness is determined from the values given by the force/indentation depth curve during the increasing of the test force, preferably after reaching the specified test force. Martens hardness includes the plastic and elastic deformation, thus this hardness value can be calculated for all materials.

Martens hardness is defined for both pyramidal indenters. It is not defined for the Knoop indenter or for ball indenters.

Martens hardness is defined as the test force F divided by $A_s(h)$ the surface area of the indenter penetrating beyond the zero point of the contact and is expressed in N/mm².

The relationship between Martens hardness, indentation depth and test force is given in Fig. 7.34.

$$\begin{array}{ll}
 \text{(a) Vickers indenter} & \text{(b) Berkovich indenter} \\
 \text{HM} = \frac{F}{A_s(h)} = \frac{F}{26.43h^2} & \text{HM} = \frac{F}{A_s(h)} = \frac{F}{26.44h^2}
 \end{array}
 \quad (7.29)$$

$$A_s(h) = \frac{4 \sin\left(\frac{\alpha}{2}\right)}{\cos^2\left(\frac{\alpha}{2}\right)} h^2 \quad A_s(h) = \frac{3\sqrt{3} \tan \alpha}{\cos \alpha} h^2 \quad (7.30)$$

Designation of the Martens Hardness [7.184]. The Martens hardness is denoted by the symbol HM.

Example. HM 0.5/20/20 = 8700 N/mm²:

HM 0.5 Test force in N
 /20 Application time of test force in s
 /20 Duration time of test force in s
 = 8700 N/mm² Hardness value

Indentation Hardness (H_{IT})

Determination of the Indentation Hardness. The indentation hardness H_{IT} is a measure of the resistance to permanent deformation or damage.

$$H_{IT} = \frac{F_{\max}}{A_p}, \quad (7.31)$$

where F_{\max} is the maximum applied force, A_p is the projected (cross-sectional) area of contact between the

Fig. 7.34 Relationship between Martens hardness, indentation depth and test force (Key: 1 – Macro range; 2 – Micro range; 3 – Nano range; 4 – Rubber; 5 – Plastics; 6 – Nonferrous metals; 7 – Steel; 8 – Hardmetals, ceramics)

indenter and the test piece determined from the force-displacement curve and a knowledge of the area function of the indenter, see 4.5.2 of ISO 14577-2.

Equation (7.31) defines hardness as the maximum applied force, divided by the projected (cross-sectional) contact area of the indenter with the test piece. This definition is in accord with that generally agreed and first proposed by Meyer [7.185].

For indentation depths $< 6 \mu\text{m}$ the area function of the indenter cannot be assumed to be that of the theoretical shape, since all pointed indenters will have some degree of rounding at the tip and spherically ended indenters (spherical and conical) are unlikely to have a uniform radius. The determination of the exact area function for a given indenter is required for indentation depths $< 6 \mu\text{m}$, but is beneficial for larger indentation depths (see 4.2.1 and 4.6 of ISO 14577-2).

For indentation depths $> 6 \mu\text{m}$ a first approximation to the projected area A_p is given by the theoretical shape of the indenter.

For a perfect Vickers indenter:

$$A_p = 24.5h_c^2;$$

For a perfect Berkovich indenter:

$$A_p = 23.96h_c^2;$$

For a modified Berkovich indenter:

$$A_p = 24.5h_c^2,$$

where h_c is the depth of contact of the indenter with the test piece calculated as:

$$h_c = h_{\max} - \varepsilon(h_{\max} - h_r).$$

Figures 7.32 and 7.33 schematically show the different depths monitored during an indentation test. The theoretical basis of the method for the determination of contact depth is given in [7.203]. The contact depth is derived from the force removal curve using the tangent depth h_r and the maximum displacement h_{\max} correcting for elastic displacement of the surface according to *Sneddon's* analysis [7.186], where ε depends on the indenter geometry (Table 7.14).

h_r is derived from the force–displacement curve and is the intercept of the tangent to the unloading cycle at F_{\max} with the displacement axis.

Designation of Indentation Hardness H_{IT} . The indentation hardness is denoted by the symbol H_{IT} .

Example. $H_{IT} 0.5/10/20/30 = 11\,300\text{ N/mm}^2$:

$H_{IT} 0.5/$	Test force in N
$10/$	Application time of test force in s
20	Duration time of test force in s
$/30$	Time taken to remove the test force during the fitted portion of the test force removal curve in s

$= 11\,300\text{ N/mm}^2$ Hardness value

Indentation Modulus (E_{IT})

Determination of Indentation Modulus. The indentation modulus E_{IT} can be calculated from the slope of the tangent for the calculation of indentation hardness H_{IT} and is comparable with the Young's modulus of the

material

$$E_{IT} = \frac{1 - (\nu_s)^2}{\frac{1}{E_r} - \frac{1 - (\nu_i)^2}{E_i}}, \quad (7.32)$$

$$E_r = \frac{1}{\beta} \frac{\sqrt{\pi}}{2} \frac{1}{\sqrt{A_p}} \frac{1}{C_s}, \quad (7.33)$$

where

ν_s is the Poisson's ratio of the test piece;

ν_i is the Poisson's ratio of the indenter (for diamond 0.07) [7.187];

E_r is the reduced modulus of the indentation contact;

E_i is the modulus of the indenter (for diamond $1.14 \times 10^6\text{ N/mm}^2$) [7.187];

C_s is the compliance of the contact, i.e. dh/dF of the (frame stiffness corrected) test force removal curve evaluated at the maximum test force;

β is the correction factor for different tip geometry (Table 7.15).

Designation of Indentation Modulus. The indentation modulus is denoted by the symbol E_{IT} .

Example. $E_{IT} 0.5/10/20/30 = 222\,000\text{ N/mm}^2$:

$E_{IT} 0.5/$	Test force in N
$10/$	Application time of test force in s
20	Duration time of test force in s
$/30$	Time taken to remove the test force during the fitted portion of the test force removal curve in s

$= 222\,000\text{ N/mm}^2$ Indentation modulus

Nanoindentation Method

The elastic and plastic properties of a coating are critical factors determining the performance of the coated product. Indeed many coatings are specifically developed to provide wear resistance that is usually conferred by their high hardness. Measurement of coating hardness is often used as a quality-control tool. Young's modulus becomes important when calculation of the stress in a coating is required in the design of coated components.

Table 7.14 Correction factor ε for different indenter geometries

Indenter geometry	ε
Flat punch	1
Conical	$2(\pi - 2)/\pi = 0.73$
Paraboloid of revolution (includes spherical)	3/4
Berkovich, Vickers	3/4

Table 7.15 Correction factor β for different indenter geometries [7.195]

Indenter geometry	β
Axis symmetric (e.g. conical, spherical)	1
Berkovich	1.034
Vickers	1.012

For example, the extent to which coated components can withstand external applied forces is an important property in the capability of any coated system.

It is relatively straightforward to determine the hardness and indentation modulus of bulk materials using instrumented indentation. However, when measurements are made normal to a coated surface, depending on the force applied and the thickness of the coating, the substrate properties influence the result.

The purpose of this part of handbook is to provide guidelines for conditions where there is no significant influence of the substrate and, where such influence is detected, to provide possible analytical methods to enable the coating properties to be extracted from the composite measurement.

The analysis used here does not make any allowances for pile-up of indents. Use of atomic force microscopy (AFM) to assess the indent shape allows the determination of possible pile-up of the surface around the indent. This surface effect results in an underestimate of the contact area in the analysis and hence may influence the measured results. Pile-up generally occurs for fully workhardened materials. Pile-up of soft, ductile materials is more likely for thinner coatings due to the constraint of the stresses in the zone of plastic deformation in the coating. It has been reported that the piled-up material results in an effective increase of the contact area for the determination of hardness, while the effect is less pronounced for the determination of indentation modulus, since the piled-up material behaves less rigidly [7.197].

Verification and Calibration of Testing Machines. The instrument shall be calibrated according to the procedures set out in ISO 14577-2 [7.204].

Indirect verification using a reference material shall be made to ensure the direct calibration is valid and that no damage or contamination has occurred to the indenter tip. If the results of these initial indentations indicate the presence of contamination or damage then the indenter should be cleaned using the procedure recommended in ISO 14577-1 before further trial indents are made. If indentation into the reference material still indicates the presence of contamination or damage after cleaning, inspection with an optical microscope at a magnification of 400 \times is recommended. Detection of submicroscopic damage or contamination is possible using appropriate microscopy of indents or the indenter. Where damage is detected the indenter shall be replaced.

The machine compliance C_f and the area function $A_p(h_c)$ calibration/verification shall be implemented be-

fore a new indenter is used, see subclause “Procedures for determination of machine compliance and indenter area function”.

The instrumented indentation instrument shall achieve the required mechanical and thermal stability before starting an indentation cycle, see subclause “Measurement procedure”.

Indentation experiments may be performed with a variety of differently shaped indenters, which should be chosen to optimize the plastic and elastic deformation required for a given coating substrate system. Typical indenter shapes are Vickers, Berkovich, conical, spherical and corner cube. For the determination of coating plastic properties, pointed indenters are recommended. The thinner the coating, the sharper the indenter should be. For the determination of coating elastic properties, spherical indenters are recommended. Ideally, a large-radius sphere is used, which enables indentation in the fully elastic regime over a reasonable indentation displacement. If the radius is too large, the surface effects (roughness, surface layers etc.) will dominate the uncertainties. And if the radius is too small, the maximum force or displacement before plastic deformation begins will be very low. The optimum radius can be identified by preliminary experiments or modeling.

Test Piece. Generally surface preparation of the test piece should be kept to a minimum, and if possible, the test piece should be used in the as-received state if surface flatness is consistent with the criteria given in ISO 14577-1.

The test piece shall be mounted using the same methods as employed for determination/verification of the instrument frame compliance, and shall be such that the test surface is normal to the axis of the indenter and such that the local surface at the proposed indentation site is less than $\pm 5^\circ$ from perpendicular to the indentation axis. Perpendicularity can be checked in practice by imaging the indent made by a non-axisymmetric indenter.

Indentation into rough surfaces will lead to an increased scatter in the results with decreasing indentation depth. Clearly when the roughness value R_a approaches the same value as the indentation depth the contact area will vary greatly from indent to indent, depending on its position relative to peaks and valleys at the surface. Thus it is recommended that the final surface finish shall be as smooth as available experience and facilities permit. The R_a value should be less than 5% of the maximum penetration depth whenever possible.

It has been shown that, for a Berkovich indenter, the angle that the surface normal presents to the axis of

indentation has to be greater than 7° for significant errors to result [7.198]. The important angle is that between the indentation axis and the local surface normal at the point of contact. This angle may be significantly different to the average surface plane for rough surfaces.

While R_a has been recommended as a practical and easily understood roughness parameter, it should be borne in mind that this is an average, and thus single peaks and valleys may be greater than this, as defined by the R_z value, although the likelihood of encountering the maximum peak, for example, on the surface is small. Modeling to investigate the roughness of the coating surface has concluded that there are two limiting situations for any R_a value. When the *wavelength* of the roughness (in the plane of the coating surface) is much greater than the indenter tip radius, the force–penetration response is determined by the local coating-surface curvature, but when the wavelength is much less than the tip radius, asperity contact occurs and the effect is similar to having an additional lower-modulus coating on the surface.

In cases where coatings are used in the as-received condition, nevertheless, random defects occur such as nodular growths or scratches and where an optical system is included in the testing machine, it is recommended that flat areas away from these defects are selected for measurement.

The roughness profilometer probe radius should be comparable to the indenter radius. If the roughness parameter R_a is determined with an AFM on a scan area, the size of this area should be agreed upon between the customer and the measurement laboratory. A scan area of $10\text{ }\mu\text{m}$ by $10\text{ }\mu\text{m}$ is recommended.

It should be appreciated that mechanical polishing of surfaces may result in a change in the workhardening and/or the residual stress state of the surface and consequently the measured hardness. For ceramics this is less of a concern than for metals, although surface damage may occur. Grinding and polishing shall be carried out such that any stress induced by the previous stage is removed by the subsequent stage and the final stage shall be with a grade of polishing medium appropriate to the displacement scale being used in the test.

Many coatings replicate the surface finish of the substrate. If it is acceptable to do so, surface-preparation problems can be reduced by ensuring that the substrate has an appropriate surface finish, thus eliminating the need to prepare the surface of the coating. In some cases, however, changing the substrate surface roughness may affect other coating properties; therefore, care should be taken when using this approach.

In coatings it is common for there to be relatively large residual stresses e.g. arising from thermal expansion coefficient mismatch between the coating and the substrate and/or stress induced by the coating deposition process. Thus, a stress-free surface would not normally be expected. Furthermore, stress gradients in coatings are not uncommon, so that removal of excessive material during a remedial surface preparation stage may result in a significant departure from the original surface state.

Polishing reduces the coating thickness and so the effects of the substrate will be enhanced. Where the data analysis requires an accurate knowledge of the coating thickness indented, polishing will require remeasurement of the coating thickness. This again emphasizes the need to carry out minimum preparation.

Generally, provided the surface is free from obvious surface contamination, cleaning procedures should be avoided. If cleaning is required, it shall be limited to methods that minimize damage, e.g.:

- application of a dry oil-free filtered gas stream,
- application of subliming particle stream of CO_2 (avoiding surface temperatures below the dew point),
- application of ultrasonic methods,
- rinse with a solvent (which is chemically inert to the test piece) and then dry.

If these methods fail and the surface is sufficiently robust, the surface may be wiped with a lintless tissue soaked in solvent to remove trapped dust particles and the surface shall be rinsed in a solvent as above. Ultrasonic methods may not be used as these are known to create or increase damage to coatings.

Test Conditions. Indenter geometry, maximum force and/or displacement and force displacement cycle (with suitable hold periods) shall be selected by the operator to be appropriate to the coating to be measured and the operating parameters of the instrument used.

It is important that the test results are not affected by the presence of an interface, free surface or by any plastic deformation introduced by a previous indentation in a series. The effect of any of these depends on the indenter geometry and the materials properties of the test piece. Indentations shall be at least three times their indentation diameter away from interfaces or free surfaces and, where multiple indentations are planned, the minimum distance between indentations shall be at least five times the largest indentation diameter.

The indentation diameter is the in-plane diameter at the surface of the test piece of the circular impres-

sion of an indent created by a spherical indenter. For non-circular impressions, the indentation diameter is the diameter of the smallest circle capable of enclosing the indentation. Occasional cracking may occur at the corners of the indentation. When this occurs, the indentation diameter should enclose the crack.

The minimum distances specified are best applicable to ceramic materials and metals such as iron and its alloys. For other materials it is recommended that separations of at least ten indentation diameters be used. If in doubt, it is recommended that the values from the first indentation are compared with those from subsequent indentations in a series. If there is a significant difference, the indentations may be too close and the distance should be increased. A twofold increase is suggested.

The following parameters of coating/substrate influencing the measurement result should be considered:

1. substrate hardness, Young's modulus and Poisson's ratio
2. coating thickness
3. surface roughness
4. adhesion of the coating to the substrate

All these parameters should be kept constant if a direct comparison is to be made between two or more test pieces.

The time dependence of the materials parameter should be taken into account.

Variations in test-piece parameters other than hardness or modulus can affect measurement of these quantities. If the indentation depth is a sufficiently small fraction of the coating thickness, or the coating thickness is well known, it is possible to compare coatings of different thickness. The exact limits depend on the ratio of properties of coating and substrate. It is recommended that methods for normalizing results to determine coating properties from coatings of different thickness always be used.

Measurement Procedure. Introduce the prepared test piece and position it so that testing can be undertaken at the desired location. Carry out the predetermined number of indentation cycles using the selected test conditions.

A single force application and removal cycle shall be used. A decision tree to assist in estimating the thermal drift during the experiment is shown in Fig. 7.35. If the drift rate is significant the displacement data shall be corrected by measuring the drift rate during a hold at as close to zero force as is practicable or at 90% removed force. The hold period shall be sufficient to allow determination of the drift in displacement due to temperature fluctuations. Drift (as opposed to noise) in displacement values determined during the hold period at 90% force removal or at close to zero is believed to result from temperature changes, and, a linear correction should be

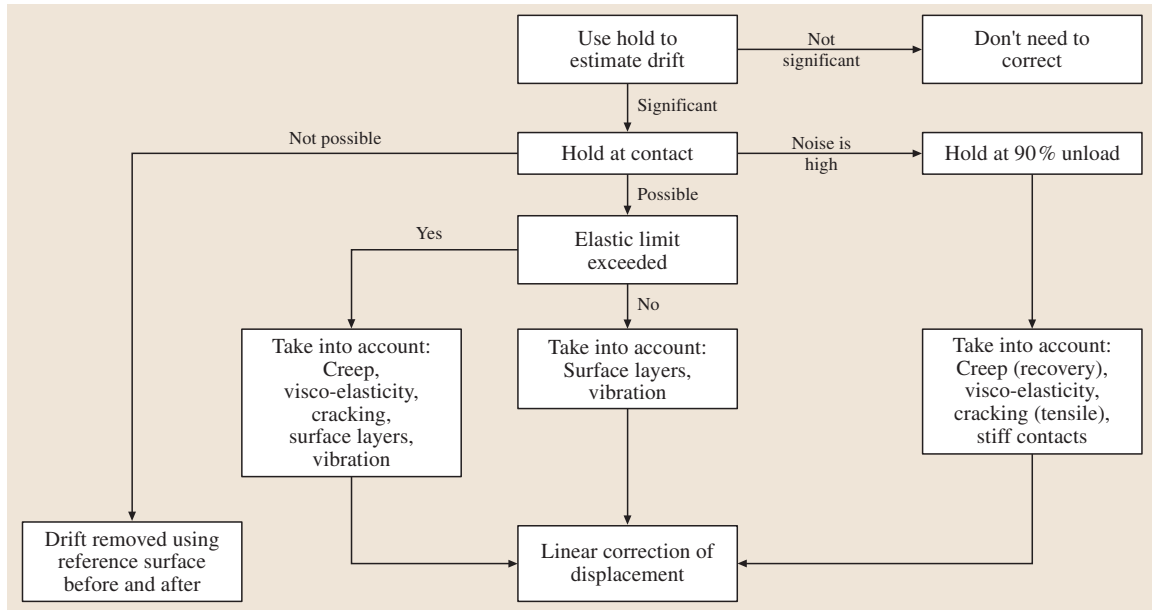

Fig. 7.35 Decision tree to assist in estimating the drift during a force-controlled experiment

applied such that:

$$\begin{aligned} & \text{(corrected displacement)} \\ &= (\text{displacement}) - (\text{thermal drift rate}) \times \text{time} \end{aligned}$$

If a contact in the fully elastic regime can be obtained, a hold at initial contact is preferred. In this way, material influences (creep, viscoelasticity, cracking) can be avoided. If no elastic contact can be obtained, depending on the material under investigation, a hold at initial force (e.g. viscoelastic material) or at 90% removed force (e.g. soft material) may be preferred. For difficult materials, a hold period at both ends of the indentation cycle may be included. It is recommended that the first 10–20 s of the hold data should be discarded for the analysis since these initial data may be significantly influenced by time-dependent effects (material time-dependent deformation, formation of capillary surface layers) [7.199, 200].

A further hold period shall be performed at maximum force to allow for completion of any time-dependent deformation. In all cases this hold period shall be long enough to reduce the error in the slope of the force removal curve to less than 1%. The minimum hold-period length is therefore dependent on the instrument capability and the material being tested. The hold period shall be long enough and/or the time to remove force shall be short enough such that:

$$(\text{creep rate}) \times (\text{time to remove force}) < F_{\max}/S/100$$

Force application and removal rates may be the same but it is recommended that the removal rate should be higher than the application rate (if possible) to minimize the influence of creep. Slower force application reduces the hold period length required at F_{\max} to achieve the necessary reduction in creep rate.

The influence of the material creep behavior on hardness and modulus results has been reported [7.199]. The results show that, especially for materials with low hardness-to-modulus ratio (among them most metals), the modulus results are not reliable if the hold period is too short. A modulus error, due to creep, of more than 50% may arise. The variation of the hold period produced a hardness change of up to 18%. [7.199] proposes hold periods dependent on the material type that range from 8 s for fused quartz to 187 s for aluminum. The criterion used was that the creep rate should have decayed to a value where the depth increase in one minute is less than 1% of the indentation depth. It is recommended that the creep rate be assessed in preliminary experiments.

Data Analysis and Evaluation of Results. The hardness and indentation modulus of the test piece can be calculated using (7.31–7.33). The properties thus calculated are composite properties for the coating/substrate combination. This clause provide methods for extracting the indentation modulus of the coating from the composite properties measured, assuming that the coating properties are constant with depth.

For hardness measurement of electroplated coatings on steels [7.201], it is recommended that the indentation depth does not exceed one tenth the thickness of the coating, while for paint films [7.202] penetration of up to one third the coating thickness may be allowed. These approximations can be unsatisfactory in many cases. Test parameters for ductile and brittle coatings need to be considered separately.

For in-plane indentation, elastic deformation of the substrate will mostly occur for all coatings, even though this could be negligibly small for a thick compliant coating on a stiff substrate. Thus the measured modulus will be the composite modulus of the coating and substrate and the value obtained will be a function of indentation depth.

For hardness measurement it is recommended to use as small a radius indenter (i.e. as sharp) as possible to limit the plastic deformation to be within the coating. A measurement of the uncoated substrate hardness is a useful guide to the appropriate choice of analysis (soft versus hard). In some circumstances it is possible to identify a range of indentation depth over which the measured hardness is constant (i.e. before the onset of substrate plastic deformation) and then carry out indentation experiments within this range.

Estimates of coating hardness and modulus may be extracted from the composite values E_{IT} , H_{IT} obtained from in-plane indentation by expressing those composite values as a function of the contact radius a or indentation depth h_c normalized to the coating thickness. Measurement of the coating thickness t_c is recommended for reproducible measurement of coating properties. For indenters of different geometries (e.g. Berkovich, Vickers, spherical, cone, etc.), a is approximated by the radius of a circle having the same area as the projected area of contact with the indenter,

$$a = \sqrt{\frac{A_p}{\pi}}. \quad (7.34)$$

This value has exact equivalence for a spherical or conical indenter but becomes increasingly less physically meaningful as the axial symmetry of the indenter reduces, i.e. cone = sphere > Vickers > Berkovich.

It is relatively easy to measure the hardness of ductile coatings or the elastic modulus of brittle coatings. It is more difficult to determine the hardness of brittle or hard coatings or the elastic modulus of ductile coatings. Where t_c is not measured, nominal values of t_c may be used but comparison between coatings of different thicknesses will be less accurate.

In the case of force-controlled cycles and test pieces of unknown indentation response, a set of trial indentations shall be performed (e.g. at two widely spaced forces) and analyzed to enable estimates of the test force required for the range of a/t_c specified below.

In the case of soft/ductile coatings indentation force or displacement and indenter geometry shall be chosen such that data shall be obtained in the region where $a/t_c < 1.5$. The coating indentation modulus E_{IT} is obtained by taking a series of measurements at different indentation depths and extrapolating a linear fit to indentation elastic modulus versus a/t_c to zero (Fig. 7.36).

A linear fit to indentation elastic modulus versus a/t_c to zero is a first approximation in the range $a/t_c < 2$. However, in general, a nonlinear relationship appears and can be reproduced by finite element analysis (FEA). The exact nature of this nonlinear relation is not known and so a linear fit over the restricted range indicated is a robust first approximation but is not applicable over a range wider than this.

For the determination of coating indentation hardness, it is recommended that an elastic stress analysis of the coating/substrate system be undertaken using the approximation of a spherical indenter of a radius equivalent to the tip radius of the self-similar-geometry indenter. This will determine whether the coating or the substrate will yield first during indentation and therefore whether it is possible to determine the coating hardness at all. It is recommended that hardness values for the substrate be obtained for comparison, by testing if necessary. Delamination or fracture of the coating can be recognized by the hardness values obtained, clustering at the substrate value, even at low h_c/t_c . Note that sharper indenters may cause fracture at lower forces than blunter indenters.

In the case of hard coatings on a softer substrate, the indentation force or displacement and indenter geometry shall be chosen such that h_c/t_c (or $\approx a/t_c$) is in a range where H_{IT} is a maximum. Commonly, the range is $0 < h_c/t_c < 0.5$. If a constant maximum value of H_{IT} (a plateau) is observed over this range, this is the coating indentation hardness. If only a maximum in H_{IT} occurs and indentation of a thicker coating yields the same value, then this is a strong indicator that this

Fig. 7.36 Indentation reduced elastic modulus versus normalized contact radius Au on Ni, selected data for spherical (filled circle), Berkovich (filled triangle) and Vickers (filled square) indenter

is the value for the coating. Otherwise this is only the minimum estimate of the coating indentation hardness.

The extent of substrate plastic deformation will depend upon a number of factors, including the relative difference in hardness and modulus between the coating and the substrate, adhesion, the coating thickness, the indenter radius of curvature (sharpness) and the maximum force.

To measure the coating hardness the coating must yield sufficiently before the substrate yields. The best conditions for this are when the maximum of the von Mises stress is inside the thickness of the coating and causes plastic deformation whilst the stress in the substrate below does not exceed the substrate yield stress. In a spherical contact, the maximum of the von Mises stress is approximately $0.47\times$ (mean pressure) at $0.5a$ below the surface.

Procedures for Determination of Machine Compliance and Indenter Area Function. The calibration procedures detailed below require the use of reference materials (see ISO 14577-3 [7.205]) which shall be isotropic and homogeneous. The Young's modulus and Poisson's ratio are assumed to be independent of the indentation depth. Some procedures need reference materials of known Young's modulus and Poisson's ratio.

Currently recommended materials are freshly polished tungsten and fused silica. The forces used should not exceed the threshold at which cracking occurs

($\approx 80\text{--}100\text{ mN}$ for an average radius Berkovich tip indenting fused silica).

Principle. The total measured compliance C_T is the sum of contact compliance C_s and the machine compliance C_f thus:

$$C_T = C_s + C_f, \quad (7.35)$$

where C_T is derived from the derivative of the (uncorrected) test force removal curve at maximum force

$$C_T = \left(\frac{dF}{dh} \right)^{-1} \quad (7.36)$$

and C_s is the contact compliance of the specimen material

$$C_s = \frac{\sqrt{\pi}}{2E_r} \cdot \frac{1}{\sqrt{A_P(h_c)}} \quad (7.37)$$

with

$$\frac{1}{E_r} = \frac{1 - \nu_s}{E_{IT}} + \frac{1 - \nu_i}{E_i} \quad (7.38)$$

and

$$h_c = h_{\max} - \varepsilon F_{\max} C_T, \quad (7.39)$$

where E_i and ν_i are, respectively, the Young's modulus and the Poisson number of the indenter.

Thus the total compliance is

$$C_T = C_f + \frac{\sqrt{\pi}}{2E_r} \frac{1}{\sqrt{A_P(h_c)}}. \quad (7.40)$$

If it can be assumed that the elastic modulus is constant and independent of indentation depth, a plot of C_T versus $A^{-1/2}$ is linear for a given material and the intercept

of the plot is a direct measure of the machine load-frame compliance. The best values of C_f are obtained when the second term on the right-hand side of (7.39) is small, i. e., for large indentations. In addition, the largest indentations are advantageous to find area function. A perfect modified Berkovich indenter, for instance

$$A(h_c) = 24.5h_c^2 \quad (7.41)$$

can be used to provide a first estimate of the contact area. Initial estimations of C_f and E_r are thus obtained by plotting C_T versus $A^{-1/2}$ for the two largest indentations in the reference block. Using these values, contact areas are computed for all, at least six, indentation sizes by rewriting (7.39) as

$$A_P = \frac{\pi}{4} \frac{1}{E_r^2} \frac{1}{(C - C_f)^2}, \quad (7.42)$$

from which an initial guess at the area function is made by fitting A_P versus h_c data to the relationship

$$A(h_c)_P = 24.5h_c^2 + C_1h_c^1 + C_2h_c^{1/2} + C_3h_c^{1/4} + \dots + C_8h_c^{1/128}, \quad (7.43)$$

where $C_1\text{--}C_8$ are constants. The lead term describes a perfect modified Berkovich indenter; the others describe deviations from the Berkovich geometry due to blunting of the tip.

The procedure is not complete at this stage because the exact form of the area function influences the values of C_f and E_r , so using the new area function the procedure shall be applied again and iterated several times until convergence is achieved.

7.4 Strength

The strength of materials is influenced by the strain rate, temperature, loading manner and chemical environment. The conventional test for the examination of the strength of materials is tension testing with a slow strain rate of around 10^{-3} s^{-1} at room temperature. Tensile properties obtained using this test are widely used in engineering practices such as mechanical design, fabrication and maintenance of products. In the case of brittle materials, compression or bending tests are frequently used to examine their strength. These tests are done under so-called quasistatic-loading conditions. Tests at very slow strain rates are performed to examine creep or stress-relaxation behavior. To consider automobile collision, earthquakes etc., strength at a high strain rate

such as 10^3 s^{-1} is required; impact or high-speed deformation testing, such as a Hopkinson pressure-bar test, is employed. Resistance to fracture under cyclic loading is called fatigue strength. Strength is also influenced by temperature as well as the environment accompanied by chemical reactions such as corrosion, or radiation damage. Fracture is frequently found to occur under combined conditions of stress, microstructural change and chemical reaction. In some cases, high-temperature strength or low-temperature toughness are of importance for engineering application of materials, so that the meaning of the strength of materials is not unique but depends on the conditions of their use.

7.4.1 Quasistatic Loading

Strength

According to their loading speed, tests are classified as quasistatic (or simply static) or dynamic. The most common quasistatic measurement of the strength of materials is tension testing. The strength of a material has three different meanings, which it is important not to confuse. First, when the applied load is small, deformation is reversible, that is, elastic deformation occurs. Stresses are proportional to elastic strains and the so-called Hooke's law holds. The slope between tensile stress and tensile elastic strain is called the Young's modulus, as was explain in Sect. 7.1. A material with high Young's modulus is strong, or rigid to elastic deformation. Secondly, when the applied stress becomes higher, materials usually show plastic deformation. The stress at the onset of plastic flow is called the *yield strength*, which has no direct relation with the Young's modulus. The yield strength indicates resistance against plastic flow. In the case of engineering materials, it is necessary to define how to determine the yield strength for mechanical design. Usually, 0.2% proof stress or lower yield strength is employed. Thirdly, materials show fracture under applied stress. Since there are many fracture mechanisms, the strength against fracture is different from the yield strength. Ductile materials show workhardening with plastic deformation and plastic instability, i. e., necking in the case of tension, resulting in dimple fracture. Frequently fracture occurs after a considerable amount of plastic flow, but fracture takes place with little or no plastic deformation. This is called *brittle fracture*, so that the resistance to brittle fracture is another aspect of strength. Fracture is also strongly dependent on the chemical environment.

Tension Test

This test is usually performed at room temperature with a strain rate of 10^{-4} – 10^{-1} s^{-1} . The testing procedure and the shape and dimensions of a tensile specimen should be taken from the ISO or other related standards, depending on the materials and products under consideration. The loading speed, or extending speed, should be controlled within the above strain-rate range using a gear-driven type or servo-hydrostatic-type tester. During testing, the applied load and displacement of a gage length of a tensile specimen should be recorded. Then, the load–displacement diagram can be obtained. The curve is converted to a nominal stress–strain curve and sometimes further to a true stress–strain curve. Typical tensile properties such as the yield strength,

tensile strength, uniform elongation, total elongation, workhardening exponent (n -value), r -value etc., can be obtained from the results of the tension test.

Stress–Strain Curves of Ductile Materials

An example of the standard tension specimens is shown in Fig. 7.37. Depending on the purpose, a strain gage or extensometer is attached to monitor the change in gage length (ΔL), while the load (F) is measured simultaneously with a load cell. Based on the initial area (A_0) and gage length (L_0), the nominal stress (σ) and nominal strain (ε) are obtained by the following equations:

$$\sigma = F/A_0, \quad (7.44)$$

$$\varepsilon = \Delta L/L_0. \quad (7.45)$$

Here, the units for F and ε are Pa ($= \text{N/m}^2$) and m/m (non-dimensional), respectively. In Fig. 7.38, two typical examples of nominal stress–strain curves are presented; one shows the case of discontinuous yielding (a) and the other shows continuous yielding (b). Most metals and alloys show the type of yielding shown in (b). However, annealed mild steels, which are widely used, show the type shown in (a). As can be seen, these curves are divided into three regions:

1. A linear elastic region at the beginning, where stress is proportional to strain and the deformation is reversible.
2. After the onset of plastic flow, the curve deviates from the elastic line. The flow stress increases with increasing strain, meaning that the material is

Fig. 7.37 Tension specimen and macroscopic tensile deformation behavior

Fig. 7.38a,b Nominal stress–strain curves: (a) discontinuous yielding and (b) continuous yielding

strengthened by plastic deformation; this is called workhardening. When unloaded, only the elastic strain is recovered but a permanent deformation, i. e., plastic strain, remains. In this region, uniform plastic deformation occurs. For plastic strains, the condition of *constant volume* is often assumed. Figure 7.37b [7.206].

3. After reaching the maximum stress, which is called the *ultimate tensile strength* (UTS) or simply the

tensile strength (TS), a lower stress is enough to continue to deform the material plastically because necking occurs (Fig. 7.37c). After the onset of necking, deformation is localized to a necked region in which the stress condition is no longer uniaxial but is triaxial. Microvoids form inside the necked region, grow, connect to each other and lead to slip-off of the remaining, outside ring region. Thus, the view after fracture looks like a cup and a cone and hence is called *cup-and-cone fracture*. This phenomenon is typical of ductile fracture. The inner, flat area consists of dimples; the dimple pattern observed on the fracture surface is shown in Fig. 7.39a.

4. When a material is brittle, as is the case for ceramics, necking is not observed and the flow curve stops suddenly at the fracture stress, often within the elastic regime. In such a case, the fracture surface consists of cleavage or transgranular facets. Examples of these fracture surface are presented in Figs. 7.39b and 7.39c,

True Stress–Strain Curves and the Workhardening Exponent (n -Value)

Within the uniformly elongated regime in Fig. 7.38, the assumption of constant volume for plastic strains holds approximately. This means that the cross section in the gage volume in Fig. 7.37 decreases with increasing tensile strain. Hence, the area (A) to support the applied stress decreases with deformation so that the stress per unit area is given by

$$\sigma^* = F/A \quad (7.46)$$

instead of (7.44); σ^* is called the *true stress*. Similarly to σ^* , the gage length l_0 changes continuously with deformation. Then, the *true strain* (ϵ^*) is defined by

$$\epsilon^* = \int_{l_0}^l dl/l = \ln(l/l_0). \quad (7.47)$$

Fig. 7.39a–c Fracture surface: (a) dimple, (b) cleavage and (c) intergranular fracture

Fig. 7.40 Stress condition in a necked region in tension test

One of the merits of using ε^* is its additive nature. For instance, when a length changes from L_A to L_B , and then to L_C , the true strain from L_A to L_B is $\ln(L_B/L_A)$ and from L_B to L_C is $\ln(L_C/L_B)$. Therefore, $\ln(L_B/L_A) + \ln(L_C/L_B) = \ln(L_C/L_A)$ holds. In contrast, in the case of nominal strain, we have $(L_B - L_A)/L_A + (L_C - L_B)/L_B \neq (L_C - L_A)/L_A$, and hence this property is not additive. Taking the assumption of constant volume ($A_0 L_0 = AL$) we obtain the following conversion from nominal stress and strain to true stress and strain. Thus, we find the relation for true stress versus true strain starting from Fig. 7.38 by using

$$\sigma^* = F/A_0 = \sigma(1 + \varepsilon), \quad (7.48)$$

$$\varepsilon^* = \ln(L/L_0) = \ln(1 + \varepsilon). \quad (7.49)$$

After the onset of necking, the specimen geometry changes and the stress condition is also altered. As shown in Fig. 7.37c and Fig. 7.40, the stress condition in a necked region is not uniform but is a complicated triaxial stress condition. According to *Bridgman's* analysis [7.207], the tensile stress at the surface of the smallest cross section, σ_0 (Fig. 7.40), is given by

$$\sigma_0 = \frac{F/A}{(1 + 2R/a) \ln(1 + a/2R)}, \quad (7.50)$$

where R and a are given in Fig. 7.40. Microvoids form in the center of the necked region under triaxial stresses, as explained above, leading to cup-and-cone fracture.

An example of curves of true stress versus true strain converted from the nominal stress-strain curve by using (7.49) and (7.50) is shown in Fig. 7.41. This shows

Fig. 7.41 True stress-strain curve in which the workhardening rate is plotted to indicate the onset of necking

that workhardening continues even in local deformation; the necking is caused from the balance between cross-sectional area reduction and workhardening with increasing tensile plastic strain. Hence, the crossing point of the true stress σ^* and the workhardening rate $d\sigma^*/d\varepsilon^*$ shows the onset of necking (Fig. 7.41).

Tensile Properties

Tension testing is simple and gives us lots of useful information on mechanical properties. So, this test is the most basic and popular to understand the mechanical behavior of materials. Several parameters for engineering use obtained by tension testing are explained below.

Elastic Limit and Proportional Limit

Most mechanical products are designed to be used within the regime of elastic deformation. The rigorous limit of elastic deformation is determined by the elastic limit or proportional limit on the stress-strain curve. The proportional limit is the point of deviation from the linear relationship between stress and strain. On the other hand, the elastic limit is found as the maximum stress without permanent strain after unloading. These stresses are very sensitive to the method used to measure strain. Within the linear stress-strain regime, as was explained in details in Sect. 7.1, the Young's modulus (E) is determined from the slope, while the Poisson's ratio (ν) is determined by the absolute ratio between the transverse strain and tensile strain. When the tensile direction is taken as the x_3 -axis, these are determined by

$$E = \sigma_{33}/\varepsilon_{33}, \quad (7.51)$$

$$\nu = |\varepsilon_{11}/\varepsilon_{33}| = |\varepsilon_{22}/\varepsilon_{33}|. \quad (7.52)$$

In the case of steel, E is nearly 200 GPa and ν is approximately 0.3. The elastic strain in steels is usually less than 1%, which is very small compared with the uniform elongation of the order of 10%. We note here that the constant-volume assumption is not applicable to elastic deformation.

Yield Strength

Special measurements such as those based on strain gages are required for the measurement of elastic strains less than 0.01 so that the yield strength (YS) is determined for mechanical design using the conventional tensile test. In the case of discontinuous yielding observed in mild steel, as shown in Fig. 7.38a, the upper or lower yield point is observed on the stress–strain curve and used as the yield strength in engineering. After the upper yield point, a plastic-deformation regime called the *Luders band* appears and spreads within the specimen gage volume under the lower yield stress. Since the upper yield strength is strongly dependent on the tensile speed, i. e., the strain rate, the lower yield strength is more popularly used. The strain during this heterogeneous deformation is called the Luders elongation, which is also dependent on grain size.

On the other hand, Fig. 7.38b shows the case of continuous yielding, which is observed in many metals and alloys such as aluminum, austenitic stainless steel etc. 0.2% proof stress is usually employed, which means a plastic (permanent) strain of 0.2% remains after unloading. Usually the elastic linear line is shifted by 0.2% and the intersection with the stress–strain curve is found. Macroscopic yielding can be observed to take place at this point. Although 0.2% strain is the choice for engineering, other strains, for instance 0.1%, are employed in other industrial fields.

Tensile Strength

The maximum stress appearing in Fig. 7.38 is determined by the tensile strength (TS), frequently called the ultimate tensile strength (UTS). In the case of an extreme design that allows plastic flow, TS is employed as the design strength.

Ductility

Parameters to describe the ductility includes uniform elongation, total elongation and reduction in area after fracture. Uniform elongation is important for plastic forming etc. and is determined as the strain at the tensile strength. After the tensile strength, local deformation, i. e. necking, starts. The total strain is given as the strain to fracture in Fig. 7.41. It should be noted that

the total elongation is dependent on the gage length adopted. Therefore, fracture strain (ϵ_f) is sometimes used, which is defined as $\ln(A_0/A_f)$, where A_f refers to the smallest area in the necked region after fracture. Conventionally, the reduction in area (φ) defined by $[(A_0 - A_f)/A_0] \times 100\%$ is used. The extreme case observed in a pure metal is a point fracture, where $A_f = 0$.

Workhardening Exponent (n -Value)

The true stress–strain curve shown in Fig. 7.41 is often fitted by using the following Hollomon's equation:

$$\sigma^* = K(\epsilon^*)^n, \quad (7.53)$$

where K and n stand for the strengthening factor and the workhardening exponent (n -value), respectively. By taking two measuring points or by using the least-squares method for $\ln \sigma^*$ versus $\ln \epsilon^*$ within an appropriate strain regime, these K and n values are determined. The n -value is important because it is equivalent with uniform elongation. The plastic instability condition, i. e., the onset of necking can be given by

$$dF = \sigma^* dA + A d\sigma^* = 0, \quad (7.54)$$

where F is the applied tensile load. This equation is rewritten by $\sigma^* = d\sigma^*/d\epsilon^*$ under the assumption of constant volume and therefore $\epsilon^* = n$ is obtained. A large n -value means excellent plastic formability.

Rankford Value (Plastic Anisotropy: r -Value)

Another parameter that indicates the plastic formability, and which is also obtained by the tension test for sheet metals and alloys, is the r -value. When tensile strain reaches 10–20%, the strain for a thickness of ϵ_t and the strain for a width of ϵ_w are measured and the r -value is determined by

$$r = \epsilon_w / \epsilon_t. \quad (7.55)$$

If the assumption of constant volume is used, this becomes

$$r = \ln(W_0/W) / \ln(LW/L_0W_0), \quad (7.56)$$

where W_0 , L_0 and W , L refer to the width and gage length in the tensile direction before and after the tension test, respectively. These values are much more easily measured precisely than the thickness because most cases use thin sheets. In an isotropic material, the r -value equals unity. Commercially available materials generally show anisotropic feature in plastic flow because of their texture. Materials with high r -values are desirable

for heavy drawing because the thickness change is small. To achieve this, texture control is important.

The Compression Test

The compression test looks like the reverse of the tension test, but more skill is required to obtain reliable stress-strain curves. A schematic illustration of compression of a round column is presented in Fig. 7.42, where the top and bottom surfaces of the specimen should be maintained with good parallelism. Friction between the specimen and the anvil must be minimized using an appropriate lubricant such as graphite or MoS_2 powder otherwise bulging, shown in Fig. 7.42b, becomes serious and leads to constrained deformation. If the compression alignment is not satisfactory with respect to the specimen axis, buckling or bending occurs easily at small strains. To avoid such buckling, the length of the specimen should be designed taking the cross-sectional

Fig. 7.42 Compression test where bulging is illustrated

Fig. 7.43 Compression flow curve compared with that in tension

area into consideration. Usually, the ratio of the diameter of the cross-sectional area d_0 to the length h_0 is chosen as 1.0–3.0. When the top and bottom of a specimen are plastically constrained by an anvil, the stress distribution within the cross section is not uniform and plastic deformation occurs in an inhomogeneous manner within the specimen.

The nominal stress-strain curve obtained by the compression test is higher than that obtained by the tension test because the cross-sectional area increases with deformation. Hence, flow curves measured by the tension test and the compression test should be compared in terms of true stress-strain curves. If a material shows isotropic plastic deformation, these two flow curves (the true stress-strain curves) coincide, as shown in Fig. 7.43. However, if a material contains phase or intergranular residual stress, so-called second-type residual stresses, the yield strength will differ between compression and tension, which is called the *strength difference* (SD) effect. The SD effect is also caused by crystallographic features in plastic flow or stress-induced martensitic transformations.

In general, the flow stress (true stress) in compression after some amount of tensile plastic deformation is smaller than that for continuous tension, as shown in Fig. 7.44. This is called the Bauschinger effect (BE). As seen in Fig. 7.44, the magnitude of the BE is often expressed by the BE stress or BE strain (Fig. 7.44). Generally speaking, the flow stress becomes smaller when the strain path changes, even under biaxial or triaxial stresses. In a stress space (the general stress condition is described by six components, as will be described later), the yield condition is shown using the yielding

Fig. 7.44 Tension-compression test to examine the Bauschinger effect (BE) in which the parameters of BE stress ($\sigma_P - \sigma_R$) and BE strain $\beta_{0.5}$ are defined

surface. When a material is plastically deformed and thus workhardened, the yielding stress surface expands and moves in the stress space. Hence, the yield strength after plastic deformation depends on the loading conditions. Typical cases are: (1) isotropic hardening, where the yield surface expands homogeneously, and (2) kinematic hardening, where the surface moves without changing its shape and size. The BE is important in order to understand plastic forming, which is used to make mechanical parts. In addition, the BE behavior is closely related to low-cycle fatigue behavior. In the case of brittle materials such as concrete, in which the SD effect for fracture is remarkable, the compressive fracture strength is much higher than the tensile value.

Hardness Test and Strength/Hardness Relations

In addition to the treatment of hardness measurements methods given in Sect. 7.3, relations between strength and hardness are briefly considered. The most popular measurement is a kind of compression test with an indenter. The indenter is made from a hard material such as diamond or high-carbon martensite steel. As explained above and shown again in Fig. 7.45 an indenter is pressed on the surface of a testing material, and the indentation after unloading is measured. Since the Vickers hardness test employs a pyramidal diamond indenter, the applied stress is almost proportional to the area, which means that the Vickers hardness number is insensitive to the applied load. As is estimated in Fig. 7.45, the deformation zone is limited to just underneath of the indenter and is complicated. According to an elasto-plastic analysis, the representative plastic strain in the plastic zone is about 8%, so that the hardness number

Fig. 7.45 Hardness tests by indenting deformation

should correspond to 8% flow stress in the simple tension or compression test [7.208,209]. Figure 7.46 shows the relationship between the hardness and tensile properties, the yield strength or tensile strength (8% proof stress is usually not recorded). Excellent correspondence is found between the yield or tensile strength and hardness. The experimental relationship of (7.57) is used to connect the Vickers hardness number (HV) to the yield or tensile strength (Y)

$$HV = cY, \quad (7.57)$$

where the coefficient c is 2.9–3.0. Therefore, the hardness test is a convenient way to check the strength of materials, particularly for engineering products.

Supplementing the discussion of nanohardness measurements given in Sect. 7.3.4, strengthening mechanisms will be considered briefly. In most cases, the

Fig. 7.46 Relationship between hardness and tensile properties

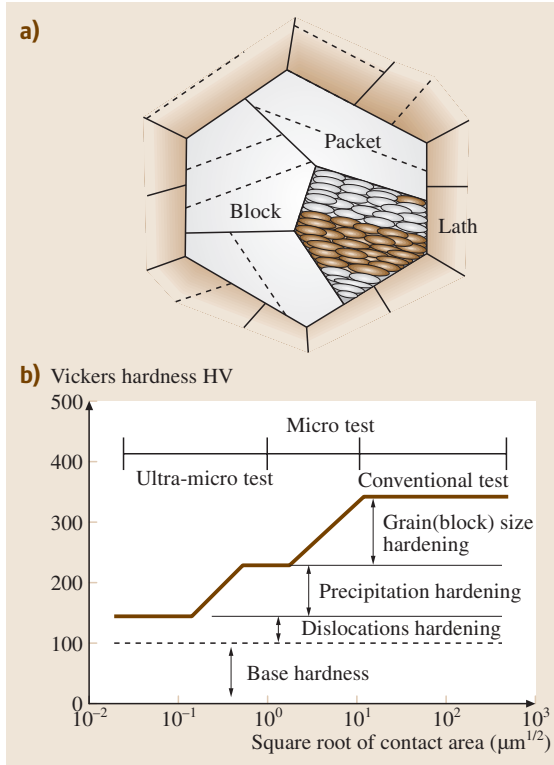

Fig. 7.47 Hardness with various loads to examine the strengthening mechanism in a tempered martensite steel

shape of a diamond indenter is triangle pyramid because the tip of square pyramid is difficult to make precisely. The test is performed under very small loads, such as a few grams, and is widely used for thin-film or electronics devices. One of the recent application [7.210] is summarized in Fig. 7.47, where the hardness was measured using a wide range of applied loads for

a tempered martensite steel. Because an engineering material shows multiscale heterogeneous microstructure that brings the multiscale heterogeneous plastic deformation. For example, the tempered martensite is composed of laths, blocks and packets as shown in Fig. 7.47a and hence the strengthening mechanisms due to grain refinement, dislocation density, carbon solid solution and carbide precipitation overlap. By examining the hardness with various loads, using three kinds of hardness testers, the contribution of individual strengthening mechanism can be found separately, as illustrated in Fig. 7.47b.

The Bending Test

Schematic illustration of the bending test is presented in Fig. 7.48. This test is frequently used to measure the strength of brittle materials or the bending formability of ductile materials. As shown in Fig. 7.48, two kinds of tests, three- and four-point bending are used. three-point bending is easy to carry out. However, four-point bending is preferable because the bending moment M is then constant in the central part of the specimen. When a rectangular specimen is bent, as shown in Fig. 7.48a, strain and stress distribution occurs in the cross section, where the upper surface is in compression and the lower surface is under tension. There exists a neutral stress-free plane, which is denoted by the x -axis. If the curvature is expressed by ρ , the normal strain under elastic deformation is given by

$$\varepsilon = y/\rho. \quad (7.58)$$

The normal stress is proportional to the strain, and hence we obtain the maximum stress by

$$\sigma = 6M/(bh^2), \quad (7.59)$$

where b and h refer to the width and thickness of the specimen, respectively. The stress distribution is shown in Fig. 7.48b.

After yielding at $M = \sigma_s bh^2/6$, the stress distribution changes from Fig. 7.48b–c, where σ_s stands for the yield strength. When M is further increased, the boundary between the elastic region and the elasto-plastic region moves towards the neutral plane. The stress or strain distribution in the plastic region is dependent on the workhardening of a material. A schematic illustration is given in Fig. 7.48c. When the applied moment is removed, the residual stress distribution remains: tensile stress at the upper surface and compression at the bottom surface.

Fig. 7.48a–c Bending test: (a) deformation aspect, (b) stress distribution in elastic deformation and (c) that in elasto-plastic deformation

The Torsion Test

Shear deformation is related to the combination of bi-axial deformation of tension and compression. This conversion is achieved by rotating the coordinate system by 45° . In particular, the torsion test is used for wires and bars. Figure 7.49 shows a schematic illustration of torsion (a) and the shear stress distribution (b) in the cross section of a round bar with radius r . The engineering shear strain γ is related to the shearing angle θ and the bar length L by

$$\gamma = r\theta/L. \quad (7.60)$$

Considering the stress equilibrium, the torsion moment (for torque T) is given by

$$\tau = 16T/\pi d^3, \quad (7.61)$$

where d refers to the diameter of the round bar specimen. Similarly to the bending test depicted in Fig. 7.48, the stress distribution changes after yielding, as represented in Fig. 7.49c. Fracture usually takes place perpendicularly to the specimen axis. In some cases, fracture along the longitudinal direction occurs, which is called delamination. Delamination fracture has to be avoided for practical application of wires.

Yielding Criteria under Multiaxial Stresses

Tension and compression tests are performed with uni-axial loading. The general stress condition is a triaxial stress, which is described by six components:

$$\begin{pmatrix} \sigma_{11} & \tau_{12} & \tau_{31} \\ \tau_{12} & \sigma_{22} & \tau_{23} \\ \tau_{31} & \tau_{23} & \sigma_{33} \end{pmatrix}.$$

When a special coordinate related to the principal stresses, $\sigma_i(\sigma_1, \sigma_2, \sigma_3)$ is employed, the shear stress components all become zero. For instance, in the case of the tension test along the tensile direction of the x_3 -axis, the six stress components or three principal stresses are written as

$$\begin{aligned} \sigma_{33} = \sigma_3, \quad \sigma_{11} = \sigma_1 = 0, \quad \sigma_{22} = \sigma_2 = 0, \\ \tau_{23} = \tau_{31} = \tau_{12} = 0. \end{aligned} \quad (7.62)$$

The yield strength σ_s is determined by σ_{33} at 0.2% plastic strain, or the Luders deformation. In the case of the general stress condition, the stresses are converted to principal stresses by changing the coordinate system. For example, in the torsion test, $\tau = 16T/\pi d^3$ and the other stresses are zero at the surface of a bar specimen from (7.61). Rotating the coordinate by 45° gives

Fig. 7.49a–c Torsion test: (a) deformation aspect, (b) stress distribution in elastic deformation and (c) that in elasto–plastic deformation

$\sigma_1 = -\sigma_2 = 16T/\pi d^3$ and the other stress components are zero.

Two of the most popular criteria for yielding under general stress conditions are the Tresca and von Mises criteria. The Tresca criterion is based on the maximum shear stress theory. When $\sigma_3 > \sigma_2 > \sigma_1$, the maximum shear stress is given by $|\sigma_3 - \sigma_1|$. Therefore, the yielding criterion is written by

$$|\sigma_3 - \sigma_1| = 2k, \quad (7.63)$$

where k is a constant and is given by $\sigma_s/2$ for the tension test.

On the other hand, the von Mises criterion is based on the theory of shear strain energy. The shear strain energy per unit volume is given by

$$\frac{1+\nu}{6E} [(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2].$$

Using the results of the tension test, the criterion can be written as

$$[(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2] = 2\sigma_s^2. \quad (7.64)$$

In general, yielding is found to occur at a stress condition between these two criteria. Hence, the general stress condition is projected to the case of the tension test and the equivalent stress is then determined. For instance, in the case of the von Mises criterion, the equivalent stress σ_{eq} is given by

$$\sigma_{eq} = [(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2]^{1/2}$$

or more generally,

$$\begin{aligned} \sigma_{eq} = [(\sigma_{11} - \sigma_{22})^2 + (\sigma_{22} - \sigma_{33})^2 + (\sigma_{33} - \sigma_{11})^2 \\ + 6(\sigma_{23}^2 + \sigma_{31}^2 + \sigma_{12}^2)]^{1/2} \end{aligned} \quad (7.65)$$

Another interpretation of the von Mises criterion is the maximum shear stress acting on the pyramidal plane in the principal stress space.

Fig. 7.50 Yielding under combined tension and torsion stresses

A schematic illustration of the yielding surface under combined torsion and tension loads [7.211, 212] is shown in Fig. 7.50. Such a yielding condition under general stress conditions is given by the yielding surface in the stress space (six-dimensional or principal stress space (three dimension)), which changes with plastic deformation. This is called workhardening, which includes isotropic hardening and kinematic hardening. The Baushinger effect in Fig. 7.44 is an example of kinematic workhardening, as already mentioned.

The Creep Test

Plastic deformation and fracture usually show time dependence. When an external load is kept constant, a specimen deforms plastically gradually, which is called creep deformation. This is clearly observed at high temperatures ($T > 0.3T_m$), where T_m denotes the melting temperature of a material. In general, creep deformation at constant temperature is divided into three stages in the creep curve, as shown in Fig. 7.51.

Here, after the initial strain that occurs during loading to a certain fixed stress, plastic strain initially increases gradually, which is called *transient creep*. The rate of increase of the strain in transient creep saturates to a constant rate in the second regime. This is called *steady creep*. The third regime, called *tertiary* or *accelerated creep*, leads to the rupture of the specimen. This effect is important, but it is not clear why and when this acceleration from steady to tertiary creep takes place. When the external load is small, tertiary

Fig. 7.51 General creep deformation behavior under constant load and temperature

creep is not observed and hence the specimen does not fracture.

The experimental methods to examine creep behavior include the constant-stress creep test, the torsion creep test, the tension-torsion combined test, cyclic loading creep, and the creep crack-propagation test. A tester with an electric furnace and a lever-type loading system for a round bar specimen is popular. In general, creep rupture requires a long time, so that many testers are used simultaneously. A dial gage or differential transducer with a high sensitivity is also required for strain measurement. When the experimental data obtained at various temperatures are summarized by employing the following Larson–Miller parameter,

$$\lambda = T(20 + \log t_r) \times 10^{-3}, \quad (7.66)$$

where t_r stands for the rupture time, the experimental data for applied stress (σ) versus t_r are well summarized by a σ – λ master curve. The master curve is influenced by strengthening mechanisms such as solid solution hardening, grain refinement, precipitation, etc. The speed of crack growth is evaluated from the viewpoint of fracture mechanics as will be explained in Sect. 7.4.

Stress Relaxation

Plastic deformation shows time dependence, as explained for creep where the external stress is kept constant. On the other hand, when a specimen is pulled to induce plastic flow and then kept at a constant total strain, plastic flow occurs with holding time and hence stress (elastic strain) decreases, which is called stress relaxation. To measure relaxation behavior, a high-sensitivity strain detector is necessary because the change in the elastic strain is very small. In other words, this is a ten-

sile test with extremely low strain rates, and the strain rate decreases continuously while the stress is held.

7.4.2 Dynamic Loading

Dynamic means that the loading or deformation speed is high compared with the quasistatic case. Several kinds of dynamic loading are found. These include high-speed tension or compression tests such as the Hopkinson pressure-bar method, impact tests, and fatigue tests. These three tests are explained below.

High-Speed Tension or Compression Tests

These testing methods include the split pressure-bar tester, the one-bar method, the load-sensing block-type tester, and the servo-hydrostatic loading machine. The most popular method is the Hopkinson split-bar method in which either tension or compression impact deformation can be carried out. The outline of the test is shown in Fig. 7.52, where the input bar and the output bar are pictured. A specimen is set between them. To avoid the reflected stress pulse, the specimen gage length should be sufficiently short. Examples of flow curves obtained at a strain rate of $2 \times 10^3 \text{ s}^{-1}$ are presented in Fig. 7.53 [7.213, 214]. As seen, the flow stress becomes higher at a high speed, similarly to the case of lowering test temperature. Very-high-speed deformation occurs almost under adiabatic conditions, so that the temperature of a specimen increases with plastic deformation. Hence workhardening decreases in a low carbon steel with a large temperature dependence of flow stress.

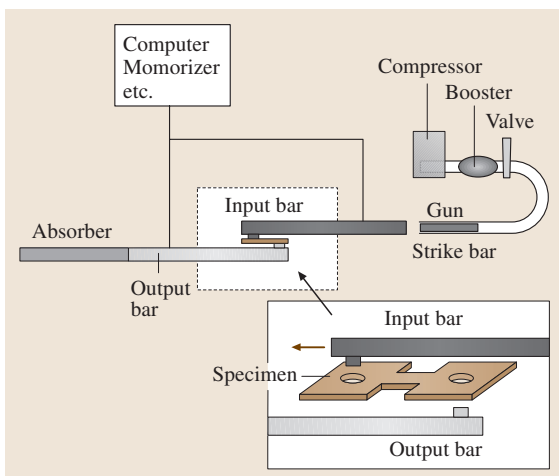

Fig. 7.52 Schematic illustration of a high-speed tension test using the Hopkinson split-bar method

Fig. 7.53a,b Flow curves observed under high-speed deformation (the Hopkinson split-bar tension test): (a) low-carbon steel and (b) austenitic steel

Such workhardening behavior is the difference between the deformation at lower temperature with a low strain rate and that at room temperature with a high strain rate. These data are useful for the safety design of automobiles with respect to traffic collisions or the safety of infrastructures such as buildings with respect to the occurrence of earthquakes.

The dislocation structure that evolves during plastic deformation is strongly dependent on the test temperature and strain rate. As shown in Fig. 7.54 [7.213] for the case of a low-carbon steel, the dislocation cell structure evolves at room temperature under a low-strain-rate deformation. However, planar dislocation arrays are observed either during low-temperature deformation with a low strain rate or at room temperature with a high strain rate.

Impact Test

Impact testing is performed to evaluate the toughness of materials. There are several loading methods, including tension, compression, bending, and torsion. The typical test is the Charpy impact test in which three-point bending is employed. As shown in Fig. 7.55, a hammer is dropped to hit a rectangular specimen. A V- or U-type notch is introduced to allow easy fracture due to stress concentration for ductile materials. In the case of brittle materials such as ceramics, cast iron etc., a notch is not introduced. Parts of the hammer before and after hitting (breaking) a specimen are compared. The balance is considered to show the resistance to fracture, and the energy needed to bend and fracture the specimen. The impact tester can impart 300 J for metallic mater-

Fig. 7.54a–c Dislocation structures evolved by tensile deformation (10%) in ferritic steels: (a) 77 K, $3.3 \times 10^{-3} \text{ s}^{-1}$, (b) 295 K, $2 \times 10^3 \text{ s}^{-1}$ and (c) 295 K, $3.3 \times 10^{-3} \text{ s}^{-1}$

Fig. 7.55 Outline of impact testing: Charpy and Izot tests

Fig. 7.56 Ductile-to-brittle transition behavior observed by the Charpy impact test

ials use, and 3 J for resin or plastics. The Izot tester is another typical device but is now rarely used. The specimen is held in a different way, as shown in Fig. 7.55. The absorbed energy K is calculated from the angle of the hammer and the starting (α) and maximum (β) height

after hitting,

$$K = WR(\cos \beta - \cos \alpha), \quad (7.67)$$

where W and R refer to the weight and the arm length, respectively.

Some materials fracture in a ductile manner under quasistatic testing but fracture in a brittle manner under impact testing. As the fracture mode is strongly dependent on the testing temperature, the Charpy impact test is carried out at a variable test temperature. The absorbed energy is then plotted as a function of the test temperature, as presented in Fig. 7.56 [7.208]. In the case of ferrite steel, for example, the energy changes at a certain temperature, known as the *ductile-to-brittle transition temperature* (DBTT). At higher temperatures, specimens fracture in a ductile mode so that the fracture surface exhibits a dimple pattern. However, intergranular or cleavage (transgranular) fracture facets are observed in specimens fractured at lower temperatures. The DBTT is determined either from the absorbed energy or the percentage of dimple facet on the fracture surface. The results of impact tests are often used for material selection. It is difficult to use the results quantitatively for machine design, e.g., for the determination of design stress. On the other hand, the quantitative resistance to fracture is determined by other tests using pre-cracked specimens based on fracture mechanics (see Sect. 7.4 for details).

Fatigue

Several fatigue testing methods have been utilized to date.

Rotating (four-point) bending has been used to simulate a wheel axis, where a tension–compression stress wave is repeated on the surface. The results are summarized in a diagram of stress amplitude versus number of cycles to fracture ($S-N$). As shown in Fig. 7.57, the applied stress amplitude is plotted as a function of the

Fig. 7.57 Stress amplitude versus number of cycles to failure ($S-N$) curve for fatigue fracture

Fig. 7.58 Fatigue endurance-limit diagram where the influence of mean stress is given

number of cycles to failure [7.215]. As can be seen, the relationship is almost linear in the beginning and tends to saturate at a certain stress level near 10^6 – 10^7 cycles. In general, the stress at 10^7 cycles is called the fatigue strength or endurance limit σ_w . At stresses higher than σ_w , the number determines the time to fracture and is called fatigue life. Thus, the fatigue strength and fatigue life are utilized for the design of machines or structures.

Recent studies on very-long-life fatigue reveal that some materials fracture even at stresses below σ_w . In the case of aged materials, this should also be taken into consideration.

The influence of the mean stress on the fatigue stress (stress amplitude) is discussed using the fatigue-limit diagram shown in Fig. 7.58 where the stress amplitude at 10^7 cycles is plotted as a function of the mean applied stress. The diagram is constructed with consideration of the yield strength σ_s , tensile strength σ_B , and the

Fig. 7.59 Schematic illustration on fatigue fracture; crack initiation, growth and final fracture

true fracture strength, σ_f , obtained by tension testing that corresponds to a quarter cycle of the fatigue test. A hatched area is evaluated to be safe for both fatigue fractures and macroscopic yielding (failure of elasticity).

The mechanism for fatigue fracture is illustrated schematically in Fig. 7.59. In the usual case, a fatigue crack is initiated on the surface or a stress-concentrated region such as a flaw, brittle inclusions etc. If a material is nearly free from such defects, slip deformation occurs preferentially near the surface. Because of cyclic loading of small stress below the yield strength, slip occurs locally and repeatedly, resulting in intrusion and extrusion at the surface. Since the intrusion is a kind of micro-crack at which stress is concentrated (the first stage of fatigue cracking), plastic flow occurs locally at the tip of the micro-crack. The growth direction along the maximum shear stress then changes to be perpendicular to the applied tensile stress. This crack-propagating regime is called stage 2. When the crack length has increased enough to satisfy the final fracture condition given by the fracture mechanics approach (a detailed explanation of which is given in Sect. 7.4):

$$K_{\max} \geq K_{\text{th}}^F, \quad (7.68)$$

then final fracture takes place. Here, the left-hand side of (7.68) is the maximum stress-intensity factor $K_{\max}(= \alpha \sigma_{\max} \sqrt{\pi c})$, where α , σ_{\max} , and c refer to a constant related to the specimen's geometry, the maximum stress applied to the specimen and the crack length, respectively, and K_{th}^F is the fracture toughness against fatigue.

The crack growth speed during stage 2 is measured using a prepared specimen in which a sharp pre-notch is introduced. With repeated application of the stress, the length of the crack is measured and the growth rate is then plotted as a function of the amplitude of the stress-intensity factor $\Delta K(= \Delta \sigma \sqrt{\pi c})$, as shown

Fig. 7.60 Fatigue crack growth rate as a function of stress-intensity amplitude

in Fig. 7.60. The growth rate in the low- ΔK region can be measured by decreasing $\Delta\sigma$ continuously. Here, the engineering lower limit for crack growth is determined as the threshold intensity factor, ΔK_{th} , which is sensitive to microstructural parameters. In the middle of the curve, it is approximated by a linear relationship described by Paris's equation [7.216,217]:

$$dc/dN = C\Delta K^m, \quad (7.69)$$

where C and m are constants. The crack growth rate during this stage 2 is insensitive to microstructure.

If the initial crack length c_i in a material is known, for example, by using nondestructive inspection such as X-ray transmission, the fatigue life N_f of the material can be predicted by combining (7.68) and (7.69). That is, by integrating (7.68), we obtain,

$$N_f = \int_{c_i}^{c_f} \frac{dc}{C(\alpha\Delta\sigma\sqrt{\pi c})^m}, \quad (7.70)$$

where c_f can be calculated by (7.68). In ductile materials, the fracture surface during stage 2 consists of striation, which is caused by repeated loading. Hence, the crack growth speed is estimated from fractography.

7.4.3 Temperature and Strain-Rate Effects

Flow stress is influenced by the test temperature mainly due to thermal activation mechanisms for dislocation motion. The thermal vibration of atoms leads to the vibration of the dislocation line. Therefore, the possibility per second of achieving a certain thermal activation energy is proportional to the Boltzmann probability. This means that the influence of temperature and strain rate on strength should be understood simultaneously; to achieve this, the *deformation mechanism map* has been constructed for various materials [7.218]. As an example, the deformation map for iron is presented in Fig. 7.61. Because iron shows ferrite-to-austenite and then austenite-to-ferrite transformations when heated,

Fig. 7.61 Deformation map for iron ($d = 0.1$ mm)

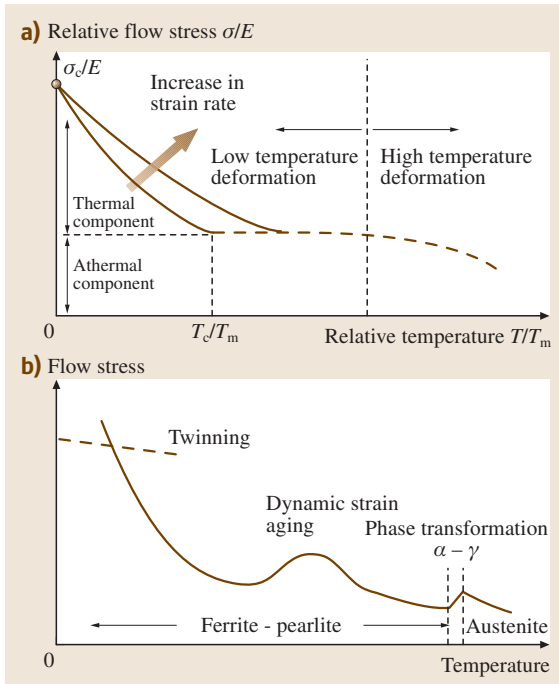

Fig. 7.62a,b Effect of temperature on the yield strength (schematic illustration): (a) general case and (b) mild steel

the curves for body-centered cubic (BCC, ferrite) is interrupted by a face-centered cubic (FCC, austenite) regime. Depending on the temperature and strain rate, various deformation mechanisms become dominant. Taking a look at the map near room temperature with a strain rate of $10^0 - 10^{-5} \text{ s}^{-1}$, the dominant mechanism is slip, i.e. dislocation motion. A simpler illustration to explain the effect of temperature on the yield strength is given in Fig. 7.62. At 0 K, the enhancement by thermal activation disappears and the strength corresponds to the theoretical strength. At a certain temperature, the strength is decreased through due to thermal activation of dislocation motion. At higher temperatures near $T_m/2$, all the short-range barriers for dislocation motion can be overcome, but some long-range barriers remain. The stresses related to overcoming these two kinds of barriers are called thermal stress (or effective stress) and athermal stress (internal stress), respectively. Thus, as shown in Fig. 7.62a, thermal stress becomes zero at T_0 . Below T_0 the temperature dependence of the yield strength is ascribed to thermal activation mechanisms for dislocation motion. Therefore, if the strain rate is increased, its effect is equivalent to decreasing temperature. The influence of strain rate on the yield

strength is also drawn schematically in Fig. 7.62a. Flow stress can also be discussed using this approach, although the evolution of the dislocation structure must also be taken into account. With increasing of plastic strain, the dislocation density (ρ) increases by ρ^+ and then workhardening occurs. At the same time, dislocations are annihilated with recovery to be decreased by ρ^- , which is influenced by temperature. Therefore, the total dislocation density ($\rho^+ + \rho^-$) is determined as a function of the strain as well as temperature and time, i.e., strain rate. The flow curve obtained at high strain rate is therefore influenced by two thermal activation mechanisms: dislocation motion and dynamic recovery.

When the test temperature is higher than T_0 , the microstructure itself changes obviously during deformation, for example exhibiting to grain growth, dynamic recovery and/or recrystallization. Such a region, as shown in Fig. 7.62a, is called high-temperature deformation. As observed in Fig. 7.61, creep deformation occurs strongly at high temperatures with small strain rates.

The behavior of a real material is complicated in comparison with that of the pure metal in Fig. 7.62a. The example of mild steel is presented in Fig. 7.62b [7.219]. The curve in the lower-temperature region corresponds to the deformation of the BCC ferrite phase, while that in the higher-temperature region corresponds to FCC austenite. Moreover, due to the intrusion of deformation twinning at cryogenic temperatures and dynamic strain aging caused by solute carbon and nitrogen atoms in the region slightly above room temperature, the typical behavior explained in Fig. 7.62a is not easy to discern.

7.4.4 Strengthening Mechanisms for Crystalline Materials

As described above, flow stress is controlled by the motion of dislocations. Hence, there are two ways to strengthen a material: remove dislocations thoroughly or introduce a large number of obstacles to prevent dislocation motion. The former approach has been achieved in the form of single-crystal whiskers. When the diameter of the whisker increases, the strength decreased rapidly due to the inevitable introduction of defects including dislocations. The latter approach has been used widely, including solid-solution hardening, precipitation hardening or dispersion particles hardening, workhardening, grain-refinement hardening and the duplex structure (composite) hardening. These mechanisms to prevent dislocation motion are described below.

Solid-Solution Hardening

The interstitial or substitutional solute atoms hinder the motion of dislocations due to the size effect and/or the effect of an inhomogeneous elastic modulus. These are elastic interactions and hence can be overcome by thermal activation for dislocation motion. The amount of hardening is given by:

$$\Delta\sigma = Ac^n, \quad (7.71)$$

where A and c refer to a material constant and the concentration of solute atoms, respectively. The constant n is about 0.5–1.0 from experimental or theoretical considerations.

Workhardening

As explained in the previous sections, the dislocation density is increased by plastic deformation and mobile dislocations have to pass through the resulting dislocation structure. There are two types of dislocation–dislocation interactions: short-range interactions, including elastic interactions, cutting, reactions etc., and long-range interaction due to internal stresses caused by the dislocation structure. The back-stress caused by piled-up dislocations is a typical example. Either model gives strengthening according to:

$$\Delta\sigma = B\sqrt{\rho}, \quad (7.72)$$

where B is constant. This equation was firstly proposed by Bailey and Hirsch [7.220].

Precipitation or Dispersion Hardening

When small precipitates are dispersed in a matrix, a dislocation line interacts with them. When the particle is weak, the dislocation line cuts through such particles and passes through, as shown in Fig. 7.63. The threshold

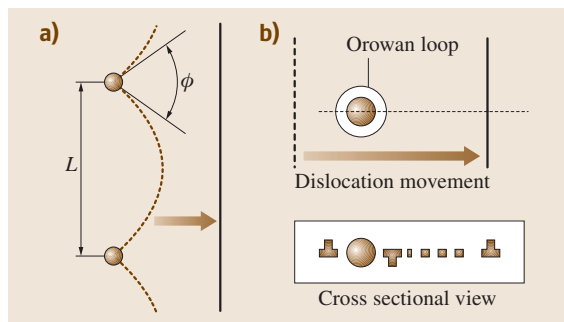

Fig. 7.63a,b Strengthening mechanisms for obstacles dispersion; (a) cut-through mechanism and (b) Orowan bypass mechanism

condition is given by the following equation:

$$\Delta\sigma = (a\mu b/\lambda) \cos(\phi/2), \quad (7.73)$$

where a is a constant, μ is the shear modulus, b is the magnitude of the Burgers vector of a dislocation, λ is the average distance between particles, and ϕ is the critical angle to cut the particle. If ϕ is 0° , a dislocation line passes through the particle, leaving a dislocation loop known as an Orowan loop (Fig. 7.63b). This is the case of a strong particle, leading to the following equation for dispersion hardening [using $\phi = 0$ and $a \approx 2$ in (7.73)]

$$\Delta\sigma = 2\mu b/\lambda. \quad (7.74)$$

Grain-Refinement Hardening

When a dislocation moves towards a grain boundary, it is stopped and induces internal stress, as is shown in Fig. 7.64. When dislocations pile up at the grain boundary, the back-stress generated hinders the further motion of dislocations, as described for the case of workhardening. Because the number of piled-up dislocations depends on the applied stress and slip distance, i.e., grain diameter (d), the amount of strengthening ($\Delta\sigma$) is given by theoretical relations such as:

$$\Delta\sigma = kd^{-1/2}. \quad (7.75)$$

Other interpretations have been proposed for the effect of grain size in this mechanism. For instance, the dislocation density is increased due to the occurrence of many

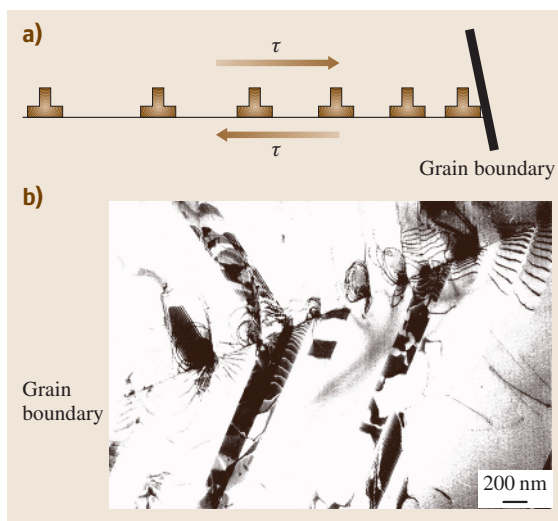

Fig. 7.64a,b Strengthening mechanism for grain boundary or interface: (a) dislocation pile-up model and (b) TEM micrograph for a high-nitrogen-bearing austenitic steel

slip systems in the vicinity of a grain boundary due to high local internal stresses. The amount of strengthening is given by the Bailey–Hirsch relation (7.72). Because the increase in the dislocation density is proportional to the grain diameter d , the resultant equation exhibits the same form as (7.75). Another interpretation for grain-refinement hardening is that new dislocations are emitted from a grain boundary in the neighboring grain to relax high local internal stresses. As (7.75) was first proposed by Hall and Petch [7.221–223] based on experimental data, it is called the Hall–Petch relation. In fact, several phenomena must be overlapping in this mechanism, but the increase in strength can be expressed roughly by (7.75).

Duplex Structure (Coarse Multiphase) Hardening

When the grain diameter of the second phase is comparable to that of the matrix, the mechanism for dispersion hardening such as the Orowan bypass model is no longer applicable. Plastic flow takes place preferentially in the soft phase, resulting in stress partitioning between the constituents, known as phase stress or averaged internal stress. Such strengthening is similar to that for composite materials. Many engineering materials such as ferrite–pearlite steel, dual-phase steels, α – β Cu–Zn alloys etc., belong to this category. Although micromechanics models have been developed to express the deformation of a multiphase material, flow stress is described roughly by a kind of mixture rule. In the case of a two-phase alloy,

$$\sigma = \sigma_1(1 - f) + \sigma_2 f, \quad (7.76)$$

where σ_1 , σ_2 , f refer to the strength of the matrix, the strength of the second phase and the volume fraction of the second phase, respectively.

Usually the above strengthening mechanisms are superposed. Hence, a suitable superposition rule has to be used for real engineering materials. This may be simply described by

$$\sigma = \sum_{i=1}^n \sigma_i^N. \quad (7.77)$$

In the case of superposition of strong and weak obstacles, the value of N is believed to be nearly unity but is less than unity in other cases where both obstacles are strong.

7.4.5 Environmental Effects

The environment where a material is used influences its strength. Such influences include chemical reactions

such as corrosion and radiation damage in a nuclear furnace. Here, two examples are explained because the social impact of these fracture is serious: hydrogen embrittlement and stress corrosion cracking.

Hydrogen-Induced Embrittlement

The most difficult barrier to the use of high-strength steels is hydrogen embrittlement, or so-called delayed cracking. Hydrogen atoms invade not only during the processing of products but also during service. Current topics in this area include the interaction of mobile dislocation and hydrogen atoms and the diffusion of hydrogen atoms within materials. The fracture mechanism is, however, not yet clear.

Figure 7.65 shows the fracture strength after 100 h in water for various kinds of steels [7.224]. The fracture strength is plotted as a function of the tensile strength obtained using the conventional tension test. It is clear the fracture strength increases with increasing tensile strength up to approximately 1.0 GPa. However, steels in the 1.5–GPa (tensile strength) class exhibit a large scatter in their fracture strength; some remain strong while others can drop below 1.0 GPa. Therefore, the strengthening in a mild environment is not necessarily valid under different environmental conditions. The occurrence of fracture depends strongly on the microstructure, i. e., strengthening mechanism.

Another fracture mechanism caused by hydrogen atoms is *hydrogen attack* which is observed for materials subjected to high temperatures in chemical atmospheres

Fig. 7.65 Hydrogen-induced embrittlement observed in various kinds of steels. (Fracture stress at 100 h in water for a notched specimen with a stress concentration factor of 10 versus tensile strength)

such as that in an oil plant. In the case of carbon steel, the invading hydrogen atoms react with cementite particles to produce methane gas, resulting in the formation of blisters that lead to rupture. The critical condition for hydrogen attack is summarized by the so-called Nelson diagram, in which the dangerous conditions are summarized in terms of temperature and partial pressure of hydrogen.

Stress Corrosion Cracking

Stress corrosion cracking (SCC) is observed in many alloys (not in pure metals) under certain combined conditions of stress, chemical environment and microstructure, as shown in Fig. 7.66a. For instance, SCC has been found for Al alloys in air and sea water, Mg alloys in sea water, Cu alloys in water or ammonium atmosphere, carbon steels in NaOH solution, austenitic stainless steels in hot water, and so on. External or

residual tensile stress always plays an important role in fracture. Stress accelerates local corrosion (anode solution) and amplifies the stress at crack tips, leading to fracture. SCC fracture occurs along either certain crystal planes in grains or grain boundaries. Macroscopic crack propagation is summarized by using the stress intensity factor K , as shown in Fig. 7.66b. The threshold K is defined as K_{ISCC} , which is dependent on the materials's microstructure. In general, the stronger the yield strength, the lower the value of K_{ISCC} , so that the balance between strength and toughness is important.

When an austenitic stainless steel is exposed to a high-temperature atmosphere, Cr carbide precipitates along the grain boundaries, leading to the formation of a low-Cr zone. Corrosion then concentrates in such low-Cr zone in the vicinity of the grain boundary and cracks are initiated along the grain boundary, influenced by local corrosion and local stress concentration. The concentration of carbon is, therefore, extremely reduced in steel-making for this use; in a nuclear reactor, it is known that stress corrosion cracking is a key problem for safe operation. Thus, extensive investigations have been made on SCC for austenitic stainless steels. It is also known that radiation damage accelerates SCC cracking. However, recent results have indicated that stress corrosion cracking on shroud plates in a nuclear reactor starts in the interior of grains at the surface, although the reason for this is not clear.

Fig. 7.66a,b Stress corrosion cracking: (a) influential factors of stress, microstructure and chemical environment for stress corrosion cracking and (b) crack-propagation rate as a function of stress-intensity factor

7.4.6 Interface Strength: Adhesion Measurement Methods

Most engineering materials consist of multiple phases. For instance, inclusions or precipitates are usually introduced into engineering materials, whether intentionally or not. Some of these are harmful to the material properties but others are useful for improving properties such as material strength. A typical example is a composite material. In the case of electronics packaging, interfaces between different materials are very important. In particular, for nanosized devices, performance is strongly dependent on the situation of interfaces. To examine the strength of an interface experimentally, several methods are employed depending on the requirements. The tests are not easy and require careful analysis, sometimes with the help of FEM calculations. The strength of an interface is theoretically predicted by means of the molecular dynamics method, which is helpful for understanding the mechanism as well as interface design.

Tensile Strength

The fracture strength perpendicular to the interface is tested in a similar method to tension test. Figure 7.67 shows the tension test used to measure the interface strength [7.225]. Here, one should note the inclination of the interface with respect to the tensile direction. If the interface is inclined, even at an angle less than 1° , the shear stress component appears to influence the fracture mode. The normal to the interface should be carefully adjusted to be parallel to the tensile direction. This test is quite simple and easy to apply to some arti-

Fig. 7.67 Tension test to measure the normal separation at the interface

Fig. 7.68a–d Bending test to evaluate cleaving stress at the interface: (a) compact tension test, (b) three-point bending loading parallel to the interface, (c) three-point bending loading perpendicular to the interface and (d) peel-off test

cially bonded parts but is not easy to apply to multiphase alloys.

Cleavage Strength (Bending)

Similar to fracture toughness testing, compact tension testing, using a specimen shown in Fig. 7.68a, is employed to examine the cleaving features of the interface where the fracture mode is tensile [7.225]. Simpler methods based on three- or four-point bending are shown in Fig. 7.68b and c. The strength for the decohesion can be evaluated by these tests, while Fig. 7.68d shows the peeling test. Some modifications of these tests are also used.

Shear Strength (Adhesive Strength)

The evaluation of shear strength at the interface, which is a key issue for composite strengthening and several mechanically bonded parts, is an interesting measurement. To measure the adhesive shear strength, the most popular test is shown in Fig. 7.69a [7.225]. The thickness of the grip is the same as that of the specimen containing the interface, so that a bending moment can be avoided. Figure 7.69b exhibits the compression-type shearing test, which is frequently employed to evaluate the strength of wire bonding in electric devices. As shown in Fig. 7.69c, a special tool is prepared to push the bonded wire to measure the decohesion stress [7.226].

The interface strength between inclusions or precipitated particles and the matrix in engineering materials cannot be measured directly. In the case of fiber-reinforced materials, methods to measure the shear strength between the reinforcement and the matrix based on pulling or pushing the fiber have been attempted. To realize such a test, a small jig to grip the fiber or a small indenter with a tiny tip must be prepared. The schematic

Fig. 7.69a–c Shearing tests: (a) tension-type test for shearing the interface, (b) compression-type test, (c) shearing test for wire bonding

Fig. 7.70a–d Shear strength of interface in a composite material: (a) model of short fiber-reinforced composite, (b) shear-stress distribution under the applied stress when the matrix is yielded. (c) tensile-stress distribution corresponding to (b) and (d) pull-out and push-down tests to evaluate the shear strength of the interface

testing arrangement is illustrated in Fig. 7.70 [7.227]. The simple shear-lag model for composite strengthening is shown in Fig. 7.70a. When the matrix yields under the external tensile stress, the load transfer from the matrix to a fiber, i.e., the shear stress τ_c , can be roughly described as in Fig. 7.70b. Within a limited length L_c , shear stress is generated and the integrated tensile stress inside the fiber is shown in (b). If the fiber is short, a pull-out phenomenon occurs, but if the fiber is long enough, the tensile stress reaches the fracture strength σ_f . Hence, in order to use the strength of fiber efficiently, the length should be larger than $\sigma_f d / (2\tau_c)$, where d is the fiber diameter. This is called the critical length $L_{c\max}$. When a fiber is shorter than $L_{c\max}$, fracture does not take place. Figure 7.70d presents mechanical tests to measure the decohesion shear strength at the interface. If the length of the fiber is shorter than $L_{c\max}$, it can be pulled out or pushed down and the interface strength can be evaluated from the relevant load–displacement curve. However, in most cases, the fiber fractures during pulling, and suitable modeling has to be considered to estimate the shear stress. When a brittle phase is formed at the interface, fracture occurs easily and the cracking of the brittle layer plays the part of a notch in reducing the fiber strength.

Scratch Test for Thin-Film Coatings

The decohesion strength of thin or thick films is frequently of concern for surface modification. Various surface treatment such as chemical vapor deposition (CVD), physical vapor deposition (PVD) etc. have been developed. For rough testing to evaluate the interface strength, adhesive tape is stuck onto the film and pulled quickly, as shown in Fig. 7.71a. If the interface strength

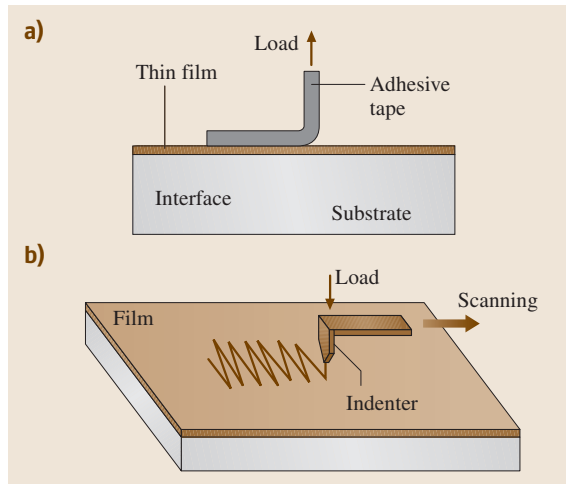

Fig. 7.71a,b Tests to evaluate the strength of interface between the deposited film and substrate: (a) peel-off test using adhesive tape and (b) scratching test for thin film on a substrate to examine decohesion behavior, where a diamond indenter with a tip radius of several μm is used

is weak, the film can be removed easily. However, this test is not sufficient to evaluate the reliability of bonding and hence more quantitative tests are used. Figure 7.71b shows a schematic illustration of such a test [7.226]. An indenter is pressed into the film and pulled along to scratch a zigzag route, during which the applied stress is increased gradually. After this test, the position where separation starts can be determined by observation with a scanning electron microscope (SEM) and the applied stress at that point can then be found. Sometimes, the test is performed inside a SEM.

7.5 Fracture Mechanics

In materials that are components of large engineering structures the presence of fabrication flaws and their development during operational service should be anticipated. It is rational to assume that flaws exist and that countermeasures against the fracture and fatigue that develop from them should be taken.

In the 1920s, A. A. Griffith conducted a series of experiments to determine the fracture strength of glass components that contained small flaws. From this experiments, he concluded that for *brittle materials* the stress required to cause failure decreased as the size of the flaw increased, even after correction is made for the reduced cross section of good material. Extending these findings to other types of materials, it was generally found that the strength of a structural component that contains a crack or crack-like flaw decreases with increasing crack size and cannot be deduced from the mechanical properties obtained in conventional tensile tests (see Sect. 7.3.1) or other mechanical tests using smooth specimens. The combined mathematical–experimental approach employed in the evaluation of the strength of cracked components is called *fracture mechanics*; it provides a methodology to determine the amount of crack growth and the residual strength of cracked components during operational service.

7.5.1 Fundamentals of Fracture Mechanics

The fundamental principle of fracture mechanics is that the stress and strain field ahead of a sharp crack can be characterized in terms of a single parameter, such as the stress intensity factor K , that is a function of the applied stress, crack size and geometrical boundary conditions. Crack growth or fracture initiation from a pre-crack must be controlled by the stress or strain state at the crack-tip region. This implies that the fracture behavior from a crack can be described by the frac-

ture mechanics parameter, as an analogy with the plastic yielding behavior of materials described in the form of σ_{eq} (equivalent stress) = σ_{ys} (yield strength of the material). The crack-tip stress/strain similarity anticipates to result in the same type of fracture under the same environmental condition. Once the fracture resistance of a material is described in terms of its fracture mechanics parameter in laboratory tests, one can deduce its fracture behavior under different applied stresses, crack sizes and geometrical boundary conditions without any discussion of the mechanisms of fracture concerned. The fracture mechanics approach has three variables for the evaluation of strength, as shown in Fig. 7.72.

Fracture mechanics can be subdivided into two general categories, namely linear elastic and elastic–plastic. Materials with relatively low fracture resistance fail under small-scale yielding at the crack tip and can be analyzed through linear-elastic fracture mechanics (LEFM), in which the stress intensity factor, K , is based on the elastic stress analysis. Metallic materials often show large-scale plastic yielding preceding crack growth or fracture initiation from the crack. Elastic–plastic fracture mechanics (EPFM) is applied for these large-scale yielding conditions. The J integral and the crack-tip opening displacement (CTOD) can be used as alternative fracture mechanics parameters to K .

Linear Fracture Mechanics

Consider an elastic body of arbitrary configuration with an ideally sharp crack, subjected to arbitrary external forces. There are three types of relative movements of the two crack surfaces, as Fig. 7.73 illustrates. The opening mode, mode I, is the most popular displacement mode in practical components, and is characterized by opening displacements in the direction of the principal load. Mode II and mode III correspond to in-plane shear loading and out-of-plane shear loading, respectively. In

Fig. 7.72 Comparison of the fracture mechanics approach (b) to design with the (a) traditional design approach

Fig. 7.73a–c Three modes of crack deformation. (a) Mode I (opening) (b) Mode II (in-plane shear) (c) Mode III (out-of-plane shear)

Fig. 7.74 Crack-tip stresses in polar coordinate

any problem a cracked body can be treated as one or a combination of these three modes.

The theory of elasticity derives closed-form expressions for the stresses around the crack tip for each of these modes of deformation, assuming isotropic linear elastic material behavior [7.228–230]. For a polar coordinate axis as shown in Fig. 7.74, the stress field in any cracked body is given by

$$\sigma_{ij}(r, \theta) = \left(k \sqrt{\frac{a}{r}} \right) f_{ij}(\theta) + \sum_{n=0}^{\infty} A_n \left(\sqrt{\frac{r}{a}} \right)^n g_{ij,n}(\theta), \quad (7.78)$$

where σ_{ij} is the stress tensor, k and A_n are constants, and f_{ij} and g_{ij} are functions of θ . The higher-order terms depend on the geometrical boundary conditions. The first leading term approaches infinity as r reaches 0, but the other terms remain finite. Thus, the stress at the crack-tip region has a singularity of order $1/\sqrt{r}$, regardless of the configuration of the cracked body. The stress fields ahead of a crack tip, where r is sufficiently small compared with the crack length a , can be rewritten as

$$\sigma_{ij, I} = \frac{K_I}{\sqrt{2\pi r}} f_{ij, I}(\theta), \quad (7.79a)$$

$$\sigma_{ij, II} = \frac{K_{II}}{\sqrt{2\pi r}} f_{ij, II}(\theta), \quad (7.79b)$$

$$\sigma_{ij, III} = \frac{K_{III}}{\sqrt{2\pi r}} f_{ij, III}(\theta), \quad (7.79c)$$

for modes I, II, and III, respectively. These field equations show that the magnitude of the elastic stress field can be described by the single-term parameters K_I , K_{II} , and K_{III} . The stress intensity factor K , given a subscript to denote the mode of crack deformation, is a function of the applied force, the crack shape and size, and the structural configuration. However, since mode I cracking is often question in practical constructions, the subscript I is usually abbreviated for the mode I.

The general form of the stress intensity factor is given by

$$K = F \sigma \sqrt{\pi a}, \quad (7.80)$$

where F is a parameter that depends on the geometry of the specimen or component with a crack. For an infinite plate subjected to uniform tensile stress σ containing a through-thickness crack of length $2a$, the stress intensity factor is

$$K = \sigma \sqrt{\pi a}. \quad (7.81)$$

Equations (7.79) show the elastic stress field in the singularity zone ahead of the crack for an idealized crack model. In real materials, the stresses at the crack tip do not take an infinite value because the crack-tip radius must be finite, and the metallic material in this region undergoes plastic deformation and leads to further relaxation of the crack-tip stress. However, the size of the plastic zone or the ambiguity zone that surrounds the crack tip is so small compared with the singularity zone (for small-scale yielding) that the stresses in the surrounding zone still take the form (7.79). Thus, the stress intensity factor K is still a representative parameter for the stress field at the crack tip, although the crack-tip stresses are devoured in black box.

The small-scale yielding condition is given by the ASTM [7.231] as

$$a \geq 2.5 \left(\frac{K}{\sigma_{ys}} \right)^2, \quad (7.82)$$

which gives one of the limitations for linear elastic fracture mechanics.

Elastic–Plastic Fracture Mechanics

Under the large-scale yielding condition, where (7.82) is not satisfied, the stress intensity factor loses its physical

Fig. 7.75 Contour integral around the crack tip

basis as a fracture mechanics parameter. An alternative parameter for a nonlinear elastic material is the J integral. Rice [7.232] presented a path-independent contour integral, which is called J , for a cracked body. The J integral is given by

$$J = \int_{\Gamma} \left[W(\varepsilon_{ij}) dy - T_i \frac{\partial u_i}{\partial x} ds \right] \quad (7.83)$$

where $W(\varepsilon_{ij})$ is the strain energy density, T_i are the components of the traction vector, u_i are the components of the displacement vector, and ds is a length increment along the contour Γ , as illustrated in Fig. 7.75.

The value of the J integral is independent of the path of integration and is equivalent to the energy-release rate for a nonlinear elastic material. It can be shown that the J integral characterizes the crack-tip stress field in a nonlinear elastic material [the Hutchinson–Rice–Rosengren (HRR) stress field] [7.232, 233] as well as the stress intensity factor in a linear elastic material. Under the large-scale yielding condition, the size of the HRR stress field depends on the magnitude of the plastic yielding scale and the plastic constraint of a specimen. Whether the HRR stress field exists or not gives a limitation on the J integral approach for large-scale yielding [7.234].

Another parameter in elastic–plastic fracture mechanics is the crack-tip opening displacement (CTOD), the plastic deformation blunted an initially sharp crack, as illustrated in Fig. 7.76. Wells [7.235] proposed the opening at the crack tip as a measure of fracture toughness. The CTOD can be related to the stress intensity factor and the J integral under the small-scale yielding condition as given by

$$J = m \delta \sigma_{ys} = \frac{K^2}{E(1 - \nu^2)}, \quad (7.84)$$

Fig. 7.76 Crack-tip blunting and CTOD

where δ is the CTOD, m is a dimensionless constant that depends on material properties and stress triaxiality, and E and ν are the elastic modulus and Poisson's ratio, respectively.

Details of the J integral and CTOD are well described in [7.234]. To evaluate the J integral according to (7.83), numerical analysis with a constitutive equation for the material (relationship between plastic strain and stress) is needed. The CTOD has an ambiguity in its definition for numerical analysis. Thus, the evaluation of parameters during the application of the elastic–plastic fracture mechanics for actual structures is difficult. For a deeply cracked specimen subjected to bending load, simple experimental procedures have been proposed to evaluate the J integral and CTOD [7.234, 236, 237].

7.5.2 Fracture Toughness

The fracture mechanics parameter uniquely stipulates the stress and strain state at the crack tip provided that the constraint in a direction parallel to the crack front is the same. The constraint on deformation in the crack-tip region is closely related to the triaxial stress state and depends on the geometry of the specimen, the scale of plastic yielding, and strain hardening of the material.

Linear elastic fracture mechanics describes unstable fracture as fracture occurs when the stress intensity factor K reaches a critical value K_c . The fracture toughness, K_c for mode I deformation under small-scale yielding and plane-strain stress state (sufficient constraint), is designated K_{Ic} [7.231]. The toughness in terms of the J integral is designated by J_{Ic} and J_c [7.236]. J_{Ic} is the toughness for onset of slow crack growth from a crack and J_c is the toughness for unstable fast fracture. It should be noted that there is no harmonization in terminology of K_{Ic} and J_{Ic} . The CTOD criterion is

also applied to evaluate the fracture toughness under large-scale yielding. Historically, the cleavage fracture toughness of structural steels has often been evaluated in terms of the critical CTOD δ_c .

In the standards for toughness testing, several specifications are prescribed so that the constraint effect can be negligible. Single-parameter fracture mechanics breaks down in the presence of excessive plasticity, or for specimens with too shallow a notch, and fracture toughness depends on the size and geometry of the test specimen.

K_{Ic} Testing

The standard test methods for determining plane-strain fracture toughness (K_{Ic}) of metallic materials are specified in several standards [7.231, 237, 238]. In these standards, ASTM E399-90 [7.231], which was originally published as E399-70, is widely used.

For the standard K_{Ic} test, a single-edge notched (SEN) bend specimen or a compact test (CT) specimen is used; these standard geometries are shown in Figs. 7.77 and 7.78, respectively. The standard bend specimen has a rectangular cross section ($B \times 2B$, $W = 2B$, where B is the specimen thickness and W is the specimen width). Alternative a specimen geometry with square cross section ($B \times B$, $W = B$) can also be used for the bend test. However, the size requirement for the plane-

strain fracture toughness test, which will be described later, should be satisfied. In the CT specimen, $W = 2B$ is recommended.

The fatigue pre-crack is introduced at the notch tip by cyclic loading and the recommended value for the total crack length (machined notch plus fatigue crack) is $0.45\text{--}0.55W$. The fatigue pre-cracking load can affect the fracture toughness results, so the cyclic loading conditions are strictly limited. The stress ratio (minimum load to maximum load) of cyclic loading is between -1 and 0.1 . The maximum fatigue stress intensity (K_{max}) does not exceed 80% of the K_{Ic} value of the material. For the final stage of fatigue crack extension, K_{max} must not exceed 60% of the K_{Ic} value, and the ratio of K_{max} to the Young's modulus of the material K_{max}/E should not exceed $0.00032\text{ m}^{1/2}$. Usually, the number of cycles for fatigue pre-cracking is $10^4\text{--}10^6$. Normally, as the temperatures of the fatigue cracking and fracture toughness tests are different, the effect of temperature should be taken into account. When fatigue cracking is conducted at temperature T_1 and the fracture testing at a different temperature, T_2 , K_{max} must not exceed $0.6(\sigma_{ys1}/\sigma_{ys2})K_{Ic}$, where σ_{ys1} and σ_{ys2} are the yield stress at the respective temperatures T_1 and T_2 . It is recommended that the length of the fatigue crack be larger than 1.3 mm and 2.5% of W for a straight-through notch.

The single-edge notched specimen is loaded in three-point bending with a support span S , which is normally equal to $4W$, that is $S = 4W$. The bend testing fixture is designed to minimize friction effects by allowing the support rollers to rotate and move apart slightly when the specimen is loaded. The compact specimen is loaded in tension through pins by allowing the specimen to rotate during the test.

Fracture tests are conducted with a static loading with a rate of increase of stress intensity of $0.55\text{--}2.75\text{ MPa m}^{1/2}$. The test temperature is controlled within 3°C [7.236] and the specimen should be kept at the test temperature for 1.2 min/mm of specimen thickness before testing [7.237]. During testing, continuous measurement of load versus crack mouth opening displacement is required. The displacement is measured by a double-cantilever displacement gage or a ring-type displacement gage.

After fracture testing, the crack length is measured at the following three positions: at the crack front, and midway between the center of the crack front and the end of the crack front on each surface of the specimen. The average of these three measurements is the crack length and is used to calculate the stress intensity.

Fig. 7.77 Single-edge notched (SEN) bend specimen

Fig. 7.78 Compact test (CT) specimen

The maximum difference between these measurements is specified in the standards.

Based on the test record of load versus crack mouth opening displacement, it is first necessary to calculate a conditional result K_Q , using which the size requirement for the plane-strain condition is judged. When the size requirement is satisfied K_Q becomes K_{Ic} . The procedure is as follows:

1. Draw the secant line OP_5 from the origin of the record with the slope $(P/V)_5 = 0.95(P/V)_0$, where $(P/V)_0$ is the slope of the tangent OA to the initial linear part of the test record, as shown in Fig. 7.79. The load P_Q is then defined as follows: if the load at every point on the record which precedes P_5 is lower than P_5 , then P_5 is P_Q (Fig. 7.79, type I); if, however, there is a maximum load preceding P_5 that exceeds it, then this maximum load is P_Q (Fig. 7.79, types II and III).
2. Calculate the ratio P_{\max}/P_Q , where P_{\max} is the maximum load of the record. If this ratio does not exceed 1.10, that is,

$$\frac{P_{\max}}{P_Q} \leq 1.10 \quad (7.85)$$

then, proceed to calculate K_Q .
For an SEN bend specimen,

$$K = \frac{PS}{BW^{1.5}} f\left(\frac{a}{W}\right),$$

$$f(x) = \frac{3x^{0.5}}{2(1+2x)(1-x^{1.5})} \times (1.99 - 2.15x + 6.08x^2 - 6.83x^3 + 2.07x^4),$$

$$x = \frac{a}{W}. \quad (7.86)$$

For a CT specimen,

$$K = \frac{P}{(BW^{0.5})} f\left(\frac{a}{W}\right),$$

$$f(x) = \frac{2+x}{(1-x)^{1.5}} \times (0.886 + 4.64x - 13.32x^2 + 14.72x^3 - 5.60x^4),$$

$$x = \frac{a}{W}. \quad (7.87)$$

3. Calculate $2.5(K_Q/\sigma_{ys})^2$, where σ_{ys} is the yield stress of the material at the test temperature. If the following is satisfied, then K_Q is equal K_{Ic} .

$$B, a \geq 2.5 \left(\frac{K_Q}{\sigma_{ys}} \right)^2. \quad (7.88)$$

Fig. 7.79 Principal types of load–displacement records

4. If the test results fails to meet the requirements in (7.80) or in (7.81), or both, it is necessary to use a larger specimen to determine K_{Ic} .

J_c , J_u Testing

When the specimen size is inadequate to meet the requirement given by (7.88), a valid K_{Ic} value is not obtained. The reason for this is that the plastic deformation in the specimen is too large to meet the plane-strain condition. In such case, an alternative method is to use elastic–plastic fracture mechanics. The J integral is one such parameters, which is a line or surface integral enclosing the crack front from one crack surface to the other, and is used to characterize the local stress–strain field around the crack tip. The method for determining fracture toughness at the fracture instability based on the J integral is described in the standards [7.236, 237, 239], of which ASTM E1820-01 [7.236] covers the procedures and guidelines for the determination of the fracture toughness using fracture parameters such as K , J , CTOD (δ). The original J_{Ic} and J -R test methods were developed in the original ASTM E813-81 [7.240] and E1152-87 [7.241], respectively. These test methods are now unified in E1820.

When fracture instability occurs before stable tearing the fracture toughness, labeled J_c , is obtained. When the instability occurs after stable tearing the fracture toughness is denoted by J_u . In J_c and J_u testing, the standard specimen for K_{Ic} testing is applicable. However, in order to calculate J , it is necessary to record the curves of load versus load-line displacement. For CT test, the load-line displacement is directly measured

Fig. 7.80 Compact test (CT) specimen for the J integral test

Fig. 7.81 Double-clip gage method for determining load-line displacement of the SEN bend test

by using the specimen shown in Fig. 7.80. For the SEN bend test, special care must be paid to indentation of the specimen by the loading jig. One possible method for measuring the load-line displacement is to use double clip gages. The load-line displacement V_L may be calculated by (Fig. 7.81) [7.237]

$$V_L = \frac{W(V_2 - V_1)}{z_2 - z_1} \quad (7.89)$$

For fatigue pre-cracking, the maximum load should be less than

$$P_{\max} \leq P_f \quad (7.90)$$

P_f is given by

$$P_f = \frac{0.5Bb_0\sigma_Y}{S} \quad (7.91)$$

for the SEN bend specimen. For the CT specimen,

$$P_f = \frac{0.4Bb_0\sigma_Y}{2W + a_0} \quad (7.92)$$

Fig. 7.82 Definition of area for the J calculation

where, $b_0 = W - a_0$ (initial ligament depth) and σ_Y is the flow stress given as the average of the yield stress, σ_{ys} and the tensile strength σ_{uts} . The condition (7.90) is equivalent to limiting the maximum stress intensity, K_{\max} of fatigue pre-cracking, according to:

$$K_{\max} \leq 0.47\sigma_Y B^{0.5} \quad (7.93)$$

From the fracture instability point, the critical load P_Q is determined. The J -integral value J_Q corresponding to P_Q is calculated using

$$J = J_{el} + J_{pl} \quad (7.94)$$

where J_{el} is the elastic component of J and J_{pl} is the plastic component of J . At a point corresponding to V_L and P on the specimen load versus load-line displacement, J is calculated through

$$J = \frac{K^2}{E'} + \eta \frac{A_{pl}}{Bb_0} \quad (7.95)$$

where, $\eta = 2$ for the SEN bend, and $\eta = 2 + 0.522b_0/W$ for the CT method. $E' = (1 - \nu^2)/E$, and A_{pl} is the area shown in Fig. 7.82.

After testing, along the front of the fatigue crack and the front of the stable crack extension (if it exists), measure the size of the original crack and the final physical crack size at nine equally spaced points centered about the specimen centerline and extending to $0.005W$ from the specimen surface. The original crack size a_0 and the physical crack size a_p are calculated by averaging the two near-surface measurements and the remaining seven crack-length measurements. The crack extension, Δa_p is calculated as $a_0 - a_p$.

If $\Delta a_p < 0.2 \text{ mm} + J_Q/2\sigma_Y$, the fracture instability point corresponds to instability before stable tearing.

Fig. 7.83 Procedure for evaluating the significance of pop-in

For a ferritic steel with $250 \text{ MPa} < \sigma_{ys} < 725 \text{ MPa}$ and $250 \text{ MPa} < \sigma_{uts} < 725 \text{ MPa}$ for the room temperature strength of the material,

$$B, b_o \geq 50 \frac{J_Q}{\sigma_Y}, \quad (7.96)$$

and for other metallic materials,

$$B, b_o \geq 100 \frac{J_Q}{\sigma_Y}, \quad (7.97)$$

where J_Q becomes J_c . It should be noted that, even if these conditions are met, J_c might depend on thickness.

If $\Delta a_p > 0.2 \text{ mm} + J_Q/2\sigma_Y$, the fracture instability point corresponds to instability after stable tearing and J_Q becomes J_u . This is a characteristic of the material and specimen geometry and size.

When the material is heterogeneous, pop-ins are sometimes observed in the record. If the pop-in is attributed to an arrested fracture instability in the plane of the fatigue crack, the result is considered to be a characteristic of the material tested. Pop-in can be assessed by a specific change in compliance, and also post-test examination of the fracture surfaces. Pop-ins are only evaluated when the load rises with increasing displacement after pop-in, otherwise it is considered to be a fracture instability.

The following procedure is used to assess the significance of pop-ins when post-test examination indicates that they are associated with arrested fracture instability in the plane of the fatigue pre-crack. As shown in Fig. 7.83: (1) draw a line CB which is parallel to the initial slope OA and passes through the pop-in point under consideration. (2) Draw a line CF with a slope 5%

less than the line CB. (3) Mark the point G, corresponding to the load and displacement at pop-in. (4) When the point G is within the angle BCF, the pop-in is judged to be insignificant (Fig. 7.83b). (5) When the point G is outside the angle BCF, the pop-in is significant (Fig. 7.83a). The judgment of (4) and (5) is whether the arrested crack is more than 0.02 of the crack length or not.

J-R Curve Testing

The J -R curve shows resistance of a material to stable crack extension in terms of the J integral and consists of a plot of J versus crack extension. The standard test method of ASTM E1820-01 [7.236] is to use a single-specimen technique with partial unloading using an elastic-compliance method to determine the stable crack extension. The maximum J integral capacity of a specimen J_{\max} and the maximum crack extension capacity for a specimen Δa_{\max} are given by the following:

$$J_{\max} = \min\left(\frac{b\sigma_Y}{20}, \frac{B\sigma_Y}{20}\right), \quad (7.98)$$

$$\Delta a_{\max} = 0.25b_o. \quad (7.99)$$

In J -R testing, SEN and CT specimens are used, usually with side groove. Here, the net thickness is denoted by B_N and the effective thickness is expressed by $B_e = B - (B - B_N)^2/B$. The J -R curve is constructed by plotting J integral values versus the corresponding crack extension values, as shown in Fig. 7.84. The unload/reload sequences are spaced at load-line displacement intervals of about $0.005W$. The J integral

Fig. 7.84 Typical J - R curve

values are calculated by

$$J_i = \frac{K_i^2}{E'} + J_{pl,i}, \quad (7.100)$$

$$J_{pl,i} = \left(J_{pl,i-1} + \frac{\eta_{i-1}}{b_{i-1}} \frac{A_{pl,i} - A_{pl,i-1}}{B_N} \right) \times \left(1 - \gamma_{i-1} \frac{a_i - a_{i-1}}{b_{i-1}} \right), \quad (7.101)$$

$$A_{pl,i} - A_{pl,i-1} = (P_i + P_{i-1}) \frac{V_{pl,i} - V_{pl,i-1}}{2}, \quad (7.102)$$

where, for SEN specimens $\eta_i = 2$ and $\gamma_i = 1$, and for CT specimens $\eta_i = 2.0 + 0.522b_{i-1}/W$ and $\gamma_i = 1.0 + 0.76b_{i-1}/W$. The quantity $A_{pl,i} - A_{pl,i-1}$ in (7.102) is the increment of plastic area under the load versus load-line displacement record between lines of constant displacement at points $i-1$ and i , as shown in Fig. 7.85.

Using an elastic-compliance technique on an SEN specimen with crack mouth opening displacement the crack length is given as

$$\frac{a_i}{W} = 1.000 - 3.950u + 2.982u^2 - 3.214u^3 + 51.52u^4 - 113.0u^5, \quad (7.103)$$

where

$$u = \frac{1}{\left(\frac{B_e W E C_i}{S/4} \right)^{0.5} + 1}. \quad (7.104)$$

Fig. 7.85 Definition of area for the J calculation

For CT specimens, the crack length is determined using the load-line displacement as

$$\frac{a_i}{W} = 1.000 + 4.063u + 11.24u^2 - 106.0u^3 + 464.3u^4 - 650.7u^5, \quad (7.105)$$

$$u = \frac{1}{(EC_i B_e)^{0.5} + 1}. \quad (7.106)$$

J_{Ic} Testing

The property J_{Ic} characterizes the toughness of a material near the onset of crack extension from a fatigue pre-crack. Originally, the J_{Ic} test was specified in ASTM E813 [7.240] and is now unified in ASTM E1820 [7.236]. E1820-01 gives two methods to determine J_{Ic} : the basic procedure and the resistance curve procedure. The basic procedure involves physical marking of the crack extension and multiple (more than five) specimens, which are used to develop a plot from which an initiation toughness value is evaluated. The resistance curve procedure is to determine the J_{Ic} value from the J - R curve, which is an elastic-compliance method where multiple points are determined from a single specimen.

In the basic procedure, five or more specimens are used. After unloading the specimen, the crack is marked by heat-tinting at about 300 °C (for steels and titanium alloys) or fatigue cracking, and then, cooling and breaking the specimen. The physical crack size a_p is then measured at nine equally spaced points along the front of the marked region of stable crack extension. The crack extension Δa is calculated with

$$\Delta a = a_p - a_o. \quad (7.107)$$

The J value is calculated using (7.95) at the point where unloading was conducted.

In the resistance curve procedure, a correction is applied to the estimated Δa_i data to obtain an improved original crack size, a_{oq} from the compliance. Using the data set of J_i and a_i , a_{oq} is calculated from

$$a = a_{oq} + \frac{J}{2\sigma_Y} + BJ^2 + CJ^3. \quad (7.108)$$

The coefficients B and C in this equation are determined using a least-square fit procedure. In this procedure, it is necessary that there are more than eight data and that three of the eight are between $0.4J_Q$ and J_Q . Moreover, the correlation coefficient of this fit should be more than 0.96 and the difference between the optically measured crack length, a_o and a_{oq} should be less than $0.01W$. For each a_i value, the crack extension is calculated by

$$\Delta a_i = a_i - a_{oq}. \quad (7.109)$$

The J_i values are determined from (7.100–7.102).

The next step is to plot J versus Δa , as shown in Fig. 7.86. Draw a construction line in accordance with

$$J = M\sigma_Y \Delta a, \quad (7.110)$$

where $M = 2$. Then, draw exclusion lines parallel to the construction line intersecting the abscissa at 0.15 mm and 1.5 mm, as shown in Fig. 7.87. These lines give the minimum and maximum Δa values (Δa_{\min} , Δa_{\max}). At least one J – Δa point should lie between the 0.15-mm exclusion line and the 0.5-mm offset line, and one point should also lie between the 0.5-mm offset line and the 1.5-mm exclusion line. Next we draw the regression line with

$$\ln(J) = \ln(C_1) + C_2 \ln(\Delta a). \quad (7.111)$$

The J_Q value is determined as the intersection of the regression line of (7.111) and the 0.2-mm offset line. If the following size requirements are satisfied, J_Q becomes J_{Ic} ,

$$B, b_o > 25J_Q/\sigma_Y. \quad (7.112)$$

CTOD Testing

The CTOD test is especially appropriate for materials that exhibit a change from ductile to brittle behavior with decreasing temperature. Typical standards of CTOD testing method are specified in [7.237, 242, 243].

The method uses fatigue pre-cracked specimens. A rectangular- or square-cross-sectioned three-point bend specimen or compact specimen is used. The configurations of the specimens are similar to those for K_{Ic}

Fig. 7.86 Definition of construction line for data qualification

Fig. 7.87 Definition of regions for data qualification

testing (Figs. 7.77 and 7.78). A fatigue pre-crack is introduced half way along the specimen width, 0.45–0.55 times the specimen width. In order to expedite fatigue pre-cracking, a machined notch is produced by milling, sawing or disc grinding. A chevron notch may be machined if fatigue pre-cracking is difficult to control. The fatigue pre-crack is introduced by repeated loading at room temperature. The maximum fatigue pre-cracking load should be lower than a prescribed value. This restriction is to limit the plastic zone size at the fatigue

Fig. 7.88 Characteristic types of load–displacement records in a CTOD testing. (After [7.237])

pre-crack tip. Excessive plastic deformation at the crack tip may influence the critical CTOD value.

The specimens are tested in displacement-controlled and quasistatic monotonic loading. The machine for load application should be capable of applying load at a rate of stress intensity factor within the range $0.5\text{--}3.0\text{ MPa m}^{1/2}\text{s}^{-1}$. A typical set up of a specimen is shown in Figs. 7.77 and 7.78.

The notch opening displacement is measured by a displacement gage attached to the edge of the notch. Knife-edges are attached at the notch edge. Alternatively, integral knife-edges are used. A record of load versus notch opening displacement is made. Characteristic types of load versus displacement records in the test are shown in Fig. 7.88. Note that P_c is the applied load at the onset of brittle crack extension or pop-in when the average stable crack extension (Δa), including the stretched zone width (SZW), is less than 0.2 mm; P_u is the applied load at the onset of brittle crack extension or pop-in when the event is preceded by Δa of at least 0.2 mm; and P_m is the applied load at the first attainment of a maximum load plateau for fully plastic behavior. If the specimen fractures by brittle crack extension prior to the first attainment of a maximum load plateau [type (4)], the fracture surface is examined for evidence of stable crack extension in the region between the fatigue pre-crack front and the start of brittle crack extension. When an initiated brittle crack is arrested after a short extension, the load versus notch opening record exhibits pop-in, see types (3) and (5) in Fig. 7.88. Pop-ins giving both a load drop, y , and displacement increase, x , of less than 1% are ignored.

The types and the amount of Δa are recorded. The critical values of the load and notch opening displacement of F_c and V_c , or F_u and V_u , are measured at points corresponding to:

Fig. 7.89 Definition of V_p for determining the CTOD. (After [7.237])

1. Fracture, when there are no significant pop-ins: record types (1), (2) and (4);
2. The earliest significant pop-in prior to fracture: record types (3) and (5);
3. Fracture, when all significant pop-ins prior to fracture give values of $d\%F$ that are less than 5%, where

$$d\%F = 100 \left[1 - \frac{D}{F} \left(\frac{F - y}{D + x} \right) \right] \% . \quad (7.113)$$

Values of P_m and V_m are measured at points corresponding to:

1. First attainment of the maximum load plateau, when there is no fracture or pop-ins prior to the first attainment of the maximum load plateau: record type (6).

Critical CTOD values, δ_c , δ_u , δ_m , corresponding to P_c and V_c , P_u and V_u , or P_m and V_m , respectively, are calculated by

$$\delta = \left[\frac{PS}{BW^{1.5}} \times f\left(\frac{a_0}{W}\right) \right]^2 \frac{(1 - \nu^2)}{2\sigma_{ys}E} + \frac{0.4(W - a_0)V_p}{0.4W + 0.6a_0 + z} , \quad (7.114)$$

where, P is the critical value of the applied load, S is the bending span, B and W are the thickness and width of the specimen, respectively (Fig. 7.77), a_0 is average original crack length, f is a mathematical function of a_0/W (7.86) [7.237], σ_{ys} is 0.2% of the proof strength at the temperature of fracture test, z is distance of the notch

opening gage location above the surface of the specimen and V_p is the plastic component of critical notch opening displacement, as defined by Fig. 7.89.

CTOD Testing of Welds

Fracture toughness evaluation of welds is more complicated than that of base metal because the welds have heterogeneities in terms of microstructure and toughness. Therefore, toughness values of welds inherently show large scatter. The existence of local brittle zones (LBZ) in the heat-affected zone (HAZ) sometimes gives extremely low toughness values. From this viewpoint, special attention should be paid to CTOD testing for welds.

Figure 7.90 shows the variation of critical CTOD values of high-strength-steel weld HAZ as a fraction of the coarse-grained (CG) HAZ along the fatigue pre-crack front in the thickness direction [7.244]. This result indicates that at least 15% of the CG HAZ should be sampled by the fatigue pre-crack to assess the lower-bound CTOD value; see below for the definition of %CG HAZ. Most of the CTOD testing standards of weld HAZ specify the %CG HAZ for this reason. Typical standards of for CTOD testing method for welds are specified in [7.245, 246]. Among these, API RP 2Z [7.245] was the first to specify a CTOD testing method for weld HAZ. Other standards follow the same concept. The API RP 2Z standard is intended for preparing and certifying fabrication welding procedures and assuring that the steel to be supplied is inherently suitable for welding.

API RP 2Z refers to BSI 7448 part 1 [7.237] and ASTM E 1290-02 [7.242] for the CTOD testing method. Additional requirements are specified regarding the notch positioning in the weld and post-test examinations for sampling the CG HAZ regions, which is thought to have lower-bound toughness. Figure 7.91 shows the HAZ regions in a multi-pass weld. Because of the multi-thermal cycles induced by multi-pass welding, the HAZ has an extremely complex microstructure distribution. It is intended that the fatigue pre-crack certainly samples the CG HAZ. For this purpose, the fatigue pre-crack should be carefully introduced. Welding should be made carefully so that the fusion line of the weld is straight enough to sample as much CG HAZ as possible. It should be noted that proper welding consumables and welding procedures should be adopted to maintain a certain level of critical CTOD value for the weld metal. In addition, welding residual stress may be relieved prior to fatigue pre-cracking to promote crack-front straightness. This is done by lateral compression (Fig. 7.92) [7.247].

Fig. 7.90 Critical CTOD values versus %CG regions for steels showing some LBZ behavior. (After [7.244])

API RP 2Z requires three levels of weld heat inputs. At least five or eight, depending on the heat input, CTOD tests should be conducted for each welding condition. At least three specimens aim to sample the CG HAZ regions close to the fusion line and at least two specimens aim to sample the boundary region between the HAZ and base metal.

Post-test metallographic examinations are specified. Figure 7.93 shows the sectioning method for this purpose. The broken half of the specimen is sectioned at the fatigue pre-crack front, etched and its microstructure is revealed. The CG HAZ regions sampled by the fatigue pre-crack tip is measured (Fig. 7.94), and the %CG is calculated as

$$\%CG = \frac{100 \sum_{i=1}^n L_i}{B}, \quad (7.115)$$

where L_i is length of the i -th CG region sampled by the crack front and B is the plate thickness. The CG regions need not be continuous. The value of %CG should be at least 15% for the three specimens. For the other two specimens, the crack front should sample at least 50% of the boundary region between the HAZ and the base metal.

The CTOD toughness values are influenced by many other factors than the local brittle zones. One is the degree of strength matching, i. e. the ratio of yield strength of the weld metal to that of base metal. An overmatch

Fig. 7.91 Schematic of microstructures in HAZ of a multi-pass welding. (After [7.245])

Fig. 7.92 Lateral compression prior to fatigue pre-cracking, for relieving welding residual stress. (After [7.247])

may cause excessive constraint in the HAZ, which may cause unexpectedly low critical CTOD values.

7.5.3 Fatigue Crack Propagation Rate

Fatigue crack propagation results from the cyclic plastic strain cumulation at the crack tip, especially in sta-

ble crack propagation. It is expected that the crack propagation rate da/dN can be related to the stress-intensity factor range $\Delta K (= K_{\max} - K_{\min})$. Since Paris et al. [7.248, 249] first demonstrated the characterization of crack growth by fatigue in the early 1960s, a considerable number of works have covered the determination of crack growth behaviors using fracture mechanics. Figure 7.95 shows typical fatigue crack growth behavior in metallic materials, which is expressed in a schematic log-log relationship between da/dN and ΔK ; ΔK is usually defined as the positive component of the total stress-intensity factor range, which is

$$\begin{aligned} \Delta K &= K_{\max} - K_{\min} = (1 - R)K_{\max} \quad \text{for } R \geq 0 \\ \Delta K &= K_{\max} \quad \text{for } R \leq 0 \end{aligned} \quad (7.116)$$

where R is the stress ratio ($= \sigma_{\min}/\sigma_{\max} = K_{\min}/K_{\max}$). The sigmoidal curve in Fig. 7.95 can be divided into three regions. Region I is a lower bound against

Fig. 7.93 Sectioning the weld half of a CTOD specimen for post-test metallographic examination. (After [7.245])

crack growth, which is characterized by a threshold value ΔK_{th} . Below ΔK_{th} , there is no observable fatigue crack growth. In region II, for intermediate ΔK values, the relationship in Fig. 7.95 can be fitted with a linear line, which is formulated as

$$da/dN = C(\Delta K)^m, \quad (7.117)$$

where C and m are both materials constants, which should be determined experimentally. The fatigue crack growth rate in region II is mainly controlled by ΔK , and is insensitive to the R ratio. This power-law relationship for fatigue crack growth in region II was first proposed by *Paris and Erdogan* [7.249] and (7.117) is often referred to as Paris's law. In region III, crack

growth is accelerated. Even if the applied stress amplitude $\Delta\sigma$ is constant, ΔK shows a rapid increase due to fast crack extension and the increased ΔK enhances the acceleration in crack growth. When the $K_{max} [= \Delta K/(1-R)]$ reaches the fracture toughness of the material K_c , the crack growth transforms into instability, which corresponds to an infinite value in da/dN .

The **ASTM** has standardized the measurement methodology for the fatigue crack propagation rate based on fracture mechanics since 1978 [7.250]. The following is a summary of the **ASTM** standard E 647. The compact tension C(T) specimen with a side-edge crack and the middle tension specimen M(T) with a center crack are prescribed. The configurations of

Fig. 7.94 Calculation of %CG HAZ sampled by the fatigue pre-crack tip. (After [7.245])

the C(T) and M(T) specimens are shown in Figs. 7.96 and 7.97, respectively. The C(T) specimen is recommended only for tension–tension loading while the M(T) specimen can be loaded in either tension–tension or tension–compression. The configurations of both specimens are given with proportional dimensions of the specimen width W . The C(T) specimen prescribed here has the same configuration as the C(T) specimen in the toughness measurement except for the specimen thickness B . It is not necessary to adopt a large thickness in the fatigue crack growth, because the plane-strain concept is not required in the da/dN measurement. Small specimen thicknesses are rather better because a thumbnail crack front possibly enhances the uncertainty in the measurement of the crack length. From these points of view, the specimen thickness requirement in a fatigue crack growth measurement can be flexibly chosen within the recommended range.

Fig. 7.95 Schematic relation between stress intensity range ΔK and crack growth rate da/dN

Fig. 7.96 Compact tension C(T) specimen

The formula for the stress-intensity factor K for each type of specimen is given in the standard, being a function of the specimen dimensions and applied load P . It is the ΔK that is calculated from the positive component of an applied load amplitude ΔP [referring to (7.116)] and an extending crack length $a (= a_0 + \Delta a)$.

A sharpened starter crack must be introduced by fatigue from a machined notch. Sufficient size and straightness of a fatigue crack must be kept to eliminate the effect of the machined starter notch on the K calibration and the effect of the crack-front shape on the

subsequent crack growth rate data. The machined notch outline must lie within the 30° angled lines whose apex is at the end of the fatigue pre-crack shown in Fig. 7.98. The length of the pre-crack should not be less than $0.1 B$, h or 1 mm , whichever is greater. The K_{\max} value during the fatigue loading for pre-cracking must be suppressed below the initial K_{\max} value for which the da/dN data are of interest. Pre-cracking growth rates less than 10^{-8} m/cycle are suggested, especially when near-threshold growth rates are to be obtained. The pre-crack sizes measured on the front and back surfaces must not differ by more than $0.25 B$.

In da/dN measurements, the crack extension should be measured as a function of elapsed cycles under a controlled load amplitude. The crack can be visually measured with a traveling microscope. The compliance variation that is the crack opening displacement response for a specified load and the electric potential difference can be also used to estimate the crack growth, similarly to the detection of the J_{Ic} test methodology prescribed in ASTM E 1820 [7.236]. Bisual measurement is recommended, together with either the compliance technique or the electric potential-difference technique. In all methods, a minimum resolution below 0.1 mm or $0.002 W$ (whichever is greater) is required. Crack size extension is measured at a Δa interval larger than 0.25 mm . However, the Δa measurement in each crack extension of 0.25 mm is sometimes difficult in near-threshold (ΔK_{th}) testing, where it is required that there are at least five da/dN data points despite the fact that crack extension has almost stopped. In this case, the measuring interval Δa can be reduced by ten times the crack size measurement precision.

A loading procedure with either ΔK increasing or ΔK decreasing must be selected, depending on the da/dN value that is to be measured. The ΔK -increasing procedure is well suited to fatigue crack growth rates above 10^{-8} m/cycle . However, it becomes gradually more difficult for small initial da/dN values because the applied ΔK should be smaller than that in the pre-cracking.

The ΔK -decreasing test procedure can be conducted for rates below 10^{-8} m/cycle . In the ΔK -increasing test procedure, an applied load range (ΔP) and other loading variables (stress ratio and frequency) are fixed constant. The schematic variation of the ΔK value and the crack growth Δa as a function of elapsed cycles are shown in Fig. 7.99a.

In the ΔK -decreasing test procedure for da/dN measurements below 10^{-8} m/cycle , ΔK and K_{\max} must start from a level equal to or greater than the termi-

Fig. 7.97 Middle tension M(T) specimen

Fig. 7.98a,b Examples of fatigue pre-crack from machined notch. (a) ΔK -increasing test, (b) ΔK -decreasing test

nal pre-cracking values. Subsequently, the load ΔP is shed as the crack grows, until the lowest ΔK or crack growth rate of interest is reached. Load shedding is usually performed as decreasing load steps at specified crack size intervals, as shown in Fig. 7.99b. The shedding of load should be gradual enough to preclude anomalous data resulting from sudden reductions in the stress-intensity range. The load reduction in each shedding step should not exceed 10% of the maximum load P_{\max} in the previous load step. After a step reduction, a minimum crack extension of 0.5 mm is recommended. The da/dN measured using these shedding rules sometimes

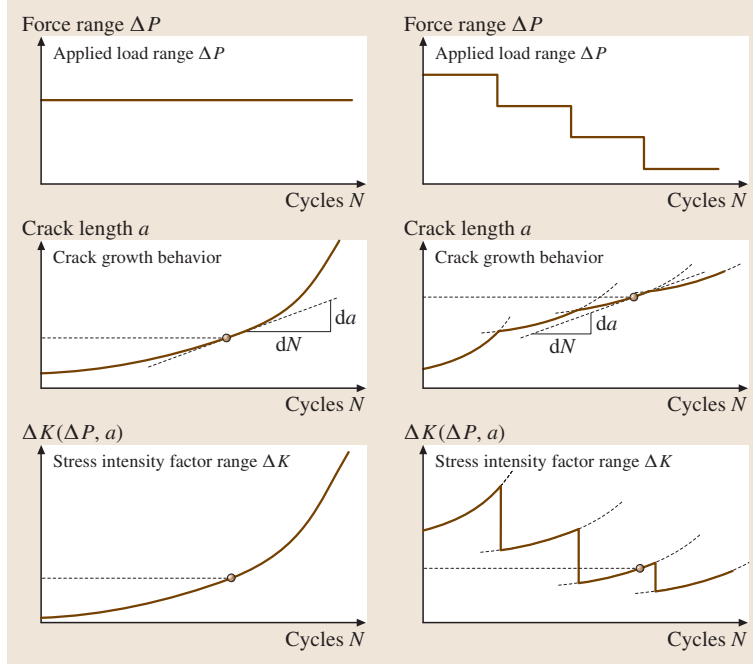

Fig. 7.99 Correspondences of applied load with crack growth and stress-intensity factor range

shows a trace different from the true material properties, as shown in Fig. 7.95. This mainly results from strain hardening and compressive residual stress in the crack-tip plastic zone formed in the previous load step. This mis-measured da/dN - ΔK relation usually gives an overestimation in the fatigue crack growth resistance of the materials.

The crack growth rate is determined from the crack size versus elapsed loading cycles data (a - N curve). The secant and incremental polynomial methods are recommended. Both methods are suitable for the ΔK -increasing test. For the ΔK -decreasing tests, where load is shed in decremented steps, the secant method is recommended. A crack growth rate determination should not be made over any increment of crack extensions that include a load step. The secant method simply involves a calculation of the slope of the straight line joining two adjacent data points on the a - N curve. It is formally expressed as follows;

$$(da/dN)_{\bar{a}} = (a_{i+1} - a_i) / (N_{i+1} - N_i). \quad (7.118)$$

Since the da/dN value calculated in this way is an average rate over the $a_{i+1} - a_i$ increment, the average crack size $\bar{a} = (a_{i+1} + a_i)/2$ is used to calculate ΔK . On the other hand, the incremental polynomial method involves fitting a second-order polynomial to a set of $(2n + 1)$ successive data points, where n is usually taken

to be 1–4. The form of the equation for the local fit is as follows:

$$\hat{a}_i = b_0 + b_1(N_i - C_1)/C_2 + b_2[(N_i - C_1)/C_2]^2, \quad (7.119)$$

where $-1 \leq (N_i - C_1)/C_2 \leq +1$ and b_0 , b_1 , and b_2 are the regression parameters that are determined by the least-square approximations over the range $a_{i-n} \leq a \leq a_{i+n}$. The value \hat{a}_i is the fitted value of the crack size at N_i . The parameters $C_1 = (N_{i-n} + N_{i+n})$ and $C_2 = (N_{i-n} - N_{i+n})$ are used to scale the input data. The crack growth rate da/dN at N_i is calculated from the derivative of the parabola above, as follows:

$$(da/dN)_{\hat{a}_i} = b_1/C_2 + 2b_2(N_i - C_1)/C_2^2. \quad (7.120)$$

The ΔK value associated with this da/dN value is calculated using the fitted crack size \hat{a}_i corresponding to N_i .

Both recommended methods can give the same average da/dN response. However, the secant method often results in increased scatter in da/dN relative to the incremental polynomial method, since the latter numerically smoothes the data.

The K_{\max} value of all data must be examined within the linear elastic fracture mechanics. When the data satisfy the specimen size requirements below, the specimen

can be predominantly identified as elastic.

$$W - a \geq (4/\pi)(K_{\max}/\sigma_Y)^2 \text{ for a C(T) specimen,}$$

$$W - 2a \geq 1.25 P_{\max}/(B\sigma_Y) \text{ for an M(T) specimen.}$$

(7.121)

This specimen size requirement here is rather more relaxed than that in the fracture toughness K_{Ic} for unstable fracture prescribed in ASTM E-399 [7.231].

The relation as shown in Fig. 7.95 appears on the log-log graph plots between da/dN and valid ΔK . At least five data points of approximately equal spacing at growth rates 10^{-9} – 10^{-10} m/cycle are needed to determine the threshold value of ΔK , denoted by ΔK_{th} .

The best-fit straight line from a linear relation of $\log da/dN$ versus $\log \Delta K$ using a minimum of five data points of approximately equal spacing at growth rates of 10^{-9} – 10^{-10} m/cycle. The ΔK_{th} value is determined from the ΔK that corresponds to a growth rate of 10^{-10} m/cycle on the fitted line.

The da/dN – ΔK relation and/or the ΔK_{th} value, which are measured with laboratory specimens, can be applied to the crack growth assessment of the structures. As ΔK is a function of both an applied stress range and a crack length, an integration of the da/dN – ΔK relation or (7.117) with an assumed initial crack size predicts the crack growth for a elapsed loading cycles in service. When the calculated ΔK for a stress range in service and an initial crack size is smaller than the ΔK_{th} value, no crack growth is predicted.

However, it is necessary to examine the crack closure effect in testing. Compressive residual stress and/or crack deflection often suppress crack-tip opening in spite of the applied tensile load. The effective stress-intensity factor range for a crack-tip opening of ΔK_{eff} is smaller than the apparent value, which enhances the overestimation in the ΔK_{th} value of the material. The da/dN – ΔK_{eff} relation is sometimes evaluated using the compliance variation procedure or the high-stress-ratio loading.

The effect of small cracks in practical applications should also be considered. When an initial crack in a structure is smaller than a certain crack size, the crack sometimes behaves differently from Fig. 7.95. Even for smaller values of ΔK than ΔK_{th} , small cracks can grow. da/dN for a small crack is generally faster than the value of da/dN estimated using the long-crack method, even for the same ΔK . This small-crack effect may result from both the effect of discontinuities in the microstructure and limitations of fracture mechanics.

Fig. 7.101a–d SEM micrographs for most common fracture appearances: (a) microvoid coalescence fracture/dimple pattern; (b) microvoid coalescence fracture/dimple pattern; (c) cleavage fracture/river pattern; (d) Intergranular fracture

7.5.4 Fractography

Important information can be obtained from microscopic examination of the fractured surface. This study is usually called fractography. The scanning electron

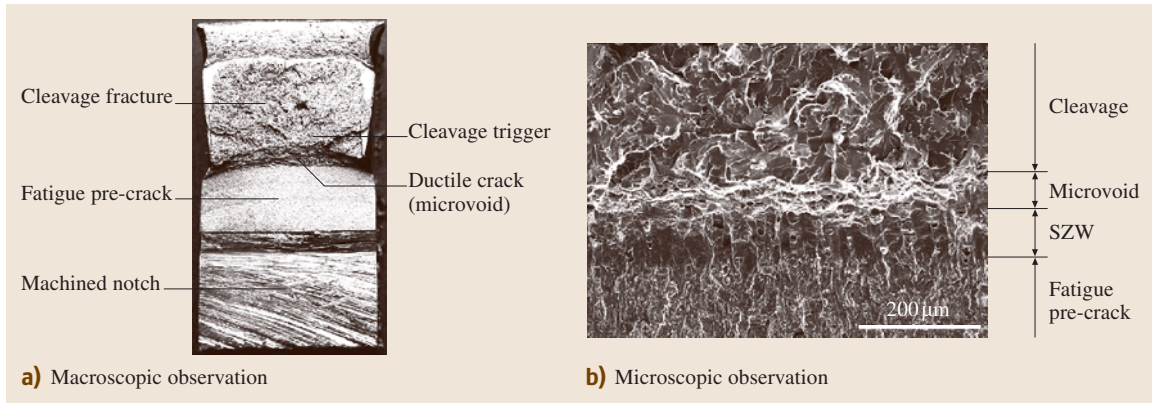

Fig. 7.102a,b Fracture appearance of toughness specimen in low carbon steel: (a) macroscopic observation, and (b) microscopic observation

microscope (SEM) is commonly employed in fractography because of its large depth of focus. Fractography is sometimes applied in order to find the cause of accidental failures.

Figure 7.100 shows schematically three of the most common fracture mechanisms, which are caused by monotonic tension in metallic engineering materials.

Ductile materials usually show microvoid coalescence type of fracture, shown in Fig. 7.100a. Microvoids nucleate at second-phase particles or inclusions due to either interface decohesion or particle cracking. After growth of the voids, adjacent voids coalesce due to ligament fracture. The appearance of the fracture is characterized by the *dimples* shown in Fig. 7.101a. In material with many inclusions, the dimple size on the fracture surface is small because they coalesce easily (Fig. 7.101b).

The BCC and hexagonal close-packed (HCP) crystalline systems have cleavage planes along specific crystallographic planes. Once cleavage fracture is triggered, a crack along a cleavage plane propagates unstably. The propagating crack changes its direction each time it crosses a grain boundary, as shown in Fig. 7.100b. Figure 7.101c shows the appearance of the fracture, observed by an SEM. The fracture surface consists of several flat facets. The facet edges converge to a single line like tributaries of a river. When a propagating cleavage crack encounters a grain boundary, the nearest cleavage-plane angle in the adjacent grain is often oriented at a twist angle to the current cleavage plane. Cracking in a number of parallel cleavage planes just beyond a grain boundary accommodates the twisted-angle mismatch. This river pattern is caused by the convergence of multiple

cracks into a single crack during its propagation within a grain.

Under special circumstances, cracks can propagate along grain boundaries, as shown in Fig. 7.100c. This intergranular fracture sometimes appears when the strength of the grain boundary is weakened by the following mechanisms: segregation of embrittling elements or precipitation of a brittle phase on the grain boundary, grain-boundary cavitation at elevated temperature, or attack of the grain boundary by corrosion or hydrogen. The grain boundary, which looks like rock candy, is shown under SEM observation in Fig. 7.101d.

The macroscopic appearance of fractures such as the ductile and brittle types described do not necessarily correspond to the microscopic fracture. In low-carbon steels, however, ductile fracture is generally caused by microvoid coalescence, and cleavage fracture leads to brittle fracture with less ductility.

In fracture toughness tests for low-carbon steels, cleavage fracture is often triggered after a certain crack extension due to microvoid coalescence. Figure 7.102a shows the macroscopic appearance of a fracture toughness specimen obtained at the ductile–brittle transition temperature. The dark thumbnail area following the fatigue pre-crack shows stable crack extension due to microvoid coalescence. A triggered cleavage crack at the ductile crack tip propagates unstably. Figure 7.102b shows the fracture appearance transition observed by SEM. The stretched zone (SZ) can be observed between the fatigue pre-crack and the ductile crack. The SZ is not caused by fracture, but by a blunting deformation of the fatigue pre-crack. The stretched zone (SZ) conceptually corresponds to the crack-tip opening displacement CTOD. The fracture toughness of material can be esti-

Fig. 7.103 Plastic blunting process for striation formation. (After [7.251])

mated from the depth and/or the width of the stretched zone on the fracture surface.

Fatigue crack propagation often produces *striations* on the fractured surface. Figure 7.103 shows one of the proposed mechanisms for striation formation [7.251]. When the tensile stress is applied, the crack tip is blunted due to the concentrated slip deformation (Fig. 7.103b). The fatigue crack incrementally extends as a result of the formation of this stretched zone. When the stress changes to compression, the slip direction at the crack tip is reversed (Fig. 7.103c). This process causes the buckling to form a resharpened crack tip. The ripples left by these process above can be observed as striations.

Figure 7.104 shows typical striations for aluminum alloy and steel. Striations are formed in a similar manner

Fig. 7.104a,b Fatigue striations in: (a) aluminum alloy, and (b) steel

in materials with plasticity. According to the mechanism in Fig. 7.103, the striation spacing is equal to the crack growth rate da/dN .

7.6 Permeation and Diffusion

The diffusion of small molecules in materials has attracted significant interest, primarily because it is of great significance to many applications in the chemical, petrochemical and medical industries [7.252, 253]. For example, a polymer matrix has the ability to exhibit different permeation rates for various chemical species, thus providing the basis for separation [7.252]. Current applications include water desalination, gas and vapor purification, and medical applications such as controlled-release devices and the artificial kidney [7.252, 253]. Separations using membranes have inherent advantages over conventional separation technologies, including low energy cost (since no phase transition is involved in the separation), high reliability (no moving parts) and small footprint [7.254]. Of particular interest are gas separations, where polymeric membranes behave as molecular filters. For example, an O_2/N_2 selectivity of 5.9 can be achieved in poly-

meric membranes such as polysulfone, even though the kinetic diameter difference between O_2 and N_2 is only 0.018 nm [7.255]. Additionally, if a polymeric material is not very permeable to penetrants such as O_2 and H_2O , it acts as a barrier, which can be useful for packaging applications [7.256].

This section reviews experimental techniques used to study gas and vapor sorption, diffusion and permeation in polymeric films. The more detailed fundamental theory and industrial applications pertinent to gas transport in polymers are available in several books [7.257–260] and review articles [7.261–263]. Specific reviews of experimental methods to measure gas transport properties are also available [7.264–267]. In particular, *Felder and Huvar* reviewed experimental methods from a historical perspective and critically evaluated the strengths and weaknesses of the various techniques in 1980 [7.264]. Without intending to review the subjective exhaustively,

the main objective of this section is to provide readers with a self-consistent set of manual-like instructions to choose and design the most suitable and reliable experimental techniques for specific systems based on our laboratory's experience.

7.6.1 Gas Transport: Steady-State Permeation

Gas transport through a dense or nonporous polymeric film is often described by the solution–diffusion mechanism [7.268]. As illustrated in Fig. 7.105, feed gas at a high (i. e., upstream) pressure p_2 dissolves into the feed-side surface of the film, diffuses through the film due to a concentration gradient, and finally desorbs from the permeate-side surface at the downstream (i. e., low pressure) face of the film. In the absence of chemical reaction between the gas and polymer, the diffusion of dissolved penetrant is the rate-limiting step in this process. The one-dimensional flux of gas A through the film in the x -direction (i. e., N_A) can be described by Fick's Law [7.263, 269]

$$N_A = -D \frac{dC_A}{dx} + w_A(N_A + N_P), \quad (7.122)$$

where D is the gas diffusion coefficient in the film, C_A is the local concentration of dissolved gas and w_A is the weight fraction of gas A in the film; N_P is the flux of the membrane, which is typically taken to be zero. Consequently, (7.122) reduces to [7.263]

$$N_A = -\frac{D}{1 - w_A} \frac{dC_A}{dx} \quad (7.123)$$

Steady-State Permeation

The steady-state permeability of gas A, P_A , through a film of thickness l is defined as [7.261, 263, 270]

$$P_A \equiv \frac{N_A l}{p_2 - p_1}, \quad (7.124)$$

where p_2 and p_1 are the upstream (i. e., high) and downstream (i. e., low) pressures, respectively. Permeability coefficients are commonly expressed in Barrers, where $1 \text{ Barrer} = 1 \times 10^{-10} \text{ cm}^3(\text{STP}) \text{ cm/cm}^2 \text{ s cmHg}$. Combining (7.123) and (7.124) and integrating from $x = 0$ ($C = C_2$) to $x = l$ ($C = C_1$), one obtains:

$$P_A = D_A \frac{C_2 - C_1}{p_2 - p_1}, \quad (7.125)$$

Fig. 7.105 Transport of gases A and B across a membrane

where D_A is the concentration-averaged effective diffusion coefficient in the range C_1 – C_2 :

$$\begin{aligned} D_A &= \frac{1}{C_2 - C_1} \int_{C_1}^{C_2} \frac{D}{1 - w_A} dC \\ &= \frac{1}{C_2 - C_1} \int_{C_1}^{C_2} D_{\text{eff}} dC, \end{aligned} \quad (7.126)$$

where D_{eff} is the local effective diffusion coefficient.

In general, it can be challenging to measure the average gas diffusivity directly. Instead, gas permeability and gas solubility are often measured independently, and gas diffusivity is inferred from these measurements, as described below. For simplicity, experiments are often designed so that $p_1 \ll p_2$ and, consequently, $C_1 \ll C_2$. In this limit, (7.125) reduces to:

$$P_A = D_A \times S_A, \quad (7.127)$$

where $S_A = C_2/p_2$ is the apparent sorption coefficient or solubility of penetrant A in the polymer. Therefore, by measuring the gas permeability at an upstream pressure of p_2 and solubility at a pressure of p_2 , one can calculate the average gas diffusivity D_A . As indicated in (7.126), this diffusion coefficient is an average over the concentration range 0 – C_2 . The local effective diffusion coefficient D_{eff} , characterizing the penetrant diffusivity in the polymer at a penetrant concentration of C_2 , can be evaluated using an equation obtained by taking the derivative of both sides of (7.125) with respect to

C [7.271]

$$D_{\text{eff}}(C_2) = \left(P_A + p \frac{dP_A}{dp} \right)_{p_2} \left(\frac{dp}{dC_2} \right)_{p_2}, \quad (7.128)$$

which requires the pressure dependence of the permeability and solubility to calculate D_{eff} . Methods to measure pressure dependence of permeability and solubility are discussed in this chapter.

Gas sorption isotherms in polymers are typically described using simple models, such as Henry's law, the Flory–Huggins theory or the dual-mode sorption model [7.263]. These models have been extensively investigated in the literature [7.272] and, therefore, will only be briefly introduced. Once the gas sorption in a polymer has been measured, values of dp/dC_2 can be easily calculated for use in (7.128).

Henry's law corresponds to a linear relationship between C and p [7.273]

$$C = k_D p, \quad (7.129)$$

where k_D is the solubility coefficient, or Henry's law constant. This equation is typically valid for light gas sorption in rubbery polymers at low concentrations, such as $1 \text{ cm}^3(\text{STP})/\text{cm}^3$ polymer. For example, N_2 and O_2 sorption in poly(dimethylsiloxane) (PDMS) at 35°C obey Henry's law over a rather wide pressure range [7.271].

For highly sorbing penetrants in rubbery polymers, such as organic vapors, penetrant concentration in the polymer is often described using the Flory–Huggins model [7.273]

$$\ln a = \ln \phi_2 + (1 - \phi_2) + \chi(1 - \phi_2)^2, \quad (7.130)$$

where a is the penetrant activity, χ is the Flory–Huggins interaction parameter, and ϕ_2 is the volume fraction of penetrant dissolved in the polymer matrix. For ideal gases, the activity is equal to p/p_0 , where p_0 is the penetrant vapor pressure at the experiment temperature. The volume fraction ϕ_2 is given by [7.273].

$$\phi_2 = \frac{(C/22\,414)V_2}{1 + (C/22\,414)V_2}, \quad (7.131)$$

where V_2 is the partial molar volume (cm^3/mol) of the penetrant in the polymer, and C has units of $\text{cm}^3(\text{STP})/(\text{cm}^3 \text{ polymer})$. For low concentrations of sorbed gas, $\phi_2 \ll 1$, (7.130) and (7.131) reduce to Henry's law [7.274]. For high concentrations of sorbed gas, this model predicts an increasing value of solubility (i. e., C/p) as pressure increases. Equation (7.130)

successfully describes the sorption of strongly sorbing penetrants in rubbery polymers, such as CO_2 in poly(ethylene oxide) at 35°C [7.274].

The dual-mode sorption model was originally used to describe gas sorption in glassy polymers, which contain both equilibrium volume (i. e., Henry's law sorption sites) and nonequilibrium excess volume (i. e., microvoids or Langmuir sorption sites). The model is expressed as follows [7.275]

$$C = C_D + C_H = k_D p + \frac{C'_H b p}{1 + b p}, \quad (7.132)$$

where C_D and C_H are the gas concentrations in the Henry's law sorption sites and Langmuir sites, respectively, b is the Langmuir affinity constant, which characterizes the affinity between penetrants and microvoids, and C'_H is the Langmuir capacity constant [$\text{cm}^3(\text{STP})/\text{cm}^3$ polymer], which characterizes the maximum sorption capacity of the nonequilibrium excess volume. This model has also been applied to describe the gas sorption in hybrid systems such as blends of rubbery polymers and additives [7.276, 277]. These additives could be fillers that physically adsorb the gas or dissolved species that chemically interact with the gas.

The dependence of permeability on pressure is often described using empirical equations. For example, the following equation is often used to describe the pressure dependence of gas permeability in rubbery polymers [7.271, 274]

$$P_A = P_{A0}(1 + m \Delta p), \quad (7.133)$$

where P_{A0} and m are constants, and $\Delta p = p_2 - p_1$. For glassy polymers at $p_1 = 0$ (or, equivalently, $\Delta p = p_2$), the following equation, based on the dual-mode model, has been used [7.278]

$$P_A = k_D D \left(1 + \frac{FK}{1 + b p_2} \right), \quad (7.134)$$

where $K = C'_H b / k_D$, and D and F are constants obtained by fitting the model to experimental sorption and permeation data. For example, Koros and coworkers obtained k_D , b and C'_H by fitting gas sorption isotherms to (7.132) and then fitting the permeability data at various upstream pressures to (7.134) to obtain D and F [7.278]. Equation (7.133) or (7.134) can be used to calculate dP_A/dp , which can be substituted into (7.128) along with dp/dC_2 to calculate D_{eff} .

The ideal selectivity of a membrane for gas A over gas B (i. e., $\alpha_{A/B}$) is the ratio of their pure-gas perme-

abilities [7.261]

$$\alpha_{A/B} = \frac{P_A}{P_B} = \left(\frac{D_A}{D_B}\right) \times \left(\frac{S_A}{S_B}\right), \quad (7.135)$$

where D_A/D_B is the diffusivity selectivity, which is the ratio of the diffusion coefficients of gases A and B. The ratio of the solubility coefficients of gases A and B, S_A/S_B , is the solubility selectivity. For a binary gas mixture, the selectivity of gas A to gas B ($\alpha_{A/B}^*$) is defined as

$$\alpha_{A/B}^* \equiv \frac{y_A/y_B}{x_A/x_B} = \alpha_{A/B} \frac{\Delta p_A/x_A}{\Delta p_B/x_B}, \quad (7.136)$$

where y_i and x_i are the mole fractions of component i in the upstream and downstream gas phases, respectively, and Δp_i is the partial pressure difference of component i across the membrane. When the downstream pressure is much less than the upstream pressure, $\alpha_{A/B}^*$ approaches the ideal separation factor $\alpha_{A/B}$.

7.6.2 Kinetic Measurement

The kinetics of gas transport through a thin uniform film have been modeled, and such measurements can yield solubility, diffusivity and permeability in a single experiment. The penetrant concentration as a function of time and position in the film is given by Fick's second law [7.269]

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x} \left(D_{\text{eff}} \frac{\partial C}{\partial x} \right). \quad (7.137)$$

The analytical solution of (7.137) depends on initial conditions, boundary conditions and the concentration dependence of the diffusion coefficient, if any. The diffusion coefficient could be a function of concentration, which makes the solution to (7.137) more complex [7.260]. However, Crank and Park have shown that solutions to (7.137) assuming constant D_{eff} values are also applicable when the diffusion coefficient depends on concentration [7.267]. In general, this approximation is sufficiently accurate to model experimental data [7.267], except that the diffusion coefficient obtained from such an analysis should be interpreted as an average effective diffusion coefficient as defined in (7.126).

Constant Diffusion Coefficient

In the simplest scenario, the gas diffusion coefficient is constant over the concentration range of interest. This assumption is usually valid for low-sorbing penetrants in rubbery polymers. However, care must be taken

since gas diffusion coefficients can exhibit concentration dependence at concentrations where gas sorption still obeys Henry's law, i. e., when gas solubility is independent of pressure [7.279]. Nevertheless, in a typical experiment, initially (i. e., at $t = 0$) the membrane is at a uniform concentration C_0 . At $t > 0$, one face ($x = 0$) of the membrane is exposed to a constant concentration C_2 by changing the gas pressure in contact with the membrane, and the other face at $x = l$ is exposed to C_1 [7.260]. The analytical solution to (7.137) under these conditions is [7.260]

$$\begin{aligned} C = & C_2 + (C_1 - C_2) \frac{x}{l} \\ & + \frac{2}{\pi} \sum_{n=1}^{\infty} \frac{C_1 \cos n\pi - C_2}{n} \\ & \times \sin\left(\frac{n\pi x}{l}\right) \exp(-Dn^2\pi^2 t/l^2) \\ & + \frac{4C_0}{\pi} \sum_{m=0}^{\infty} \frac{1}{2m+1} \sin\left(\frac{(2m+1)\pi x}{l}\right) \\ & \times \exp[-D(2m+1)^2\pi^2 t/l^2]. \end{aligned} \quad (7.138)$$

The direct measurement of penetrant concentration in the film as a function of position and time is very difficult and is usually not done. Instead, a much more straightforward experiment, measurement of the gas flux out of the film is usually performed. Two methods are typically used to monitor this kinetic process: (1) transient permeation, and (2) sorption (or desorption).

In a transient permeation study, C_0 and C_1 are zero. The gas molecules diffusing out of the membrane at $x = l$ (i. e., the downstream side) are collected in a closed volume of known size. The gas flux [i. e., $-D(\partial C/\partial x)_{x=l}$] can be easily calculated from the rate of gas accumulation in the closed volume. The total amount of gas transported across the membrane at time t , Q_t , is given by:

$$\begin{aligned} Q_t = & \int_0^t -D \left(\frac{\partial C}{\partial x} \right)_{x=l} dt \\ = & \frac{DtC_2}{l} - \frac{lC_2}{6} - \frac{2lC_2}{\pi^2} \\ & \times \sum_{n=1}^{\infty} \frac{(-1)^n}{n^2} \exp(-Dn^2\pi^2 t/l^2), \end{aligned} \quad (7.139)$$

which reduces to the following equation when the gas flux reaches a steady state or, equivalently, as $t \rightarrow \infty$:

$$Q_t = \frac{DC_2}{l} \left(t - \frac{l^2}{6D} \right). \quad (7.140)$$

Fig. 7.106 A typical curve for the amount of accumulated permeate Q_t as a function of time in a transient permeation experiment

A typical curve for the amount of accumulated gas as a function of time appears in Fig. 7.106. The intercept of the steady-state region of Q_t with the time axis (i. e., $l^2/6D$) is defined as the time lag θ . The diffusion coefficient is given by:

$$D = l^2/6\theta \quad (7.141)$$

The above theoretical analysis was developed by *Daynes* in 1920 [7.280]. In 1939, *Barrer* and coworkers reported a system to measure the time lag and steady-state flow in polymers. Using this instrument, permeability, diffusivity and solubility can be estimated from a single experiment [7.281].

In a kinetic sorption or desorption study, the migration of gas into or out of a film is monitored by measuring the weight change of the polymer film containing the sorbed gas as a function of time. Typically, a polymer film with an initial gas concentration C_0 is suddenly exposed to an environment with a constant gas pressure p_2 , i. e., at $t > 0$, $C = C_2$ at $x = 0$ and l . C_2 is the concentration of gas in the polymer in equilibrium with the applied gas pressure p_2 . When $C_2 > C_0$, sorption occurs, and penetrant diffuses into the film. Desorption happens when $C_2 < C_0$. The kinetics of these processes are given by [7.260]

$$\begin{aligned} \frac{M_t}{M_\infty} &= 1 - \frac{8}{\pi^2} \sum_{n=0}^{\infty} \frac{1}{(2n+1)^2} \exp[-D(2n+1)^2 \pi^2 t / l^2], \end{aligned} \quad (7.142)$$

where M_t and M_∞ denote the total amount of penetrant sorbed or desorbed in the film at time t and at equilib-

rium, respectively. For a film of cross-sectional area A and thickness l , M_t is given by:

$$M_t = \left| A \int_0^l C(x, t) dx - C_0 A l \right| \quad (7.143)$$

and M_∞ is given by:

$$M_\infty = |C_2 - C_1| A l. \quad (7.144)$$

Therefore, by determining the weight change of the sample with time, diffusion coefficients can be obtained by fitting the experimental data to (7.142). When $M_t/M_\infty > 0.7$, all terms with $n > 0$ in (7.142) can be neglected, and (7.142) becomes:

$$\frac{M_t}{M_\infty} = 1 - \frac{8}{\pi^2} \exp(-D\pi^2 t / l^2), \quad (7.145)$$

which can be rearranged to [7.260]

$$\ln(1 - M_t/M_\infty) = \ln \frac{8}{\pi^2} - \frac{D\pi^2}{l^2} t. \quad (7.146)$$

In this way, the diffusion coefficient can be easily obtained by fitting the experimental data to (7.146).

Another way to analyze kinetic sorption data is based on an alternative analytical solution to (7.138), which is [7.260]

$$\begin{aligned} \frac{M_t}{M_\infty} &= 2 \left(\frac{Dt}{l^2} \right)^{1/2} \left[\pi^{-1/2} \right. \\ &\quad \left. + 2 \sum_{n=1}^{\infty} (-1)^n \operatorname{erfc} \frac{nl}{\sqrt{Dt}} \right]. \end{aligned} \quad (7.147)$$

The above solution can be simplified to the following equation at short times (i. e., $M_t/M_\infty < 0.6$):

$$\frac{M_t}{M_\infty} = \left(\frac{16D}{\pi l^2} \right)^{1/2} t^{1/2}. \quad (7.148)$$

Equation (7.148) predicts that the amount of penetrant sorbed or desorbed exhibits a linear dependence on $t^{1/2}$, and the diffusion coefficient can be calculated from the slope of the fractional uptake (or desorption) kinetics versus $t^{1/2}$.

In general, penetrant solubility can be derived from M_∞ and the initial concentration C_0 :

$$S_A = \frac{1}{p_2} \left(C_0 \pm \frac{M_\infty}{Al} \right), \quad (7.149)$$

where p_2 is the gas-phase pressure at equilibrium. The “+” sign is for sorption, and the “−” sign is for desorption.

Variable Diffusion Coefficient

In many situations, penetrant diffusion coefficients vary with concentration [7.260]. For example, strongly sorbing penetrants in rubbery or glassy polymers often swell the polymer at sufficiently high activity, leading to changes in polymer properties (e.g., glass-transition temperature, fractional free volume, etc.) and penetrant diffusion coefficients [7.263]. *Frisch* developed an explicit expression for the time lag when the diffusion coefficient is concentration-dependent [7.282]. *Crank* treated this subject in detail using both analytical and numerical methods [7.260]. Strictly speaking, most of these treatments require knowledge of the functional form of the relationship between diffusion coefficient and concentration [7.260]. In contrast, the steady-state measurements discussed in Sect. 7.6.1 can provide a reliable way to evaluate diffusion, solubility and permeability coefficients without making a priori assumptions regarding the concentration dependence of the diffusion coefficient.

Various experimental approaches have been reported to measure gas transport through polymeric films. In principle, most of the techniques directly measure gas flux through the film or gas uptake by the film (i.e., solubility). Diffusion coefficients are typically derived indirectly from permeability and solubility measurements based on the theory introduced earlier. In the following sections, general strategies are described for measuring gas transport properties in polymers.

7.6.3 Experimental Measurement of Permeability

Film Preparation

The measurement of gas flux requires the successful preparation of a uniform, nonporous thin film. In general, polymer films for permeation testing have thicknesses of less than 250 μm , unless special situations require a thicker film. For example, thicker films may make it easier to prepare nonporous specimens for study, or they may be used to increase the time lag when studying penetrants with high diffusion coefficients (e.g., He or H_2). Uniformity of thickness is important for reducing the uncertainty in permeability, as illustrated in (7.124). A nonporous film is required if one wishes to determine the inherent properties of the material under study, because gas flow through a pinhole obeying Knudsen diffusion can be orders of magnitude faster than that through a dense film obeying the solution-diffusion mechanism [7.257]. Thus, any pinhole defects in a sample can compromise the accurate measurement of gas

flux through a polymer film. The first challenge in successfully measuring gas permeation properties typically lies in the ability to prepare uniform, pinhole-free films.

Polymer films are typically prepared in the laboratory by melt-pressing and solvent-casting [7.283, 284]. Melt-pressing is used less often than solvent-casting to prepare films for study. In melt-pressing, one applies heat to melt a polymer powder, and then a film is made by pressing the molten polymer under high pressure. Solvent-casting is a widely used method to prepare films. In this method, solid polymer is dissolved in a solvent, the resulting solution is cast on a leveled support, and the solvent is allowed to evaporate slowly, leaving a solid film behind. Gas permeation properties of films are often influenced by many processing factors. One critical factor is the solvent used in preparing the film, which can strongly affect polymer morphology and, in turn, gas permeation properties. For example, poly(4-methyl-1-pentene) films were prepared by solvent-casting using chloroform and carbon tetrachloride [7.284]. The N_2 permeability at 35 $^\circ\text{C}$ and 2 atm is 1.1 Barrers for a film prepared from chloroform solution, but it is 6.0 Barrers for a similar film prepared from carbon tetrachloride solution, even although the two films exhibit almost the same crystallinity values (i.e., 57% and 56%, respectively) [7.284]. Other possible factors influencing gas transport properties include polymer concentration, evaporation temperature, annealing conditions, etc. Pinholes in a solid film can be introduced during the solvent-casting process by bubbles present in the solution before casting, the presence of insoluble impurities in the solution (such as dust), and very rapid solvent evaporation. Typically, before casting, the solution is filtered to remove any impurities, and the solvent evaporation rate is controlled during film drying. For highly crystalline polymers such as poly(ethylene oxide), thermal annealing above the melting temperature could be critical to form defect-free films, although the reason for this is not clear [7.274].

Uniform thickness films can be obtained by spreading the solution onto a support using tools such as a Gardner knife or a doctor blade, which controls the liquid film thickness [7.283]. Alternatively, the solution may be poured into a glass ring resting on a flat solid support. The glass ring is typically stuck to the support using silicon caulk to achieve a leak-free boundary. The film thickness is controlled by the amount of liquid solution added and its concentration. The solid support needs to be leveled to obtain films of uniform thickness. The choice of the support material can be important. If the solution cannot wet the support, the liquid polymer

solution will bead up, and it will not form a continuous film. If the solid film adheres too strongly to the support, it can be difficult or impossible to remove the film intact from the support. Common supports are glass plates, Teflon plates, metal plates, plastic plates (which do not interact with the solvent) and even liquid surfaces such as water and mercury [7.283].

Permeation Cell

Gas permeability is the steady-state flux through a film normalized by the pressure difference and film thickness, as indicated in (7.124). Pressure is measured using commercial sensors or gauges with high precision in different pressure ranges. For example, Dresser Instruments (Shelton, USA) provides a digital indicator for pressure measurement with an accuracy of 0.025% of full scale over the pressure range 0–20 atm. Film thickness can be measured using a digital micrometer (Mitutoyo Corp., Japan), which can measure thickness to the nearest micrometer. To measure the thickness of rubbery polymers, the film should be covered with a uniform thin plate (quartz, glass or other flat, rigid materials) to prevent direct contact of the measuring tip of the digital micrometer with the soft film. The measurement tip can press into flexible films or even penetrate them; in either case, the thickness value provided by the micrometer is an underestimate of the true film thickness.

The gas flux through the film, which is the key parameter for permeability measurements, is typically measured from the permeate side ($x = l$) using a permeation cell. Figures 7.107a–c present schematics of typical permeation cell designs for constant-pressure variable-volume, constant-volume variable-pressure and mixed-gas systems, respectively. These cells are

commercially available from Millipore Corporation (Billerica, USA) under the tradename of high-pressure filter holder. A flat polymer film with the same size as the inner diameter of the cell is placed on a sintered-metal support inside the cell, dividing the system into upstream (i.e., above the film) and downstream (i.e., below the film) compartments. A silicon or Viton o-ring is often used to prevent gas leakage at the film edge from the upstream (i.e., high-pressure) to the downstream (i.e., low-pressure) side of the cell and to avoid gas exchange between the upstream portion of the cell and the exterior atmosphere. In this way, only the feed gas permeating through the film is collected in the downstream section of the cell. For a pure-gas study, the upstream portion of the cell can be designed as a dead end, and gas permeating into the downstream side of the film will be collected as illustrated in Fig. 7.107a and b. For mixed-gas studies, the gas flow pattern requires a special cell design to minimize gas composition changes in the upstream and downstream chambers of the permeation cell. The upstream gas enters the cell at the center of the film, flows radially to the film edge and then flows out of the cell, which eliminates any trapped gas or dead zones in the cell [7.285]. Typically, trapped gas does not mix well with the entering feed gas, which results in gas concentration variations across the film and, therefore, errors in estimating the partial pressure that the film experiences during the measurement. The design of the permeate side follows similar principles. Additionally, to reduce the change of feed gas composition during flow from the film center to the edge, due to the preferential permeation of a gas component, the gas flow rate in the upstream is much higher than the gas flow rate due to permeation through the film. Typically, the ratio of the

Fig. 7.107a–c Schematic of a typical permeation cell (a) for pure-gas measurements using the continuous flow method; (b) for pure-gas measurements using the constant-volume variable-pressure method and (c) for mixed-gas measurements

permeate gas flow rate to feed gas flow rate (the so-called stage cut) would be 1% or less.

Films are typically supported on filter paper and then on a sintered-metal support. In general, the mass transfer resistance of the paper and the metal support should be negligible relative to that of the polymer film so that the measured gas flux reflects only the inherent properties of the film. The practical film area available for gas diffusion is not the same as the area of the entire film, because the contact area between the o-ring and the film area is not accessible to gas diffusion. Typically, after the cell is clamped in place for measurements, the o-ring would leave an imprint on the film. The inside diameter of the imprint is often used to calculate the active test area. In many cases (for example, films that are too soft or viscous or when the area of the films is smaller than the cell size), films need to be partially masked using impermeable aluminum tape so that there is no direct contact of the o-ring with the films [7.274, 286, 287].

Temperature Control

Thermal uniformity is an important factor since gas permeability can depend strongly on temperature [7.264]. Two typical media are used as temperature-control fluids: air and liquids. An air bath can conveniently provide operational temperatures above room temperature. Such a system includes a fan to circulate air past a heating element and the permeation instrumentation, a heater element [which can be as simple as a light bulb for temperatures near ambient or commercially available heating elements from, for example, Omega Engineering Inc. (Stamford, USA)] and a temperature control system. Commercially available temperature controllers, such as a CN76000 microprocessor-based temperature/process controller made by Omega Engineering, work well for this purpose. A liquid bath, such as a mixture of methanol and water (50/50 by weight) can provide temperatures as low as -30°C . For low-temperature operations, cooling is typically accomplished using a chiller. Generally, good circulation in the bath is required to achieve a uniform temperature around the cell and other components of the measurement system.

7.6.4 Gas Flux Measurement

Gas flux is commonly measured using one of the following three methods: (1) constant-pressure variable-volume, (2) constant-volume variable-pressure and (3) a method using a special sensor for mixed-gas permeation measurements. These techniques are discussed below.

Constant-Pressure Variable-Volume Method

A schematic of a constant-pressure variable-volume (or continuous flow) permeation system is shown in Fig. 7.108. A schematic of a typical cell for such a system is given in Fig. 7.107b. The feed gas enters the cell and leaves in the residue stream, and the downstream is typically purged using the feed gas before beginning measurements to remove any impurities from the downstream. This apparatus operates by applying a target gas at a constant pressure to the upstream face of the film and measuring the resulting steady-state gas flux on the downstream side of the film or membrane being tested using a flow meter. Electronic flow meters are commercially available, such as the Agilent model ADM1000 (Wilmington, USA). However, a simple and convenient device is a soap-bubble flow meter (Alltech Associates, Inc. Deerfield, USA). By timing the movement of the soap film in a graduated capillary tube, the steady-state permeability $[\text{cm}^3 \text{ (STP) cm/cm}^2 \text{ s cmHg}]$ is given by:

$$P_A = \frac{l}{p_2 - p_1} \frac{273 p_{\text{atm}}}{T A 76} \left(\frac{dV}{dt} \right), \quad (7.150)$$

where the downstream pressure p_1 is atmospheric pressure (cmHg) in this case, p_{atm} is the atmospheric pressure (cmHg), T is the absolute temperature of the gas in the bubble flow meter (K), and dV/dt is the steady-state volumetric displacement rate of the soap film (cm^3/s). The accuracy of this method depends on the sensitivity of the bubble flow meter. Typically, the accuracy of the bubble flow meter becomes higher as the capillary tube diameter decreases. This method is typically used to study polymeric films with high gas fluxes, such as poly(dimethylsiloxane) (PDMS), poly(1-trimethylsilyl-1-propyne) (PTMSP) and composite membranes with

Fig. 7.108 Schematic of a constant-pressure variable volume apparatus for gas permeability measurements (R: regulator; P: pressure transducer). The parts within the dashed box are in a temperature-controlled chamber

very thin polymer coatings on porous membrane supports [7.288]. The authors have good experience with such materials and bubble flow meters with ranges such as 0–1.0 ml, 0–10 ml and 0–100 ml, which are made by Alltech Associates, Inc. (Deerfield, USA).

Constant-Volume Variable-Pressure Method

As illustrated in Fig. 7.109, a constant-volume variable-pressure system measures permeate flux by monitoring the pressure increase of collected permeate gas in a closed volume using a pressure transducer. A typical cell is presented in Fig. 7.107a. Unlike the cell used for the continuous-flow method, the cell used here does not require a residue or purge stream since any volatile impurities or air gases can be removed from the sample by exposing the whole system to vacuum prior to beginning a measurement. The apparatus operates by initially evacuating the upstream and downstream volumes to degas the film. Then the valve connecting the permeation cell to the vacuum pump is closed, and a slow pressure rise in the downstream volume (i. e., the leak rate of the system) is observed. This rate of pressure rise should be at least ten times less than the estimated steady-state rate of pressure rise due to permeation to obtain accurate permeability estimates. The feed gas is then introduced to the upstream side of the membrane, and the pressure rise in the downstream volume is recorded as a function of time. Gas permeability [$\text{cm}^3(\text{STP}) \text{ cm}/(\text{cm}^2 \text{ s cmHg})$] is calculated from the following expression [7.274, 289]

$$P_A = \frac{V_d l}{p_2 A R T} \left[\left(\frac{dp_1}{dt} \right)_{ss} - \left(\frac{dp_1}{dt} \right)_{\text{leak}} \right], \quad (7.151)$$

where V_d is the downstream volume (cm^3), l is the film thickness (cm), p_2 is the upstream absolute pressure (cmHg), A is the film area available for gas transport (cm^2), the gas constant R is $0.278 \text{ cmHg cm}^3/[\text{cm}^3(\text{STP}) \text{ K}]$, T is absolute temperature (K) and $(dp_1/dt)_{ss}$ and $(dp_1/dt)_{\text{leak}}$ are the steady-state rates of pressure rise (cmHg/s) in the downstream volume at fixed upstream pressure and under vacuum, respectively. The downstream pressure must be kept much lower than the upstream pressure to maintain an effectively constant pressure difference across the membrane. In our laboratory, the downstream pressure is typically lower than 0.03 atm, compared with a typical upstream pressure of 4.4 atm or more. If steady-state permeation cannot be achieved before the downstream pressure increases to a significant value, the downstream should be evacuated using the vacuum pump, and the recording of the pressure rise in the downstream volume is restarted. Additionally, the design of the downstream in Fig. 7.109

Fig. 7.109 Schematic of a constant-volume variable-pressure apparatus for gas permeability measurements (R: regulator; P: pressure transducer; V_0 , V_1 and V_2 : tubing volume, volumes 1 and 2, respectively). The parts within the dashed box are in a temperature-controlled chamber

allows one to choose a suitable downstream volume to achieve a reasonable rate of pressure rise for films of different fluxes. If the flux is rather low, the smallest volume (i. e., the volume of the downstream tubing only) can be used to observe the pressure rise. On the other hand, one or two additional volumes can be used if the flux is high.

In this method, the upstream and downstream pressures can be accurately measured using commercially available pressure gauges or transducers. The key parameter to be measured is the downstream volume, for example V_0 (defined as the tubing volume), which includes part of the permeation cell (i. e., beneath the film), tubing, tubing connections and valves, as illustrated in Fig. 7.109. The direct measurement of V_0 is impossible. One way to circumvent this issue is to measure volume 1, V_1 , including a short section of tubing and a vessel (as illustrated in Fig. 7.109) first by liquid filling followed by Burnett gas expansion [7.290]. Volume 1 is filled with a volatile liquid, such as methanol, and the value of V_1 equals the volume of the liquid required to completely fill volume 1. To obtain the value of V_0 , an impermeable aluminum foil film is installed in the permeation cell to isolate the downstream from the upstream. Initially, V_0 and V_1 are under vacuum (i. e., the pressure is 0 cmHg). Volume 1 is isolated from V_0 by turning off valve 1, and gas is introduced into the tubing at a pressure of p_0 (which is typically much lower than 1 atm). Light gases such as N_2 and He are typically used since they exhibit ideal gas behavior at sub-atmospheric

pressure. After the value of p_0 stabilizes, the valve is opened, and the gas expands into volume 1; the pressure reaches p_f in both volumes. Assuming ideal gas behavior, the ratio of the two volumes is given by

$$V_1/V_0 = p_0/p_f - 1, \quad (7.152)$$

which permits one to obtain an accurate value of the tubing volume. Following the same procedure, V_2 can be estimated. V_2 can also be estimated using the liquid-filling method.

To simplify the data acquisition process, automatic recording of the downstream pressure can be employed. Typically, transducers (such as those from MKS Instruments, Wilmington, MA, USA) used in the downstream sense the pressure and give an analog voltage output signal. The pressure is typically linearly related to the transducer output voltage, and this relationship can be obtained by calibrating the transducer using a standard pressure indicator. The voltage signal can be recorded using a chart recorder. More conveniently, the signal can be digitized and monitored using a computer via data-acquisition programs such as Labtech Notebook™ (Laboratory Technologies Corp., Andover, MA, USA) or Labview (National Instruments Corp., Austin, TX, USA), which show and record the pressure in real time and allow one to analyze the data with widely used software such as Microsoft Excel. The required hardware, including computer boards, terminals, readouts etc., is provided by commercial sources, such as Measurement Computing Corp. (Middleboro, MA, USA).

Due to the ability to measure pressure accurately, the constant-volume variable-pressure system is able to measure a wide range of flux values, including mater-

ials exhibiting flux values too low to be measured by a constant-pressure variable-volume system.

Mixed-Gas Permeability Measurement

The measurement of mixed-gas permeability coefficients follows principles similar to those used for pure-gas permeability measurements, except that the mixed-gas measurement requires a sensor to detect gas concentration in the feed, residue and permeate streams. A gas chromatograph (GC) is the most widely used concentration detection method [7.289, 291]. A schematic of a mixed-gas permeation instrument is provided in Fig. 7.110 [7.288]. In general, the permeate is swept away from the membrane surface using a carrier gas (e.g., He, H₂ or N₂) at a pressure of about 1 atm. The preferred carrier gas should have a thermal conductivity that is very different from that of the permeate gas, since thermal conductivity detectors are widely used for concentration detection in the GC. Consequently, helium or hydrogen is often used as the carrier gas [7.292]. By measuring the permeate gas concentration in the sweep gas and the sweep gas flow rate (i.e., S), permeability can be calculated as follows [7.288]

$$P_A = \frac{x_{1A} S_F l}{x_{He}^P A (p_2 x_{2A} - p_1 x_{1A})} \quad (7.153)$$

where x_{1A} and x_{He}^P are the mole fractions of component A and helium in the permeate stream, respectively; x_{2A} is the mole fraction of component A in the feed gas.

Mixed-gas measurements require a specially designed permeation cell, as illustrated in Fig. 7.107c, to ensure good mixing in the gas phase above and below the membrane. Low stage-cut values (the stage cut is the ratio of the permeate gas flow rate to the feed gas flow rate) are used to improve mixing efficiency on the feed side of the membrane. Typically, the stage cut is set to be less than 1%; that is, the permeate flow rate is less than 1% of the feed flow rate. Additionally, this method can be used for pure-gas studies. Compared with the continuous flow system described earlier (i.e., constant pressure/variable volume system), this apparatus is able to measure low permeate flux, mainly because of the high sensitivity of GC for gas composition detection and the ease of measurement of the high sweep gas flux using a bubble flow meter.

An alternative technique can also be used for mixed-gas permeability measurement [7.293]. Instead of using a carrier gas on the permeate side of the membrane, a closed downstream volume is used. When the gas flux reaches steady state, as detected by monitoring

Fig. 7.110 Schematic of a mixed-gas permeability apparatus for gas permeability measurements using a gas chromatograph for concentration detection (R: regulator; P: pressure transducer; MFC: mass-flow controller; GC: gas chromatograph). The parts within the dashed box are in a temperature-controlled chamber

the rate of downstream pressure rise, the downstream is evacuated to remove the gas accumulated during non-steady-state permeation. Afterwards, the downstream volume is isolated, and pressure in this volume increases. Then, a valve is opened, and the gas expands into an evacuated line connecting the gas chromatograph to the downstream volume. The gas permeability can be calculated from the steady-state rate of pressure rise in the downstream volume and the corresponding composition of the permeate gas determined using the GC.

Besides GC, other sensors have been employed for gas permeation studies. For example, oxygen transmission across films is an important property in food packaging, since the exposure of food and beverages to oxygen can significantly influence their shelf life [7.256]. The American Society for Testing and Materials (ASTM) standard F1307 describes a constant-volume variable-pressure system which employs an oxygen sensor to detect the oxygen concentration in the downstream volume [7.294]. Coupled with the rate of pressure rise in the downstream volume, O_2 permeability can be easily calculated using (7.151). This method is particularly convenient for mixed gas feeds containing O_2 and other species, where only the O_2 permeability is of interest.

Transient Transport Measurement

Based on the pioneering work by *Daynes* and *Barre* [7.280, 281], transient transport measurements (time lag) have come to be widely practised. The most common system used to detect the time lag is the constant-volume variable-pressure system [7.265], although systems employing a gas chromatograph have also been reported [7.291]. As illustrated in Fig. 7.106, the time lag is defined as the intercept of the extrapolated linear pseudo-steady-state region of the downstream pressure rise back to the time axis. A key issue is to ensure that the experiment has reached steady state. *Koros* and coworkers proposed a procedure illustrated in Fig. 7.106 [7.265]. The experiment is run for a period that is approximately five to six time lags, then the downstream volume is evacuated, and the measurement is restarted. If the slope of the downstream pressure rise versus time is consistent with the rate of downstream pressure rise measured before evacuation, then the experiment is considered to be at steady state.

This technique requires films having good mechanical properties to sustain the pressure difference across the sample and a leak-free downstream volume. To increase the sensitivity of this technique, i. e., to increase the time lag, thicker films can be used. As illustrated

in (7.141), time lag increases with the square of the film thickness. This strategy is especially useful for studies of small penetrants such as hydrogen and helium, which typically have high diffusion coefficients and, therefore, exhibit time lag values that are often too short to be detected. On the other hand, (7.141) suggests that film thickness uniformity is very important for reducing the uncertainty of this measurement.

7.6.5 Experimental Measurement of Gas and Vapor Sorption

The sorption of gas in a polymer film is usually detected by either a decrease of gas pressure or gas-phase concentration in the environment surrounding a polymer in a closed chamber or the weight increase of a polymer film due to gas sorption. An apparatus is typically designed to measure changes in either the amount of gas in the gas phase or the weight change of the polymer film due to the sorption or desorption of the penetrant. In the following section, common methods of measuring gas sorption are described. They include the dual-volume, pressure-decay method, the gravimetric method, and inverse gas chromatography.

The Dual-Volume Pressure-Decay Method

The dual-volume pressure-decay method employs dual transducers and dual cells, and is widely used to determine pure-gas solubility in polymeric samples [7.295, 296]. A schematic diagram of such a system is shown in Fig. 7.111. The system consists of a sample cell containing a polymer sample and a charge cell connected to a gas cylinder. In the first step, the sample cell is evacuated and then isolated from the charge cell, which is subsequently charged with a target gas at a known pressure. The valve between the charge and sample cells is opened briefly to introduce gas to the sample cell. The valve between the sample and charge cells is closed, and

Fig. 7.111 Schematic of a barometric pressure decay apparatus for gas sorption measurement (dual-volume dual-transducer system) (P: pressure transducer). The parts within the dashed box are in a temperature-controlled chamber

the pressure in the sample cell is monitored as a function of time. The difference between the initial and final pressure in the charge cell can be used to calculate the number of moles of gas admitted into the sample cell. As the polymer sample sorbs gas, the pressure in the gas phase of the sample cell decreases. When the sample cell pressure reaches a stable value, the polymer has sorbed all of the gas that it can at the final pressure in the sample cell (i. e., equilibrium is achieved). From the final pressure in the sample cell, the number of moles of gases in the gas phase of the sample cell can be calculated. The difference between the moles of gas admitted to the sample cell from the charge cell and the final number of moles of gas in the gas phase of the sample cell is the number of moles of gas sorbed by the sample at the final pressure of the sample cell. The second step is to add more gas to the charge cell and repeat the procedure outlined above to obtain a data point at a higher pressure. At step m , the number of moles of gas sorbed in the polymer $n_{p,m}$ is given by [7.295]

$$n_{p,m} = n_{p,m-1} + \left(\frac{p_{c,m-1} V_c}{RTZ_{c,m-1}} + \frac{p_{s,m-1} (V_s - V_p)}{RTZ_{s,m-1}} \right) - \left(\frac{p_{c,m} V_c}{RTZ_{c,m}} + \frac{p_{s,m} (V_s - V_p)}{RTZ_{s,m}} \right), \quad (7.154)$$

where V_c is the volume of the charge cell, V_s is the volume of the sample cell, and V_p is the volume of polymer sample. $Z_{c,m}$, $Z_{s,m}$, $Z_{c,m-1}$ and $Z_{s,m-1}$ are the compressibility factors of gas in the charge cell at step m , sample cell at step m , charge cell at step $(m-1)$ and sample cell at step $(m-1)$, respectively. The subscripts m and $m-1$ represent the properties at step m and step $(m-1)$, respectively. For example, $n_{p,m-1}$ is the number of moles of gas sorbed in the polymer at step $(m-1)$. In the first step (i. e., $m=1$), the sample cell is under vacuum, and $n_{p,0}$ is zero. From these sequential measurements, the gas sorption isotherm in the polymer can be obtained, and the gas solubility as a function of gas pressure can be calculated based on the definition of solubility: $S = C/p$.

Compressibility factors are related to pressure by [7.297]

$$Z = 1 + B^* p + C^* p^2, \quad (7.155)$$

where B^* and C^* are virial coefficients which depend on temperature. They have been compiled by *Dymond and Smith* for a large number of gases at various temperatures [7.297]. Virial coefficients are also available for some gas mixtures from the same source [7.297].

In general, the amount of gas in the gas phase is much greater than that sorbed in the polymer, i. e., the values of the two terms in brackets on the right-hand side of (7.154) are much larger than $n_{p,m}$ or $n_{p,m-1}$. In this sense, the value of $n_{p,m}$ is the result of a subtraction between two much larger numbers. Therefore, the accuracy of $n_{p,m}$ is sensitive to the calibration of the pressure transducers and volumes. A typical transducer used for such studies is the Super TJE model (Sensotec, Columbus, OH, USA), which measures a pressure range of 0–34 atm with an uncertainty as low as $\pm 0.05\%$ of full scale (i. e., ± 0.017 atm). It is one of the most accurate transducers commercially available. Generally, the transducers sense pressure and provide an analog signal such as a voltage, which can be related to the pressure measured by a standard pressure gauge (such as the PM indicator made by Dresser Instruments, Shelton, CT, USA) using a linear or polynomial equation. The volume calibration can be performed by a two-step Burnett expansion process [7.290]. In the first step, gas (typically helium) in the charge cell at a pressure p_0 is expanded to the empty sample cell, which is kept under vacuum before the expansion. The pressure in both cells reaches a stable value of p_f . Based on a mass balance, the following equation can be derived

$$\frac{p_0 V_c}{RTZ_0} = \frac{p_f (V_c + V_s)}{RTZ_f}, \quad (7.156)$$

where Z_0 and Z_f are compressibility factors at pressures of p_0 and p_f , respectively. Substituting (7.155) into (7.156) and letting the third virial coefficient, C^* , equal zero (since C^* is a very small number for helium [7.297] and $C^* p^2$ is typically negligible for helium), yields:

$$\frac{p_0}{p_f} = \frac{B^* V_s}{V_c} p_0 + \frac{V_c + V_s}{V_c}. \quad (7.157)$$

By varying p_0 , one can generate data to prepare a plot of p_0/p_f as a function of p_0 . The resulting line intersects the p_0/p_f axis at $(1 + V_s/V_c)$. The second step is to vary the volume of the sample cell by inserting some non-sorbing solid of known volume V_m , such as stainless-steel spheres, into the sample cell. Repeating the Burnett expansion step outlined above, the following equation is obtained

$$\frac{p_0}{p_f} = \frac{B^* (V_s - V_m)}{V_c} p_0 + \frac{V_c + V_s - V_m}{V_c}. \quad (7.158)$$

Again, one can perform gas expansions as a function of pressure to fit this model and determine $(V_s - V_m)/V_c$,

which can be coupled with the value of V_s/V_c to calculate V_s and V_c .

As discussed above, the accuracy of gas solubility measurements depends strongly on the calibration of the transducers and the volumes, especially for low-sorbing materials. Since the true volume of the sample cell in the measurement is the difference between the sample cell volume and the polymer sample volume, the accurate measurement of gas solubility depends sensitively on the measurement of polymer sample volume and, therefore, polymer density, which is used to calculate polymer sample volume. The following procedure has been developed in our laboratory to estimate the effect of these uncertainties on solubility values. After the volume calibration, a standard sorption experiment (i.e., a blank experiment) is performed using the gases of interest while still keeping the non-sorbing volume (e.g., stainless-steel spheres) in the sample cell. Ideally, the gas solubility estimated from this experiment should be zero since these nonporous spheres sorb a negligible amount of gas. However, due to the uncertainties in the pressure and volume values, a small nonzero sorption value is typically obtained. In studying gas sorption in polymers, the sample should have a volume similar to V_m , and the pressure decay sequence is kept similar to that in the blank experiments. The solubility values obtained in this experiment are compared with those obtained from blank experiments. The difference between these two series of results is regarded as the true gas sorption in the polymer samples. A principal rule of thumb to judge the validity of the data is that the gas solubility values obtained using the polymer samples need to be much larger (such as ten times larger) than the values from the blank experiments. In general, the polymer sample volume (V_m) or the added volume should be as large as possible so that the gas pressure change in the sample cell during each sorption step will be very pronounced, which reduces the uncertainty in the solubility values. In our laboratory, this technique has been used to measure solubility as low as $0.10 \text{ cm}^3(\text{STP})/(\text{cm}^3 \text{ atm})$ with a standard deviation of less than 10%.

Koros and coworkers have used data from the transient region of the pressure decay experiments to obtain gas diffusion coefficients in polymers. They monitored the pressure change in the sample cell as a function of time and interpreted the results using an analytical solution to (7.138) [7.298]. However, this method is not commonly used for kinetic studies, partially because the polymer sample is typically stacked in the small sample cell, and a uniform boundary condition during the

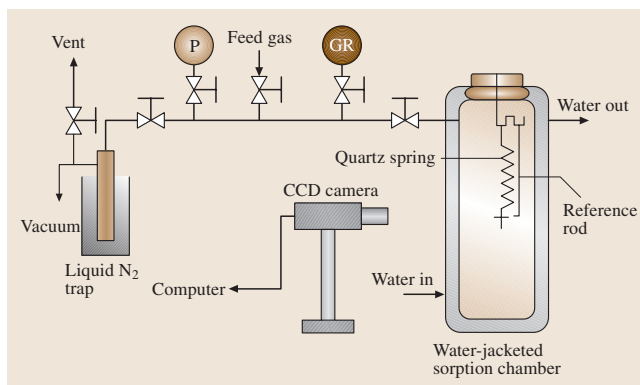

Fig. 7.112 Schematic of a McBain spring system for sorption measurements (P: pressure transducer; GR: gas/vapor reservoir)

transient sorption process for the entire polymer sample might be difficult to achieve.

Gravimetric Technique

Unlike the barometric technique described above, which is used mainly for high-pressure gas sorption measurements, the gravimetric technique is often used at sub-atmospheric pressures [7.264]. Lately, this technique has been extended for use at high pressures. For example, ISOSORP, a commercial apparatus made by Rubotherm (Bochum, Germany) and designed based on the gravimetric method, can be operated at pressures as high as 100 MPa. The basic principle is to monitor the weight change of a polymer film due to penetrant uptake. Typically, the results yield information about transient sorption kinetics and equilibrium sorption. From these data, solubility, diffusivity and permeability can be calculated using a proper model. This section focuses on the McBain spring balance apparatus, the Cahn electrobalance, and the quartz-crystal microbalance techniques.

A McBain spring balance is commonly used to track the kinetics of mass uptake in a thin polymer film, as illustrated in Fig. 7.112. The polymer sample is suspended from a calibrated quartz spring in a water-jacketed glass chamber, where the temperature is controlled by circulation of water from a temperature bath [7.264, 299]. The quartz spring typically obeys Hook's law over a wide range of loading:

$$M = kx, \quad (7.159)$$

where M is the weight, x is the spring extension, and k is the spring constant. Generally, the spring constant is calibrated by measuring the spring extension when

loaded with a series of known weights. Thus, the penetrant uptake as a function of time can be obtained by monitoring the spring extension with time, which is typically measured as the displacement of a certain point on the spring relative to the end of a reference rod using a cathetometer or a camera [7.299]. The experiment begins by degassing the polymer sample and then exposing the film to a large amount of gas or vapor at a fixed pressure. The spring extension is monitored until the sorption reaches equilibrium (i. e., until there is no further spring extension). The pressure in the chamber can be increased sequentially, and gas sorption isotherms can be obtained from such data. Additionally, gas diffusion coefficients can be obtained from kinetic sorption data. One key design element of this apparatus is to make the sorption chamber large enough so that the change in gas pressure during the sorption or desorption process is negligible, and thus the boundary condition remains $C = C_2$ at $x = 0$ and l .

Care must be taken to eliminate any external interference of the spring operation, which is very sensitive to vibrations. For example, the system needs to be fixed in an area free of vibration, and the introduction of gas or vapor into the chamber to start the experiment needs to be slow.

One limitation of conventional McBain spring balance systems is that the penetrant needs to have vapor pressure values high enough so that the pressure can be measured using a pressure transducer. For example, a pressure of 0.1 mmHg is probably the lowest practical value that could be achieved using a system such as the one in Fig. 7.112 [7.300]. However, the performance of food packaging materials can depend upon the sorption and diffusion of flavor compounds (e.g., higher hydrocarbons, benzaldehyde, benzyl alcohol, etc.), which are typically not very volatile (i. e., they have very low vapor pressure values). Additionally, these flavor compounds may be present at low thermodynamic activity, which requires the study of transport properties of these compounds at very low pressure [7.300]. In our laboratory, we have modified a McBain system to avoid the requirement of low-pressure measurement by employing gas chromatography to measure penetrant activity [7.300]. A light gas such as helium (which is essentially non-sorbing in the polymer at pressures of one atmosphere or less) is bubbled through the liquid penetrant at a controlled temperature and introduced into the sample chamber. The concentration of liquid penetrant in the gas phase can be adjusted by controlling the temperature of the liquid or by diluting the gas mixture with another stream of light

gas. The concentration of the penetrant in helium is measured using a gas chromatograph. Since the light gas essentially does not sorb into the film, the polymer weight change is due only to the sorption or desorption of the penetrant. In this way, the sorption of penetrants with very low vapor pressure can be studied.

Instead of a spring, other devices have been used to monitor the weight change of a polymer sample during sorption or desorption. Examples of such devices include the Cahn electrobalance [7.301], the magnetic suspension balance [7.302] and the quartz-crystal microbalance [7.303]. These systems have been tested at high pressure, for example, up to 200 atm [7.303], and at temperatures from room temperature to 120 °C [7.301]. The first two balances are commercially available.

A quartz-crystal microbalance contains a piezoelectric crystal which oscillates at its characteristic frequency when an alternating current is applied to it. By coating a polymer layer on the crystal and exposing the polymer coatings to gas, the crystal oscillating frequency changes as a result of the weight change by the polymer due to penetrant sorption. The mass of gas sorbed or desorbed (i. e., the mass change of the crystal, Δm) is given by [7.304]

$$\Delta m = -\Delta f / G, \quad (7.160)$$

where Δf is the frequency change due to sorption or desorption, and G is a constant determined by the vibrational frequency, frequency constant of the crystal, density of the quartz, and the effective area of the vibrating plate [7.304]. Special care is required for calibration of the quartz-crystal microbalance, since the surface properties of the coated crystal can significantly affect the frequency, thus introducing errors into the mass calculation [7.303].

Inverse Gas Chromatography

Inverse gas chromatography (IGC) has been used to measure gas sorption, though it is less widely used. IGC is an indirect method, which uses a gas chromatograph containing a solid support coated with a polymer material of interest as the stationary phase [7.305]. The penetrant of interest is introduced as the mobile phase, and its passage through the GC column depends on its interaction with the polymer. Typically, gas sorption in the polymer is related to the gas's retention time on the polymer-coated column. IGC can easily be used to study gas sorption as a function of temperature even up to high temperatures. However, the column cannot withstand high pressures.

Mixed-Gas Sorption Measurement

Mixed-gas sorption measurements are rarely reported, partly due to the complexity of these measurements. Additionally, gas sorption in polymers is often low, so the mixed-gas sorption is typically assumed to be the sum of the amounts of the components sorbed based on pure-gas sorption measurements. In some cases, however, competitive sorption is expected, and the mixed-gas sorption level could deviate from those estimated based on pure-gas sorption. CO₂ and C₂H₄ sorption in glassy poly(methyl methacrylate) (PMMA) is an example of such a system [7.315]. To understand the effect of sorbing of one penetrant on the other in PMMA, Sanders et al. designed a mixed-gas sorption system based on barometric pressure decay principles such as those described in Sect. 7.6.3. The design is similar to the pure-gas measurement, except that the gas compositions must be determined before and after the gas is introduced into the sample cell using a gas chromatograph [7.315]. For details regarding the apparatus design and operation, readers should consult reference [7.315].

Special Techniques

Advances in analytical equipment can potentially improve methods to measure gas transport properties in polymer films. In addition to the more typical systems discussed above, there are special techniques available for certain situations. *Crank* and *Park* reviewed various techniques to measure penetrant concentration directly as a function of time and position [7.267]. These techniques include refractive-index measurements, radiation

absorption methods and radiotracer methods [7.267]. From these techniques, small-molecule transport properties such as solubility, diffusivity and permeability can be obtained when these results are combined with flux measurements. *Fieldson* and *Barbari* applied Fourier-transform infrared (FTIR-ATR) spectroscopy to study small-molecule diffusion in polymers [7.316]. *Assink* used nuclear magnetic resonance (NMR) techniques to study ammonia sorption in glassy polystyrene [7.317]. As discussed in Sect. 7.6.2, glassy polymers exhibit two distinct sorption sites, Henry's law sites and Langmuir sites. It is commonly assumed that gas sorbed into these two populations of sorption sites can exchange rapidly (i. e., the local equilibrium hypothesis), and gas sorbed into the Langmuir sites is typically less mobile than that in Henry's law sites [7.317, 318]. To test that assumption, *Assink* determined gas concentration in the film using NMR and obtained the relative concentration by fitting the data to (7.132). Based on the characteristic exponential decay of the nuclear magnetization, he was able to verify the validity of the local equilibrium hypothesis [7.317].

7.6.6 Method Evaluations

In the USA, the American Society for Testing and Materials (ASTM) has published guidelines for many of the measurement techniques discussed above. Table 7.16 provides a synopsis of relevant ASTM standards. Interested readers should consult the original ASTM documents, which discuss equipment design, operat-

ing procedures, and application of the techniques. Some commercial instruments used for gas transport property measurement are listed in Table 7.17.

In general, it is important to plan the experiments needed to understand the transport of particular penetrants in a polymer. Permeability and selectivity represent the inherent separation performance of a material and are often of interest industrially. Pure-gas studies are much easier to organize and perform than mixed-gas measurements. However, mixed-gas transport properties can, in some cases, yield results that are different from the pure-gas results, especially when one of the penetrants can interact strongly with the polymer. For example, in studies of CO₂ and CH₄ permeation through cellulose acetate, CO₂ plasticizes the cellulose acetate, leading to an increase in the polymer free volume, chain flexibility and CH₄ mixed-gas permeability. At 35 °C, pure-gas CH₄ permeability is about 0.12 Barrers at a pressure of 10 atm, but it is 0.32 Barrers when the feed gas to the membrane is a mixture of CO₂ and CH₄ with CH₄ and CO₂ partial pressures of about 10 atm and 24 atm, respectively. Thus, the mixed-gas CO₂/CH₄ selectivity was 20 while the pure gas selectivity was approximately 80 [7.319].

Gas permeability must be decoupled into solubility and diffusivity components to understand the fundamentals of gas transport in polymers and polymer-based materials of interest. For new materials, equilibrium sorption and steady-state permeation are often studied independently to determine the transport parameters [7.320]. Transient transport or sorption studies (i.e., the time-lag method or McBain spring system) depend

on specific assumptions of diffusion models, which cannot always be judged a priori for new materials. The following sections give some general guidelines regarding the selection of a proper method.

A. Permeation

1. Pure-gas permeation is commonly measured using a constant-volume variable-pressure or a constant-pressure variable-volume device. The latter is suitable for polymers when the permeate gas flow is greater than 0.3 cm³/min. At this and higher flows, the gas flow can be accurately measured by a bubble flow meter. Otherwise, a constant volume/variable pressure device can be used for a wide range of flux values, as long as an appropriate downstream volume is chosen.
2. The time-lag method is most useful when the concentration dependence of the diffusion coefficient is known. In this way, both permeability and diffusivity can be obtained in one single experiment. From measurements of permeability and diffusivity, solubility can be estimated according to: $S = P/D$.

B. Sorption

1. The most common devices for sorption measurements include the barometric pressure-decay apparatus for high-pressure studies and the McBain spring system for low-pressure studies (i.e., for condensable vapors). The pressure-decay method requires equation of the state information for the

desired gas (e.g., the second and third virial coefficients), while the McBain spring system does not.

2. Diffusion coefficient can be obtained from transient studies only when the dependence of the diffusion coefficient on penetrant concentration is known or an assumption is made, as discussed in Sect. 7.6.1. The McBain spring system is most widely used in low-pressure studies.
3. If defect-free polymer films are very difficult to prepare for permeation studies, a transient sorption study could be very useful to obtain gas solubility and diffusion coefficients, and these can be used to estimate permeability. Solubility and diffusivity values obtained from kinetic sorption studies are virtually insensitive to pinhole defects in samples.

7.6.7 Future Projections

This chapter reviews basic models of gas transport in polymer films and measurement techniques to determine transport parameters. Guidelines for choosing one method over another are provided. Although phenomena such as non-Fickian diffusion are not discussed, the basic principles of equipment design still apply, except that the data analysis would be different [7.264]. Additionally, some polymers exhibit special properties which need to be considered in the experimental design. For example, poly(1-trimethylsilyl-1-propyne) (PTMSP)

ages rapidly (i.e., polymer films become denser, which decreases gas diffusion coefficients over time) during the measurement, so a standardized sample-pretreatment protocol is required to obtain reproducible results, along with rapid permeation tests and frequent confirmation of the polymer properties by measuring the permeability of a marker penetrant.

The development of experimental techniques for gas transport property measurement has benefited from other fields, such as gas absorption in liquids [7.321] and adsorption [7.322]. For example, the dual-volume pressure-decay method used to determine gas sorption in polymers at high pressures is based upon a similar principle as the one developed for gas sorption in liquids [7.295, 321]. Similarly, the principles introduced here can also be found in other applications, such as H₂ storage (or H₂ sorption in solids) [7.323]. It might be fair to predict that the future development of measurement methods would rely on knowledge transfer from related fields and advancement in sensors such as those for pressure and gas concentration measurements. Recently, molecular simulations have been extensively investigated to calculate gas solubility, diffusivity and permeability in polymers [7.324, 325]. This approach often offers a detailed description of complex polymer structure and transport mechanism, although quantitative agreement between simulated and experimental results is not always obtained [7.325]. Further information can be found in the following additional references [7.237, 238, 240–243, 245, 246, 250, 326, 327].

Thermal Prop

8. Thermal Properties

If materials – solids, liquids or gases – are heated or cooled, many of their properties change. This is due to the fact that thermal energy supplied to or removed from a specimen will change either the kinetic or the potential energy of the constituent atoms or molecules. In the first case, the temperature of the specimen is changed, since temperature is a measure of the average kinetic energy of the elementary particles of a sample. In the second case, e.g. the binding energy of these particles is altered, which may cause a phase transition.

Thermal properties are associated with a material-dependent response when heat is supplied to a solid body, a liquid, or a gas. This response might be a temperature increase, a phase transition, a change of length or volume, an initiation of a chemical reaction or the change of some other physical or chemical quantity.

Basically, almost all of the other materials properties treated in *Part C*, namely mechanical, electrical, magnetic, or optical properties, are temperature-dependent (except a material that is especially designed to be resistant to temperature variations). For example, temperature influences mechanical hardness, electrical resistance, magnetism, or optical emissivity. Temperature is also of importance to the characterization of material performance (*Part D*) as it influences materials integrity when subject to corrosion, friction and wear, biogenic impact or material–environment interactions. Temperature effects related to these areas are dealt with in the other chapters of this book dedicated to those topics. Only if those properties are needed to explain measuring methods within this chapter are they outlined in the following sections.

In this chapter, a number of materials properties are selected and called *thermal properties*, where the effect of thermal energy treatment plays the major role compared to electrical, magnetic, chemical or other effects. The presentation

of *measurement methods for thermal properties* is organized into five parts, referring to:

1. Thermal transport properties, such as thermal conductivity, thermal diffusivity or specific heat capacity, characterizing the ability of materials to conduct, transfer, store and release heat.
2. Phase transitions and chemical reactions of materials. Various calorimetric methods are presented, which are used to investigate e.g. phase transitions, adsorption, and mixing processes. Typical examples are first-order transitions such as boiling and melting, but also combustion and solution processes.
3. Physical properties, which are affected when heat is supplied to a body. The determination of the temperature dependence of these quantities requires knowledge of thermal measurement methods. Among the many different physical quantities the most important for applications in materials science and engineering are length and its relation to thermal expansion.
4. Thermogravimetry, which is important in chemical analysis, see Chap. 4.
5. Temperature measurement methods, since these techniques are essential for all the other measurements described above. Temperature scales and the principles, types and applications of temperature sensors are compiled.

8.1 Thermal Conductivity and Specific Heat Capacity

There are two main material properties (thermophysical properties) associated with heat transfer in materials. These are the ability of a material to store heat and the ability to transfer heat by conduction. If a specific amount of heat dQ is supplied to a thermally isolated specimen of mass m the relationship between heat and temperature increase dT is given by

$$dQ = mc_p dT . \tag{8.1}$$

Consequently the ability of a material to store heat is characterized by the specific heat capacity at constant pressure c_p . If two equal volumes of different materials are compared to each other, the ability to store heat is described by the product of density and specific heat capacity ϱc_p . This product is used if simultaneous heat conduction and storage processes are investigated by means of the transient heat conduction equation. In many cases the density of a material or the mass of a specimen is well known or can be easily determined with sufficient accuracy. Therefore, the problem is reduced to the determination of the specific heat capacity. For gases and some liquids a distinction between the specific heat capacity at constant pressure c_p and at constant volume c_v is made. This is due to the work required for the thermal expansion of the gas or liquid. For solids this contribution is very small in comparison to the measurement uncertainty and can be neglected.

The thermal conductivity λ is the material property associated with heat conduction and is defined by Fourier's law

$$q = -\lambda \frac{\partial T}{\partial x} = -\lambda \frac{\Delta T}{d} = \frac{\Delta T}{R_{th}} . \tag{8.2}$$

Here, q is the heat flux, the heat conducted during a unit time through a unit area, driven by a tempera-

ture gradient $\partial T/\partial x$. In practice, for thermal conductivity measurements the temperature difference ΔT between two opposite surfaces of a sample with a separation of d is determined. The quotient of distance and thermal conductivity is the thermal resistance R_{th} . In contrast to the storage of heat, conduction is considered as a steady-state process, i. e. the temperature field and the heat flux within heat-conducting materials are not a function of time.

But, in most cases both heat conduction and heat storage are simultaneously occurring processes. This is taken into account by the transient heat conduction equation. The temperature field $T(x, t)$ in one dimension is dependent on the location x and time t

$$\frac{\partial T}{\partial t} = a \frac{\partial^2 T}{\partial x^2} . \tag{8.3}$$

The thermal diffusivity a is given as the ratio of the thermal conductivity and the product of density and specific heat capacity

$$a = \frac{\lambda}{\varrho c_p} . \tag{8.4}$$

From its physical meaning thermal diffusivity is associated with the speed of heat propagation. In analogy to Einstein's relation, which connects random walks and diffusion, the mean square displacement $\langle r^2 \rangle$ of a thermal pulse is proportional to the observation time t (one-dimensional diffusion)

$$a = \frac{\langle r^2 \rangle}{2t} . \tag{8.5}$$

A further thermal property is the thermal effusivity e . The thermal effusivity is a measure of a material's abil-

ity to exchange heat with the environment (thermal impedance) and is defined according to

$$e = \sqrt{\lambda \varrho c_p}. \quad (8.6)$$

Knowing the thermal diffusivity and thermal effusivity, other complementary materials properties, e.g. λ and ϱc_p , can be calculated.

Based on the fundamental laws of heat conduction and storage three different attempts to measure these thermophysical properties can be distinguished. The first one is the steady-state approach using (8.2) in order to determine the thermal conductivity. Steady-state conditions mean that the temperature at each point of the sample is constant, i.e. not a function of time. The determination of the thermal conductivity is based on the measurement of a heat flux and a temperature gradient, i.e. mostly a temperature difference between opposite surfaces of a sample. If the specific heat capacity is the property of interest, a calorimetric method

based on (8.1) is used. In this case, heat is supplied to a sample that is isolated from the surroundings, and the change of the (mean) sample temperature is measured. The third approach is the simultaneous determination of both properties by a transient technique. For that purpose numerous solutions of the transient heat conduction equation based on one- (8.3), two-, or three-dimensional geometries have been derived.

The main experimental problem for all methods for the determination of thermal properties is that ideal thermal conductors or insulators do not exist. In comparison to electrical transport the ratio of thermal conductivities of the best conductors and the best insulators is many orders of magnitudes smaller. Therefore, instruments for the determination of thermal properties are often optimized or restricted for a specific class of materials or temperature range [8.1]. Table 8.1 gives an overview of the most important methods used for the measurement of thermal conductivity and thermal diffusivity.

Table 8.1 Comparison of measurement methods for the determination of thermal conductivity and thermal diffusivity

Method	Temperature range	Uncertainty	Materials	Merit	Demerit
Guarded hot plate	80–800 K	2%	Insulation materials, plastics, glasses	High accuracy	Long measurement time, large specimen size, low conductivity materials
Cylinder	4–1000 K	2%	Metals	Temperature range, simultaneous determination of electrical conductivity and Seebeck-coefficient possible	Long measurement time
Heat flow meter	–100–200 °C	3–10%	Insulation materials, plastics, glasses, ceramics	Simple construction and operation	Measurement uncertainty, relative measurement
Comparative	20–1300 °C	10–20%	Metals, ceramics, plastics, plastics	Simple construction and operation	Measurement uncertainty, relative measurement
Direct heating (Kohlrausch)	400–3000 K	2–10%	Metals	Simple and fast measurements, simultaneous determination of electrical conductivity	only electrically conducting materials
Pipe method	20–2500 °C	3–20%	Solids	Temperature range	Specimen preparation, long measurement time
Hot wire, hot strip	20–2000 °C	1–10%	Liquids, gases, low conductivity solids	Temperature range, fast, accuracy	Limited to low conductivity materials
Laser flash	–100–3000 °C	3–5%	Solids, liquids	Temperature range, most solids, liquids and powders, small specimen, fast, accuracy at high temperatures	Expensive, not for insulation materials
Photothermal photoacoustic	30–1500 K	Not sufficiently known	Solids, liquids, gases, thin films	Usable for thin films, liquids and gases	Nonstandard, knowledge about accuracy

8.1.1 Steady-State Methods

The principle of (one-dimensional) steady-state methods for the determination of the thermal conductivity is derived from (8.2) and based on the measurement of a heat flux and a temperature difference according to

$$\lambda = \frac{qd}{T_2 - T_1} = \frac{Pd}{A(T_2 - T_1)} \quad (8.7)$$

In many cases the heat flux q is determined by the measurement of a power P released in an electrical heater divided by the area A of the sample. The temperature difference $T_2 - T_1$ is determined between two opposite surfaces of the specimen having a separation of d .

The typical sample geometry and the configuration of a measurement system for thermal conductivity measurements depend most strongly on the magnitude of the thermal conductivity. When the thermal conductivity of a material is low, the samples are usually flat disks or plates. In the case of a high thermal conductivity the sample geometry is formed by a cylinder or rod. According to the relationship between the sample geometry (assumed to be cylindrical) and the direction of the heat flow, axial and radial heat flow methods of measuring the thermal conductivity are distinguished.

Guarded Hot Plate and Cylinder Method

The guarded hot plate method can be used for the determination of the thermal conductivity of nonmetals such as glasses, ceramics, polymers and thermal insulation materials but also for liquids and gases in the temperature range between about 80 K and 800 K. The geometry of the sample or sample chamber is a plate or a cylinder with axial heat flow. Depending on the thermal conductivity and homogeneity of the material under investigation, the sample thickness varies between a few millimeters and a few decimeters. There are two different types

of guarded hot plate instruments: the two-specimen and the single-specimen apparatus shown in Fig. 8.1.

Guarded hot plate instruments consist of one or two cold plates, a hot plate and a system of guard heaters and thermal insulation. The cold plates are liquid-cooled heat sinks, the hot plate is electrically heated. To make sure that the heat released in the hot plate is passed only through the sample, the hot plate is surrounded by guard heaters and thermal insulation. This minimizes the heat losses from the hot plate and ensures the high accuracy of this method. With guarded hot plate instruments relative expanded uncertainties of thermal conductivity measurements of about 2% can be achieved. There are two main sources of uncertainty in thermal conductivity measurements: the heat flux and the temperature difference determination. The major contributions to heat flux errors are heat losses from the hot plate and the heat exchange between the sample and the surrounding medium. With increasing thermal resistance of the sample (insulation materials) these sources of uncertainty become dominant.

The advantage of the two-specimen apparatus is that heat losses from the hot plate can be controlled more effectively because of the symmetric specimen arrangement. In contrast to the single-specimen method, only solid materials can be investigated. This is because of the influence of convection on thermal conductivity measurements. In order to avoid convection, the sample must be heated from the top.

The cylinder method with axial heat flow can be used for thermal conductivity measurements of metals with thermal conductivities up to $500 \text{ W m}^{-1} \text{ K}^{-1}$ in a temperature range between about 4 K and 1000 K. Comparing the principle of operation and the mathematical model, the cylinder method and the guarded hot plate method fully agree. The most important difference is the sample geometry, which is a flat plate or disk for the guarded hot plate method and a long cylinder or rod for the cylinder method. This is due to the fact that the main difficulty for measurements of materials with high thermal conductivity (e.g. metals) is the determination of the temperature difference. In this case the contact resistances between the sample and the heater and between the sample and the cold plate must be considered. The minimization and determination of the resulting temperature drop across these thermal contact resistances is the most important criterion for the optimization of this type of instrument.

Therefore, guarded hot plate and cylinder method are realizations of the same measurement principle optimized for different ranges of thermal conductivity.

Fig. 8.1a,b Principle of the guarded hot plate method. (a) two-specimen apparatus. (b) single-specimen apparatus

Heat Flow Meter and Comparative Method

The main disadvantage of steady-state methods is that they are very time consuming. This is because the whole system of specimen and guard heaters must reach thermal equilibrium in order to avoid unaccounted heat losses and deviations from steady-state conditions. The basic idea of the heat flow meter and the comparative method is the determination of the (axial) heat flux by means of the measurement of a temperature drop across a thermal resistor. This is in analogy to the determination of a current by the measurement of a voltage drop across an electrical resistor. The implementation of this idea for heat flux measurements is carried out either by the use of a reference sample with well-known (certified) thermal resistance or by means of a heat flux sensor. Most heat flux sensors consist of a series connection of thermocouples across a thermal resistor, e.g. a thin ceramic or plastic plate. The measured signal is a thermovoltage proportional to the temperature drop across the plate. Usually a heat flux sensor is calibrated in a steady-state temperature field with well-known heat flux, e.g. in a guarded hot plate apparatus.

The design of a heat flow meter apparatus is very similar to that of the single-specimen guarded hot plate instrument. Instead of the main heater a heat flux sensor is used. In some cases a second heat flux sensor at the cold plate is applied to determine radial heat losses and to reduce the measurement duration. This is of particular advantage for measurements of insulation materials. To avoid radial heat losses the lateral surfaces of the sample are surrounded by thermal insulation or additional guard heaters.

If a reference sample for heat flux measurements is used, the sample and reference samples are piled upon one another in a temperature field (series connection of thermal resistors). The temperature drops across both sample and reference sample are measured and compared (comparative method). To correct for radial heat losses two reference samples are mostly used and the investigated sample is sandwiched between them. Under steady-state conditions the heat flux at each point of the stack is the same. In that case the ratio of the thermal resistances of the sample and reference sample is equal to the ratio of the corresponding temperature drops. In contrast to the guarded hot plate method the heat flow meter and the comparative method are relative and not absolute methods. The heat flow meter method is mostly used for insulation materials and polymers ($\lambda < 0.3 \text{ W m}^{-1} \text{ K}^{-1}$), in some cases for glasses and ceramics, i.e. for materials with thermal conductivities less than about $5 \text{ W m}^{-1} \text{ K}^{-1}$. In contrast, the

typical application range of the comparative technique is the investigation of metals, ceramics and glasses having thermal conductivities above $1 \text{ W m}^{-1} \text{ K}^{-1}$. Typical upper temperature limits are about 200°C for the heat flow meter method and about 1300°C for the comparative method. The measurement uncertainties are about 3% for insulation materials near room temperature and between 10% and 20% at high temperatures.

Direct Heating (Kohlrausch) Method

The disadvantages of steady-state thermal conductivity measurement methods are the long equilibration time needed to reach steady-state conditions and the difficult quantification of heat losses, in particular at high temperatures. These can be avoided using the direct heating method, although this can only be used for materials with sufficiently high electrical conductivity, such as metals. Typically samples are wires, pipes or rods with a diameter d between 0.5 mm and 20 mm and a length l between 50 mm and 500 mm. Figure 8.2 shows the schematic of the most popular design of the direct heating method.

The sample is placed in a vacuum chamber, clamped between two liquid-cooled heat sinks and heated by a sufficiently high electrical current I_h to achieve sample temperatures in the range 400–3000 K. Temperatures and voltage drops are measured at three positions; one position is in the middle of the rod, while the others are placed symmetrically at equal distances from the middle

Fig. 8.2 Principle of the direct heating method

position. In most cases thermocouples are used because of their dual usability as temperature sensors and for voltage-drop measurements. The result of measurements by the direct heating method is the product of the thermal conductivity and the specific electric resistivity $\lambda\rho_{\text{el}}$.

$$\lambda\rho_{\text{el}} = \frac{(U_3 - U_1)^2}{4[2T_2 - (T_1 + T_3)]} \quad (8.8)$$

The specific electrical resistivity can be determined from the length l and cross-sectional area A of the sample, heating current I_h and voltage drop U_h according to

$$\rho_{\text{el}} = \frac{U_h A}{I_h l} \quad (8.9)$$

Pipe and Hot Wire Method

The characteristic of this class of methods is radial heat flow in a cylindrical sample (diameter d_1 , length l). Figure 8.3 shows the principle of the pipe method.

A hole on the central axis of the sample contains the core heater (diameter d_2), which is a rod, tube or wire. Depending on the temperature range of interest the sample is surrounded by a liquid-cooled heat sink or a combination of muffle heater and water jacket.

Fig. 8.3 Principle of the pipe method

Axial heat losses can be minimized by additional end guard heaters or a special sample geometry, i. e. a large length-to-diameter ratio. The thermal conductivity is determined by the measurement of the radial heat flow Φ and the temperature difference between the inner and the outer surface of the sample according to

$$\lambda = \frac{\Phi \ln\left(\frac{d_2}{d_1}\right)}{2\pi l (T_1 - T_2)} \quad (8.10)$$

Because of its simple design modified versions of this technique have been used for solids covering the thermal conductivity range between insulation materials ($20 \text{ mW m}^{-1} \text{ K}^{-1}$) and metals ($200 \text{ W m}^{-1} \text{ K}^{-1}$) for temperatures between room temperature and 2770 K . Transient modifications to this technique for the simultaneous determination of thermal conductivity and thermal diffusivity are of increasing interest (Sect. 8.1.2).

8.1.2 Transient Methods

With the availability of modern computers and data acquisition systems transient methods have become increasingly popular. The advantages of transient methods are that much less time is needed for the experiments and that various thermal properties can be determined in the same measurement cycle. A typical measurement duration of one hour for steady-state methods is reduced to a few minutes or to a subsecond interval for transient methods. In many cases the temperature measurement at two opposite surfaces of the sample is replaced by a temperature measurement as a function of time at only one position. This makes the design of instruments for transient measurements straightforward in comparison to steady-state methods and can improve the accuracy of the results.

Transient Hot Wire and Hot Strip Method

Most thermal conductivity measurements of liquids, gases and powders are carried out by means of the transient hot wire method, a modification of the steady-state pipe method with a cylindrical specimen geometry and radial heat flow. The pipe is replaced by a thin platinum wire or nickel strip [8.2, 3]. For measurements on solids the wire is embedded in grooves between two equally sized specimens. Considerable care is needed in the sample preparation to achieve sufficiently low thermal contact resistances between solid samples and the heating wire. Therefore, the use of a thin metal foil strip (hot strip method) instead of the heating wire has become increasingly popular for measurements on solids.

In this case the sample preparation is simplified by the use of a heat sink compound. The disadvantage of deviations from the radial symmetric temperature field in comparison to the wire method is compensated by an adequate mathematical model and evaluation procedure [8.2, 4, 5].

In the standard transient hot wire technique (Fig. 8.4) the platinum wire has two functions, as a heater and as a temperature sensor.

The heat source is assumed to have a constant output, which is ensured by a stabilized electrical power supply. From the slope of the resulting linear temperature rise as a function of elapsed time the thermal conductivity λ of the specimen is determined. The thermal diffusivity a can be found from the intercept of this linear temperature dependence. To eliminate the effect of axial conduction via the large-diameter current supply leads attached to the ends of the hot wire, two hot wires of differing lengths are often operated in a differential mode. Further modifications of this technique are the cross-wire and the parallel-wire techniques, where the heater and temperature sensor are separated from each other. For the cross-wire technique, the heating wire and legs of a thermocouple are in direct contact with each other and form a cross. The advantage of the parallel wire method is that it can be used for anisotropic

materials and for materials having a thermal conductivity above $2 \text{ W m}^{-1} \text{ K}^{-1}$. Further developments are the use of modulated heat input, e.g. pulse or sinusoidal modulation.

Relative expanded ($k = 2$) uncertainties of the measured values of 0.38% for thermal conductivity and 1.7% for thermal diffusivity (resp. ρc_p) of liquids have been achieved [8.5].

Laser Flash Method

The most frequently used method for the determination of thermal transport properties of solids is the laser flash method. The main reason is that it can be used in a wide temperature and thermal diffusivity range. Measurements in a temperature range between -100°C and about 3000°C are possible. In contrast to most other methods different material classes, such as polymers, glasses, ceramics and metals, can be investigated without significant limitations on the achievable measurement uncertainty.

Using this method the thermal diffusivity a is determined. If the specific heat capacity and the density of a material are known, the thermal conductivity can be calculated by using (8.4). Therefore, thermal diffusivity measurements are often supplemented by calorimetric measurements for the determination of the specific heat capacity.

The principle of the laser flash method is based on the heating of a specimen by a short laser pulse on the front side of the specimen and the detection of the temperature increase at its rear side (Fig. 8.5).

Fig. 8.4 Principle of the hot wire method

Fig. 8.5 Principle of the laser flash method

If the laser pulse can be considered to be instantaneous and if the sample is kept at adiabatic conditions, the thermal diffusivity a can be calculated according to

$$a = 0.1388 \frac{d^2}{t_{1/2}} \quad (8.11)$$

The thermal diffusivity is calculated from the thickness d of the specimen (typically 2 mm) and the time $t_{1/2}$. This is the time needed for the temperature of the rear specimen surface to reach half its maximum value. Several improvements of the evaluation methods have been developed since the introduction of this method by *Parker et al.* in 1961 [8.6]. These are the consideration of three-dimensional heat flow, heat losses, finite pulse duration, nonuniform heating, composite structures and radiation contributions to the heat transfer. In addition several modifications, e.g. for the measurement of the specific heat capacity or for the direct determination of the thermal conductivity, have been developed.

The most important advantage of the laser flash method is that, for the determination of a thermal property, neither absolute temperatures nor heat measurements are necessary. The thermal diffusivity measurement is carried out by determination of the relative temperature change as a function of time only. This is the main reason why relative measurement uncertainties in the 3–5% range can be achieved even at high temperatures [8.7–9].

Photothermal Methods

The principle of these methods is based on the investigation of a light-induced change in the thermal state of a material in solid, liquid or gaseous state. If light is absorbed by a sample, subsequent changes in temperature, pressure or density are detected. There are methods in which the sample is in contact with the detection system and others that involve remote, noncontact detection systems.

Photothermal and photoacoustic methods for the determination of optical absorption and thermal properties of materials can be classified according to the detection technique used. These are based on the measurement of changes in:

- Temperature: Changes in temperature are usually investigated by means of contact thermometry (e.g. the photopyroelectric technique), radiation thermometry or calorimetric methods.
- Pressure: Pressure changes are determined via acoustic methods.

- Density: The investigation of density changes include the detection of refractive index variations or of surface deformations. The most important techniques are the thermal lens method, thermal wave technique, beam deflection, refraction or diffraction methods.

The general idea of thermal diffusivity measurement by photothermal methods is modulated heating of a sample surface and detection of the amplitude and phase of the temperature at the opposite sample surface as a function of modulation frequency. This technique can be modified by simultaneous heating of both surfaces with a single modulation frequency and measurement of the phase difference between both surface signals.

Photoacoustic Technique. Typically the sample is placed in an acoustically sealed cell containing a contact gas and a microphone. A monochromatic light source periodically heats the sample and the resulting expansion causes a pressure wave which is sensed with the microphone pressure transducer. Liquid or solid samples can be measured either by direct coupling of the acoustic wave to the microphone or via a gas (coupling fluid). A great variety of photoacoustic configurations have been developed depending on the aggregate state of the sample, the property to be measured (e.g. thermal diffusivity, effusivity, optical properties) or the temperature and pressure range of interest.

Optical Beam Deflection Technique. An excitation beam heats the material periodically while a continuous wave (cw) probe beam is used either in order to detect density changes of the gas near the sample surface or to probe the sample directly. Depending on the relative position between excitation and probe beam, collinear and perpendicular configurations are distinguished. If the sample surface temperature is different from that of the surrounding gas, this results in a temperature gradient between the gas near the sample surface and the bulk gas. Since the density of a gas is temperature dependent, a gradient of the refractive index of the gas is observed. This method, also known as the “optical mirage” technique, is based on the refraction of the probe beam caused by the dependence of the speed of light on the gas temperature.

Thermal Lens Technique. This method is of particular interest for the determination of thermal properties of transparent liquids and solids, such as glasses, polymers or liquid crystals. The photothermal lens is created

through the temperature dependence of the refractive index of the sample resulting from the heating of the sample by an excitation laser beam. Typically the lens causes a laser beam divergence which is detected as a time-dependent decrease in power at the center of the beam.

Thermal Wave Technique. The principle of the thermal wave technique is based on measurements of temperature fluctuations in a (gaseous) sample following the absorption of intensity-modulated light. The thermal diffusivity is determined from frequency- and time-domain behavior of a thermal wave in a fixed volume. An improvement of this technique is the development of the thermal wave resonant cavity, which has been used for the measurement of the thermal diffusivity of gases with very high precision. A thermal wave cavity consists of two parallel walls. One wall is fixed and periodically heated by a laser beam or resistive heating. The other one consists of a pyroelectric thin-film transducer, which is used to monitor the spatial behavior of the thermal wave by means of cavity-length scans. By this method the thermal conductivity and thermal diffusivity of the gas in the cavity can be measured.

For a more detailed discussion we refer to [8.10].

8.1.3 Calorimetric Methods

The general principle of all calorimetric methods for the determination of the specific heat capacity is based on (8.1), i.e. the measurement of a specific amount of heat dQ and the resulting temperature increase dT . In most cases two experiments are necessary, a first one with the empty calorimeter in order to determine the instrument's heat capacity and for the correction of the remaining heat losses and a second one with the filled calorimeter including the sample.

Numerous types of calorimeters have been developed for the determination of specific heat capacities of materials. Table 8.2 shows the most important of these and their typical application range.

The most accurate methods for specific heat capacity measurements are *adiabatic calorimetry* and *drop calorimetry* (for details see Sect. 8.2). Construction of these high-precision instruments, which are not commercially available, requires considerable effort and money, while their operation demands substantial experience and time.

Therefore, probably more than 90% of specific heat capacity measurements of solids and liquids are carried out by means of a *differential scanning calorimeter*

(DSC, for a detailed description see Sect. 8.2.2). A DSC is operated in dynamic mode, which means that the furnace is heated or cooled with a constant scanning rate of, typically, 20 K/min. The measured quantities are the heat flow rate $\Phi = dQ/dt$ and the corresponding sample temperature T . Usually, three experiments are necessary: the measurement of the empty calorimeter, the sample measurement and the calibration sample measurement.

A calibration is needed because differential scanning calorimetry is a relative method. There are two materials that are considered as standards for the test or calibration of calorimeters used for the determination of specific heat capacities of solids. These are copper for the temperature range 20–320 K [8.11] and synthetic sapphire for the temperature range 10–2250 K [8.12]. The relative measurement uncertainties are less than 0.1% for copper, and less than 0.1% for sapphire in the temperature range 100–900 K and in the range 1–2% at higher temperatures.

In many cases a certified reference material such as synthetic sapphire (e.g., SRM 720 from the National Institute of Standards and Technology, Gaithersburg, USA) is used as the calibration material.

If the heating rates of the sample (s), calibration sample (cal) and empty (0) measurement are identical, the specific heat capacity of the sample $c_{p,s}$ is given by

$$c_{p,s} = \frac{m_{\text{cal}} c_{p,\text{cal}}}{m_s} \frac{\Phi_s - \Phi_0}{\Phi_{\text{cal}} - \Phi_0}. \quad (8.12)$$

Here m_s and m_{cal} are the masses of the sample and calibration sample and the corresponding heat flow rates are Φ_s and Φ_{cal} . There are several commercially available instruments that can be used in different temperature ranges between 100 K and 1900 K. For most DSCs disk-typed samples with diameters of about 6 mm and heights of 1 mm are used. But there are also cylinder-type DSCs (known as Calvet-type devices) having sample container volumes in the range 1.5–150 ml. For measurements on liquids a measurement or control of the vapor pressure and of the sample volume is necessary. This is carried out by special sample cells in cylinder-type instruments or DSCs specially developed for the purpose.

The typical measurement uncertainties of specific heat capacity measurements of solids by means of DSCs are about 5% below 700 °C and up to 10% at high temperatures. A higher accuracy requires considerable more time and effort to be spent on a proper calibration and evaluation procedure. In those cases a relative

Table 8.2 Different types of calorimeters used for the determination of specific heat capacities

Type of calorimeter	Quantities	Typical temperature range (K)	Uncertainty (%)	Merit	Demerit
Differential scanning calorimeter	Specific heat capacity, enthalpy of phase transition of solids and liquids	100–1900	1.5–10%	Standardized, easy to use, fast	Relative method
Adiabatic calorimeter	Specific heat capacity, enthalpy of phase transition of solids, liquids and gases	1–1900	0.05–2%	High accuracy	Long measurement time, expensive
Drop calorimeter	Specific heat capacity, enthalpy of phase transition of solids and liquids	273–3000	0.1–2%	High accuracy	Expensive
Pulse calorimeter	Specific heat capacity, enthalpy of phase transition of solids and liquids	600–10 000	2–3%	Fast, high temperature	Only electrically conducting materials, expensive
Flow calorimeter	Specific heat capacity and enthalpy measurements of liquids and gases	100–700	0.05%	–	–
Bomb calorimeter	Heat of combustion of solids, liquids and gases	300	0.01%	Standard method for solids, liquids	Low accuracy for gases
Gas calorimeter	Heat of combustion of gases	300	0.03–0.5%	Standard method for gases	–

uncertainty of about 1.5% is achievable using this technique [8.13].

At high temperatures there are considerable problems with most calorimetric techniques due to heat losses by thermal radiation, mechanical, electrical or chemical properties of the sample and the construction material of the calorimeters. Therefore, for measurement at temperatures above 2000 K, *pulse calorimetry* is advantageous [8.1, 14], but can only be used for materials having a sufficiently high electrical conductivity. The principle of the pulse method is based on a rapid resistive self-heating of a rod- or wire-type specimen by the passage of an electrical current pulse through it. For

the determination of the specific heat capacity measurements of the current through the specimen (typically in the range 100–10 000 A), the voltage drop across the specimen and of the specimen temperature with sub-millisecond resolution are necessary. If the heating rate is sufficiently large, investigations in the liquid state are possible. Modifications of this technique allow the additional determination of the emissivity, the electrical and thermal conductivity and of the enthalpy of fusion.

The temperature range of this technique is approximately 600–10 000 K. For specific heat capacity measurements by pulse calorimetry relative uncertainties of 2–3% can be achieved.

8.2 Enthalpy of Phase Transition, Adsorption and Mixing

According to the first law of thermodynamics the change in the internal energy of a thermodynamic system dU is equal to the difference between the heat transfer into the system dQ and the mechanical work done by the system dW (other energy forms are neglected here).

$$dU = dQ + dW = dQ - p dV. \tag{8.13}$$

The enthalpy of a thermodynamic system is defined according to $H = U + pV$ and the resulting enthalpy

change dH is:

$$dH = dU + p dV + V dp = dQ + V dp. \tag{8.14}$$

Equation (8.14) describes the relationship between the measured quantity, the exchanged heat dQ , and the quantity assigned to the material, the enthalpy change dH . The relationship between these quantities as a function of the variables of state, namely pressure p ,

temperature T and composition ξ , is given by:

$$dQ = \left[\left(\frac{\partial H}{\partial p} \right)_{T,\xi} - V \right] dp + \left(\frac{\partial H}{\partial T} \right)_{p,\xi} dT + \left(\frac{\partial H}{\partial \xi} \right)_{T,p} d\xi. \quad (8.15)$$

In many cases the pressure change is very small and the first term of (8.15) is negligible. The second term is the heat capacity at constant pressure of non-reacting systems. The third term describes the isothermal and isobaric enthalpy change due to phase transitions, mixing or chemical reactions. At constant pressure and in the absence of other energy conversions (e.g. deformation, oxidation or surface energy transformation) the enthalpy of transition of a material $\Delta_{\text{trs}}H$ is equal to the heat of transition Q_{trs} .

To understand the general principles of calorimetric measurements it is helpful to separate a calorimeter into three parts: (a) the calorimeter vessel with sample, crucible, thermometer and additional equipment for heat measurement, (b) the immediate surroundings of the calorimeter vessel, e.g. a temperature-controlled liquid bath or metal block and (c) a means for initiation chemical reactions, mixing, solution or adsorption processes. Often a calorimeter is characterized according to its mode of operation, being either adiabatic, isothermal or isoperibol. Adiabatic means that the heat exchange between calorimeter vessel and surroundings is considered to be zero. In isothermal mode the temperature of the calorimeter vessel remains constant. In isoperibol mode the temperature of the surroundings is kept constant.

There are numerous types of calorimeters in use and, as a consequence, several classification systems have been proposed. Typical criteria for the classification are the following:

Principle of (Heat) Measurement.

- *Heat-compensation calorimeters*

The heat to be measured is determined, e.g., by Joule heating, Peltier cooling or by means of the latent heat of a phase transition (e.g., Bunsen ice calorimeter). The measurements are mostly carried out under isothermal or quasi-isothermal conditions.

- *Heat-accumulation calorimeters*

The heat is determined by means of a temperature change measurement. It is based on the fact that the temperature increase of a calorimeter is proportional to the amount of heat added. The proportionality factor must be determined by calibration with

a known amount of heat. This principle of measurement requires the minimization of heat losses. Therefore, measurements are preferably carried out under adiabatic or quasi-adiabatic conditions.

- *Heat-conduction calorimeters*

In this type of calorimeter the heat is exchanged between the calorimeter and its surroundings via a well-defined heat conduction path. The corresponding heat flow rate (with dimensions of power) is measured, e.g., by means of heat flux sensors (thermopiles). Heat is determined by integration of the measured heat flow rate as a function of time. Instruments of that type are often operated at isoperibol conditions, i.e. the temperature of the surroundings remains constant.

Mode of Operation.

- *Static mode*

This mode includes adiabatic, isothermal or isoperibol operation.

- *Dynamic mode*

Either the temperature of the calorimeter vessel or that of the surroundings is changed. The linear scanning mode (constant heating rate) is most often used, i.e. the temperature of the calorimeter vessel is a linear function of time. During recent years an increasing number of variable heating rate techniques was developed. Typical modes of operation are stepwise heating or the superposition of a constant heating rate by sinusoidal or sawtooth temperature changes.

Construction Principles.

These are single, twin or differential calorimeters.

Methods of Reaction, Solution, Mixing or Adsorption Initiation.

Examples are continuous (e.g. flow calorimeters), discontinuous or incremental working instruments (e.g. incremental titration).

The use of certified reference materials or pure substances with well-known thermodynamic properties [8.15–18] to check the proper functioning of a calorimeter, the calibration of the instrument, and for validation of the reliability of the measurement uncertainty budget is highly recommended. Certified reference materials for calorimetry are available from the National Institute of Standards and Technology (NIST, USA), the Physikalisch-Technische Bundesanstalt (PTB, Germany) and the Laboratory of the Government Chemist (LGC, UK).

8.2.1 Adiabatic Calorimetry

Adiabatic calorimetry is one of the most accurate thermal methods. Relative uncertainties of less than 0.1% for enthalpy of fusion or specific heat capacity measurements can be achieved. To reach this level, substantial expenditure on the construction, measurement and control of the system is required [8.19, 20]. Typically an adiabatic calorimeter can be divided into three parts: a cylindrical inner part surrounded by a system of adiabatic shields and a furnace (Fig. 8.6).

The inner part of the calorimeter consists of a thermometer, crucible(s), sample, heater and inner radiation shields. In contrast to other calorimeters standard platinum resistance thermometers are mostly used. This allows the determination of transition temperatures with the highest accuracy ($\Delta T \approx 1$ mK).

For the realization of adiabatic measurement conditions (prevention of heat exchange with the surroundings) the inner sample part of the calorimeter is enclosed by a heated adiabatic shield, controlled to the same temperature as the inner part. For proper control of the adiabatic conditions and to ensure sufficient temperature homogeneity further guard and radiation shields are concentrically arranged around the adiabatic shield. The outer part of an adiabatic calorimeter is the furnace (or cryostat) and an enclosure for measurements in vac-

uum or at controlled inert gas flow. To minimize heat losses and temperature gradients within the calorimeter, construction materials must have a very high thermal conductivity and low emissivity in the infrared range (e.g. silver).

The basic principle of adiabatic calorimetry is the measurement of the temperature increase of the sample due to the supply of a known amount of heat. Therefore, the typical mode of operation consists of alternating heating and equilibration periods, but there are also several adiabatic calorimeters that operate in scanning mode at very low scanning rates. Under adiabatic conditions the enthalpy increment is equal to the supplied heat, which is determined by an electrical energy measurement of high accuracy ($P_{el}t = Q$, P_{el} : power, t : time). Determination of the specific heat capacity of a material is reduced to the basic relation

$$c_p = \frac{Q}{m \Delta T} = \frac{P_{el}t}{m \Delta T} \quad (8.16)$$

In real measurements very small heat losses remain, which can be determined and corrected by means of additional experiments. For that purpose in a first empty run the heat capacity of the calorimeter without a sample is measured. In a properly designed adiabatic calorimeter the heat losses are equal in the empty and filled state. Therefore, the empty measurement is also the basis for the correction of the remaining heat losses.

A measurement procedure for the determination of the enthalpy of fusion also consists of different runs and again a step heating procedure with alternating heating and equilibration periods is used. For experimental reasons each fusion experiment starts below and stops above the fusion temperature. Therefore, the heat capacity contributions of the (filled) calorimeter must be considered. Further experiments are needed to determine the fusion temperature of the material. For that purpose the method of fractional fusion is used.

Adiabatic calorimeters are used from temperatures below 1 K up to about 1900 K [8.21]. At high temperatures the main problems are deviations from adiabatic conditions because of thermal radiation. This results in measurement uncertainties of a few percent for enthalpy of fusion and specific heat capacity measurements at temperatures above 1000 K. In the low-temperature range the specific heat capacity of materials and the sensitivity of most high-precision thermometers rapidly decrease as a function of temperature. This leads to the requirement for considerable effort for the meas-

Fig. 8.6 Principle of an adiabatic calorimeter

urement of the temperature difference of the sample and for the control of the adiabatic shield. The lowest uncertainties for enthalpy of fusion measurements of less than 0.1% are achieved in the 100–900 K range.

8.2.2 Differential Scanning Calorimetry

Differential scanning calorimeters (DSCs) are twin-type systems consisting of identical measuring systems for the sample and a reference sample [8.22]. These are mounted in the same furnace and commonly subjected to a controlled temperature program (heating or cooling). During heating or cooling heat is exchanged between the furnace and sample part of the calorimeter (corresponding heat flow rate Φ_{FS}) and in the same manner between the furnace and reference part of the calorimeter (corresponding heat flow rate Φ_{FR}). The difference between these heat flow rates ($\Delta\Phi = \Phi_{FS} - \Phi_{FR}$) is measured and used for the determination of the quantity of interest, e.g. the enthalpy of fusion of the sample. A differential scanning calorimeter measures two quantities, the heat flow rate $\Delta\Phi$ (with dimensions of power) and the corresponding sample temperature. For the measurement of temperatures either platinum resistance thermometers or thermocouples are used. Heat flow rates are measured either by direct electrical power measurements or by means of thermocouples or thermopiles. The use of thermocouples or thermopiles is based on the determination of a temperature drop across a thermal resistor, in analogy to the determination of electrical currents by the measurement of the voltage drop across an ohmic resistor.

Using DSC, both the determination of a transition temperature and the determination of a heat of transition is possible. The transition temperature is determined from the extrapolated peak onset temperature T_c and the transition enthalpy from the peak area of the heat flow rate curve (Fig. 8.7).

To determine the peak area the baseline must be subtracted. The proper choice of the baseline has a major influence on the measurement uncertainty of the transition enthalpy.

A further feature of differential scanning calorimetry is the dynamic mode of operation. Typically a temperature program consists of three segments: an initial isothermal segment, followed by a scanning segment (heating or cooling) with a constant rate and a final isothermal segment. Scanning rates in the range ± 0.1 –500 K/min in a temperature range between -150°C and 1600°C are used for the determination

Fig. 8.7 Heat flow rate signal of a DSC during a transition in heating mode with extrapolated peak onset temperature T_c

of enthalpies of phase transitions and specific heat capacities.

A further development is the variable heating rate DSC, where a temperature modulation is superimposed on the constant heating or cooling rate of a conventional DSC. The simplest and most commonly used modulation type is periodic, e.g. sinusoidal, sawtooth or stepwise heating. This technique has been successfully applied for the separation of superimposed effects such as glass transitions and enthalpy relaxations or the determination of specific heat capacities during phase transitions.

There are two basic types of DSCs, the heat flux DSC and the power compensation DSC. The principle of the heat flux type of DSC is based on the measurement of the difference of the heat flow rates $\Delta\Phi$ as described above. The heat flux within the DSC takes place via a well-defined heat conduction path with low thermal resistance. There are two different principles of construction of heat flux DSCs, namely disk-type and cylinder-type systems (Fig. 8.8).

A power compensation DSC consists of two identical microfurnaces (for sample and reference sample) which are heated separately according to a prescribed temperature program. The temperature difference between the two microfurnaces is measured and controlled to achieve the same program of temperature versus time for the sample and reference sample. The compensating heating power is a measure of the heat flow rate difference $\Delta\Phi$.

Several modified DSCs have been developed for special applications. Among these are the high-pressure DSC [8.23], photo DSCs for the investigation of light-

Fig. 8.8 Different types of heat flux DSCs

induced reactions [8.24] and DSCs for measurements on fluids [8.25, 26]. Cylinder-type instruments can be modified to investigate mixing, solution or adsorption processes.

The basic requirement for reliable measurements by means of DSC is the calibration of the instrument, for several reasons. These are the possible drift of sensors and other parts of the measuring system but more importantly the dependence of the calibration on temperature, heating rates, sample holder and crucible or sample properties, e.g. mass, thermal conductivity. It is generally recommended that the calibrations be carried out at conditions similar to those of the actual measurement. A typical example is the heat flow rate calibration. In principle, a cylinder-type DSC could be calibrated using a number of methods, e.g. electrically by means of a calibration heater, by means of a reference material with known specific heat capacity or by

means of a material with known enthalpy of fusion. One would expect it to be sufficient to calibrate the instrument by any of these methods. But, depending on the actual measurement problem, very different measurement uncertainties would be achieved. Therefore, the German Society for Thermal Analysis (GEFTA) recommends [8.15, 27] to distinguish between the heat and the heat flow rate calibration of a DSC, even though the same sensor and electronics are used for both types of measurement. As an example, if the enthalpy of fusion of an unknown material is measured, a heat calibration of the DSC by means of a reference material with known enthalpy of fusion at a temperature close to the fusion temperature of the unknown material is recommended.

A metrologically flawless calibration of a DSC is very time consuming but can improve the accuracy of results by about one order of magnitude. Basic requirements for DSC calibrations are given by international standards and more detailed procedures have been published by GEFTA or the International Confederation for Thermal Analysis and Calorimetry.

With carefully calibrated instruments relative measurement uncertainties of about 1% for enthalpy of fusion measurements and 1.5% for specific heat capacity measurements can be achieved. For routine work relative uncertainties in the 5–10% range are more typical.

8.2.3 Drop Calorimetry

Drop calorimeters are used for the determination of enthalpy increments and specific heat capacities of solid or liquid materials in a temperature range between room temperature and more than 3000 K. The only requirements are that the sample should be nonreactive with its container and have a low vapor pressure to avoid mass loss and significant contributions from heat of reaction or vaporization.

The basic principle of a drop calorimeter is the rapid translation (drop) of a sample from some exterior, temperature-controlled zone (furnace) with temperature T_1 into a calorimeter with temperature T_2 , which is used for the measurement of the heat transferred.

If the instrument is properly designed then the heat loss during the translation from the furnace to the calorimeter is negligible and relative measurement uncertainties of less than 0.1% are possible [8.28]. A disadvantage of that technique is that an initial cooling rate of the sample of up to 2000 K/s is possible. In that case the sample might become frozen in a metastable state.

The calorimeter is typically an adiabatic, isoperibol or isothermal instrument. These can be considered as consisting of two parts: the central measuring part and its enclosing surroundings. In adiabatic calorimeters at any time the temperature of the surroundings is controlled to the same value as that of the central (sample) measuring part. Consequently, no heat losses occur (adiabatic conditions), and adding of heat results in a temperature increase that is used as a measure of that heat. The relationship between heat and temperature increase and the heat capacity of the empty calorimeter are determined by electrical calibrations.

An isoperibol mode of operation means that the temperature of the surroundings is kept constant. In that case two processes occur, if heat is added, firstly the temperature of the calorimeter is increased (heat is stored) and secondly heat is exchanged with the surroundings. The lowest measurement uncertainties are achieved if the amount of stored heat is considerable larger than the exchanged heat.

Several methods are in use for the determination of the heat loss correction. These are based on the validity of Newton's law of cooling $[dT_2/dt = -k(T_2 - T_1)]$. The basic idea of most methods for the correction of heat losses in adiabatic and isoperibol calorimeters is the back and forward extrapolation of the final and initial temperatures over time (Fig. 8.9). This allows the determination of the adiabatic temperature difference ΔT_{adiab} (without heat losses) at the time where areas A_1 and A_2 are equal.

In a calorimeter working in isothermal mode, both the temperature of the surroundings T_s and the temperature of the central measuring part T_m remain constant. This is achieved by using a thermostat to keep the tem-

perature of the surroundings constant and a two-phase system as the working substance for the measuring part. Using a two-phase system (usually a solid-liquid phase transition) for temperature control means that adding heat to the measuring part of a calorimeter results in a change of the phase distribution (melting of some material) at constant temperature. The amount of melted material is determined either by weighing or by a volume change measurement. The volume change measurement is based on density differences of the working substance between its solid and liquid state (e.g. Bunsen ice calorimeter). On this basis heat measurements with relative uncertainties of 0.02% have been made.

8.2.4 Solution Calorimetry

The determination of heat of solution, mixing, or adsorption [8.29] is of interest in different fields of materials research, e.g. for investigation of polymers, pharmaceutical products or ceramics. Differences in the heat of solution between different batches of a material can reflect variations in polymorphism, moisture content, degree of crystallinity, surface area or surface energy. Instruments can be classified according to the state of aggregation of the interacting materials or whether a continuous (flow calorimeters) step mode (e.g. titration) or discontinuous mode of operation is used.

A further classification scheme is the mode of operation resulting from the coupling between the central part of the calorimeter, which is used for the caloric measurements, and the surroundings. Solution calorimeters are operated either in adiabatic, isothermal or isoperibol mode.

Specific problems are the separation and the temperature control of the components before the start, complete mixing over the course of the investigations and the change in the vapor pressure during mixing. Calorimeters for discontinuous operation consist of a reaction vessel, a thermometer, a mixing unit or ampoule-breaking system, the stirrer and a resistance heater for electrical calibration. Typically thermometers are thermistors, platinum resistance (Sect. 8.5) or quartz thermometers. The principle of a quartz thermometer is based on the resonant frequency dependence of a quartz oscillator as a function of temperature. Often one of the samples is sealed in a thin-walled glass ampoule. After the system is in thermal equilibrium, the solution or reaction process under study is started by breaking the glass ampoule.

Fig. 8.9 Principle of the heat loss correction based on Newton's law of cooling

Adiabatic and some isoperibol instruments work as heat-accumulation calorimeters, i.e. the heat to be measured is detected via the temperature change of the calorimeter. The calibration of the instrument is determined either by electrical calibration or by the use of reference materials with well-known heat of solution, reaction or adsorption.

A further method is to suppress the temperature change by measuring the required compensating heat, e.g. by means of electric energy (Joule heating or Peltier cooling). In this case only a sensitive temperature sensor (no calibration is required) with sufficient long-term stability is needed because the calorimeter operates in the isothermal mode. The thermometer is used only for the control of the compensation power, so that the temperature remains constant.

A third method of heat measurement is the determination of heat exchanged between the reaction vessel and the (isothermal) surroundings by means of heat flux sensors (Sect. 8.1.1). The vapor pressure of a mixture depends on its composition. Heats of vaporization are usually larger than heats of mixing. Therefore, the determination and correction of the influence of the vapor pressure change during the experiment is very important. Measurement uncertainties of about 0.25% can be achieved [8.30].

The advantages of continuously working flow calorimeters [8.31] are that the measurements can be carried out in a shorter period of time and that less material is needed. Measurements of heat of mixing in a temperature range of 273–479 K and a pressure range between 0.1 MPa and 40.5 MPa with relative uncertainties of 0.5% being possible [8.32].

8.2.5 Combustion Calorimetry

The most common device for measuring the heat of combustion or calorific value of a solid or liquid material is the bomb calorimeter [8.33–36].

A sample is contained under a pressure (about 3 MPa) of pure oxygen in a pressure-tight stainless-steel container (bomb, $V \approx 300$ ml) and is burned under standardized conditions. During recent years several new micro-bomb calorimeters ($V < 100$ ml) have been developed. All instruments are provided with an electrical system for the ignition of the combustion process. The determination of the heat of combustion is based on the observed temperature rise, which is measured with high-precision temperature sensors such as standard platinum resistance thermometers, thermistors or quartz thermometers. Adiabatic, isoperibol or aneroid

instruments are commercially available. In most cases a correction of the measured temperature increase is needed to consider the heat exchange with the surrounding. Furthermore, the calibration factor (energy equivalent) of the calorimeter must be determined. For that purpose a reference material with a well-known heat of combustion is needed. Benzoic acid is the preferred material for that purpose. With well-designed bomb calorimeters relative measurement uncertainties of less than 0.01% can be achieved [8.37] with highly purified materials containing C, H, and O. If other elements are present, the accuracy is limited by the extent to which the stoichiometry of the combustion process can be controlled and determined. Systematic deviations can arise from incomplete combustion or from the lack of a well-defined final state.

Calorimeters for the determination of the calorific value of gases can be subdivided into three different groups [8.38]:

- combustion of the gas inside of a bomb calorimeter (isochoric combustion)
- combustion without a flame on a catalyst (isobaric combustion)
- combustion of the gas in an open flame of a gas burner (isobaric combustion)

The first two groups of methods are used only in rare cases for very specific applications, e.g. investigations on fluorochlorohydrocarbons.

Calorimetric methods in the third group are based on the combustion of the gas at constant pressure and flow rate (flow calorimeter) with an open flame. A heat exchanger is used to transfer the combustion heat to a heat-absorbing fluid (air or water). The temperature increase of the heat-absorbing fluid is a measure of the calorific value. For the calibration of these calorimeters various methods can be applied: the use of gases with well-known calorific values, electrical calibration techniques and methods based on the determination of temperature increase, volume flows and the knowledge of the heat capacity of the heat absorbing fluid. There are several gas calorimeters commercially available, e.g. the Junkers calorimeter, the Reinecke calorimeter, the Thomas–Cambridge calorimeter, or the Cutler–Hammer calorimeter. The typical relative measurement uncertainty of these instruments is about 0.5%.

A high-precision constant-pressure gas-burning calorimeter has been used for the determination of the heat of combustion of methane [8.39]. The resulting combined standard uncertainty was 0.21 kJ/mol which corresponds to a relative uncertainty of 0.024%.

8.3 Thermal Expansion and Thermomechanical Analysis

Thermomechanical analysis (TMA) measures the change in dimension (deformation) of a sample under constant (static force) compressive, tensile, or flexural loads as the temperature of the sample is changed. The special case with negligible force is called dilatometry or thermodilatometry. Typical applications of TMA are the determination of the coefficient of thermal expansion, glass-transition temperatures, softening or shrinkage behavior or the investigation of changes in dimension caused by sintering or chemical reactions. There are several instruments commercially available covering the temperature range between -260°C and 2400°C .

In dynamic mechanical analysis DMA a dynamic force is applied to the sample and the resulting displacement is measured as a function of temperature, frequency or time. A special case is the application of an oscillating force. Dynamic mechanical analysis is used for the determination of the modulus of elasticity (stiffness), viscous modulus and damping coefficient ($\tan \delta$) of materials (for details see Chap. 7). In addition, DMA measurements give insight into the temperature and frequency dependence of molecular mobility and can be used for the determination of glass-transition temperatures.

Thermal expansion is the change of the length of a specimen ΔL as a function of the temperature change ΔT

$$\Delta L = L - L_0 = L_0 \alpha \Delta T. \quad (8.17)$$

This behavior is described by the coefficient of (linear) thermal expansion (CTE)

$$\alpha = \alpha_L = \frac{1}{L_0} \frac{dL}{dT} \quad (8.18)$$

and is a function of temperature $\alpha = \alpha(T)$. The reference length L_0 of the specimen is generally given either at a temperature of 0°C or at 20°C . In crystalline anisotropic solids the coefficient of thermal expansion is direction dependent and may have up to six different contributions.

The change of the volume of a body as a function of temperature is described by the volumetric coefficient of thermal expansion

$$\alpha = \alpha_V = \frac{1}{V_0} \frac{dV}{dT}. \quad (8.19)$$

In most cases the volumetric coefficient of thermal expansion can be determined from the linear coefficient of thermal expansion with sufficient accuracy by means of $\alpha_V \approx 3\alpha_L$.

There are several different descriptions of thermal expansion in use. In the definition according to (8.18) α is often called the physical or differential coefficient of thermal expansion. Furthermore, in some cases a so called mean or technical coefficient of thermal expansion according to

$$\alpha_m = \frac{1}{L_0} \frac{L(T_2) - L(T_1)}{T_2 - T_1} = \frac{1}{L_0} \frac{\Delta L}{\Delta T} \quad (8.20)$$

is used. The third kind is the specification of a relative length change $\Delta L/L_0$ at a (mean) temperature T .

The coefficient of thermal expansion of a sample is usually determined according to its definition (8.18) by the measurement of the reference (initial) length L_0 at the temperature T_0 , and the change of the length ΔL as a result of a temperature change ΔT at different (mean) temperatures.

The shape of the samples is typically a cylindrical rod with a diameter in the range 5–10 mm and a length in the range 25–50 mm. Depending on the temperature range of interest, cryostats, liquid baths, multi-zone or heat pipe furnaces with excellent temperature stability and homogeneity are used. These are operated either by stepwise heating or by scanning at low rates. Thermocouples or radiation thermometers are mostly used for the temperature measurements. More information can be found in [8.40].

8.3.1 Optical Methods

For measurements of length changes with highest accuracy, e.g., for the certification of reference materials, for materials with very low coefficients of thermal expansion (Zerodur, Invar) and for cases when only small samples are available, optical methods are chosen. Relative measurement uncertainties of the certified values of α_L of high-purity synthetic Al_2O_3 of 0.18–1% were achieved in a temperature range between -180°C and $+400^{\circ}\text{C}$ [8.41].

The optical methods can be divided into three main types. The first one is based on the creation of an image of a sample and the determination of the spatial movement of the ends or other marks along the length. In this case the optical path is perpendicular to the displacement direction. The image is formed either by background illumination to give a silhouette effect or by the radiant light emitted from the specimen itself. These techniques are known as optical imaging, optical comparator or twin telemicroscopy.

The second type is based on interferometry. Here the displacement is determined by the measurement of the path difference of beams reflected from opposite surfaces of the sample. Because the refractive index of air or inert gases is not known with sufficient accuracy most measurements are carried out in vacuum.

In the third method speckle interferometry is used to determine the displacement by means of changes in the interference pattern on the surface of the sample.

There are further specialized techniques which do not fall into the above categories. Details can be found in [8.42].

For the certification of reference materials instruments based on Fizeau and Michelson interferometers have been used [8.43, 44]. At temperatures above 800 K several problems lead to a decrease in the accuracy of this method. Therefore, instruments based on optical heterodyne interferometers for absolute measurements at temperatures of 300–1300 K [8.45] and 1300–2000 K [8.46] have been developed. For measurements with these instruments combined standard uncertainties of $1.1 \times 10^{-8} \text{ K}^{-1}$ [0.26% for $100(\Delta\alpha/\alpha)$] at 900 K and of 1.3% in the range 1300–2000 K have been claimed.

The highest accuracies are achieved around room temperature. Measurement results on ceramic and steel gauge blocks with uncertainties of $1 \times 10^{-9} \text{ K}^{-1}$ in a temperature range between -10°C and 60°C have been published [8.47].

8.3.2 Push Rod Dilatometry

The most common method of measuring thermal expansion is push rod dilatometry. Several instruments are commercially available for the temperature range between -260°C and 2800°C .

A sample is heated in a furnace or other temperature-controlled environment and the displacement of the ends is mechanically transmitted to a displacement sensor [e.g. a linear variable differential transformer, (LVDT)] by means of push rods. There are several possible arrangements of the push rods. The first is the parallel arrangement of two push rods, the double push rod system. This arrangement can be modified by simultaneous use of sample and reference samples, known as the differential method. A further arrangement is for one of the rods to be in the form of a closed tube. The sample and the other push rod are located along the central axis of the tube. In this case the sample is clamped between the central push rod and the closed end of the other tube-shaped push rod.

The displacement sensor is maintained in a controlled-temperature environment close to room temperature. Therefore, the most critical part is the push rod, which transmits the expansion signal from the sample to the displacement sensor. The resulting temperature difference between opposite ends of push rods can be more than 2000 K. Therefore, the homogeneity of the temperature field in the furnace, the repeatability of a temperature program and the material used for the push rods are of critical importance for high-quality measurements.

The main criterion for the choice of a material used for push rods is a low, reproducible, and accurately known coefficient of thermal expansion. At low temperatures vitreous silica is the preferred material. There are very different recommendations for the upper temperature for the use of vitreous silica for this purpose, ranging from the temperature of the α – β transition of about 550°C to 1000°C as the maximum temperature to avoid devitrification, i. e. the transition from the glassy state to a crystalline structure. For temperatures up to 1600°C push rods are made from silica, either in single-crystal form (sapphire) or sintered (polycrystalline) state, at higher temperatures rods consisting of isotropic graphite are used.

Dilatometers are often operated in a dynamic mode by temperature scanning with a constant rate of typically less than 5 K/min . Depending on the method of construction more than one measurement may be necessary to determine the correction for the thermal expansion of the push rods and to calibrate both the displacement- and the temperature sensor. For this purpose certified reference materials are necessary. High-purity materials such as silicon, tungsten, platinum, copper, aluminum, sapphire or vitreous silica are mostly used for displacement calibration. The calibration of the temperature sensor is carried out by the measurement of the dimensional change of a high-purity metal during melting.

With careful work relative measurement uncertainties for the CTE of 2% at temperatures between room temperature and 973°C have been achieved [8.48].

8.3.3 Thermomechanical Analysis

The basic difference between thermomechanical analysis (TMA) and dilatometry is that for TMA a load (static force) is applied to the sample. As a consequence instruments for TMA are operated with vertical sample orientation. This is different from most dilatometers, where horizontal sample and furnace orientation is cho-

sen as this gives better temperature uniformity. There are several modes of force control and sample configuration for TMA. At negligible load the thermal expansion measurements are carried out in a very similar manner to dilatometry. In the compression mode a rod with well-known cross section or geometry presses with a known force on the sample and the compression, penetration or bending is determined as a function of force, temperature or time. From these kinds of measurements

elastic modulus, creep or cure behavior, softening temperatures or phase transition are determined. This is also of advantage for the investigation of transitions in thin films such as polymer coatings or lacquers. Further applications are measurements in tension mode and investigations of the viscous properties or gelation of fluids. There are instruments commercially available for a temperature range between -160°C and 2400°C .

8.4 Thermogravimetry

Thermogravimetry (TG) is a method of thermal analysis in which the mass of a sample is measured as a function of temperature whilst the sample is subjected to a controlled temperature program. In many cases the reaction products are analyzed by supplementary investigations. As for most other methods of thermal analysis the typical temperature program is a linear scan, i. e. the temperature changes linearly in time. During recent years so called controlled-rate thermal analysis has been increasingly used. This means that the scanning rate can vary as a function of time depending on the magnitude of the measured quantity; for example, the scanning rate of a thermogravimetric instrument is controlled as a function of the measured mass change of the sample or the amount of a specific evolved gas.

Typical applications are the evaluation of the thermal decomposition kinetics of materials such as rubbers or polymers, the investigation of processes such as sintering, drying, oxidation or reduction. There are several instruments for investigations in a temperature range between -150°C and 2400°C commercially available. Typical sample masses are in the range 5–25 mg. Mass changes can be detected with resolutions in the range $0.1\text{--}10\mu\text{g}$. Most TG instruments can be combined

with calorimetric detection systems for simultaneous differential thermal analysis or differential scanning calorimetry. Thermogravimetry is performed in a controlled atmosphere including oxygen, nitrogen, helium or argon with adjustable flow rates.

A mass spectrometer (MS) or a Fourier-transform infrared (FTIR) spectrometer can be coupled to most TG instruments for continuous, online identification and analysis of the evolved gases during heating of the sample. To avoid a separation or loss of evolved gases by condensation these are routed to the MS via a heated capillary or a system of orifices held at the same temperature as the sample (Skimmer[®] coupling).

A recent extension of TG systems is pulse thermal analysis [8.49]. This is based on the injection of a specific amount of liquid or gaseous reactant into the inert carrier gas stream and monitoring of the changes in the mass, enthalpy, and/or gas composition. By this method gas–solid reactions, adsorption or catalytic processes can be studied. A further application is the direct calibration of the mass spectrometer or FTIR spectrometer by injecting a known amount of substance into the inert carrier gas stream and relating it to the spectrometer signal. For more information the reader is referred to [8.50].

8.5 Temperature Sensors

Temperature sensors are needed for the measurement of thermal properties of materials, of course, but they are used in a much larger field of applications, since temperature is the quantity measured most frequently in science, industry, and daily life. In the following chapter a selected number of temperature sensors of sufficient reliability for scientific and industrial measurements is described as well as the temperature scale against which they should be calibrated.

8.5.1 Temperature and Temperature Scale

Temperature characterizes the thermal state of matter independently of the nature of the substance. It is an intensive quantity, not depending on the addition or reduction of the amount of matter concerned, but changed by supplying or removing heat or mechanical work. Classically, the definition of temperature is derived from the thermodynamic description of a Carnot engine re-

versibly driven in a thermodynamic cycle, the efficiency of which depends only on temperature. The ratio of the heat Q_1 fed to the engine isothermally at high temperature to the heat Q_2 removed at low temperature to get back mechanical work was found to be identical to the ratio of the temperatures T_1 and T_2 at both isothermal parts of the cycle by William Thomson, the later Lord Kelvin:

$$Q_1/Q_2 = T_1/T_2 . \tag{8.21}$$

From this definition of temperature he could derive the equation of state for an ideal gas to be

$$pV = \text{const } T . \tag{8.22}$$

This states that the product of the gas pressure p and the volume V filled with the gas is proportional to the absolute temperature. The constant in (8.22) turned out to be equal to nR , the product of the number n of moles involved and the gas constant R .

By statistical methods it was shown during the second half of the 19th century that the average kinetic

energy of a molecule of an ideal gas amounts to

$$pV = \text{const} \left\langle mv^2/2 \right\rangle , \tag{8.23}$$

a fact, which demonstrates that temperature is a measure of the averaged internal energy of the gas molecules, which are ascribed a mass m and a velocity v .

An apparatus built to determine the pressure and the volume of a known number of moles of an ideal gas can be used to measure the temperature of the gas according to (8.22). Such a gas thermometer is called a primary thermometer, since there is no need to calibrate it against another thermometer and it is based on a fundamental physical law including the thermodynamic temperature. There are several other primary thermometers based on different fundamental laws listed in Table 8.3.

Since these primary thermometers are usually complicated and difficult to handle, a temperature scale was introduced for practical purpose and refined over the years. Such a scale consists of temperature fixed points, the temperature values of which are determined with great effort by comparison with primary thermometers, and of interpolating instruments, which are calibrated at those fixed points and define the temperature in between.

Table 8.3 Primary thermometers and the fundamental relations on which they are based

Thermometer	Fundamental Relation
Constant-volume gas thermometer (ideal gas) pressure p , volume V , number of moles n , molar gas constant R , temperature T	$pV = nRT$
Acoustic gas thermometer (ideal gas) speed of sound c_s , ratio γ of specific heat capacities at constant pressure and constant volume, gas constant R , temperature T , molar mass M	$c_s = (\gamma RT/M)^{1/2}$
Dielectric-constant gas thermometer (ideal gas) pressure p , Boltzmann constant k_B , temperature T , dielectric constant ε , electric constant ε_0 , static electric dipole polarisability of a gas atom α_0	$p = k_B T (\varepsilon - \varepsilon_0) / \alpha_0$ (Clausius–Mosotti equation)
Total radiation thermometer total radiance L , Boltzmann constant k_B , temperature T , speed of light in vacuum c , Planck constant h	$L = (2\pi^5 k_B^4 T^4) / (15c^2 h^3)$ (Stefan–Boltzmann law)
Spectral band radiation thermometer spectral radiance L_ν , Planck constant h , frequency of light in vacuum ν , speed of light in vacuum c , Boltzmann constant k_B , temperature T	$L_\nu = 2h\nu^3/c^2 [\exp(h\nu/k_B T) - 1]^{-1}$ (Planck’s Law)
Noise thermometer mean square noise voltage $\langle V^2 \rangle$, Boltzmann constant k_B , temperature T , resistance R , bandwidth Δf	$\langle V^2 \rangle = 4k_B TR \Delta f$ (Nyquist formula)

After some early attempts such a scale was adopted in 1927 following a suggestion by Callendar from 1899. The actual revision of the temperature scale dates from 1990. It is called the International Temperature Scale of 1990, ITS-90. It is based on 14 fixed points from the triple point of hydrogen (13.8033 K) to the freezing point of copper (1357.77 K) and the vapor pressure of the stable helium isotopes below.

One of these fixed points is the triple point of water, the value of which is fixed to 273.16 K, as the defining point of the temperature unit kelvin. This definition states: the kelvin is the fraction $1/273.16$ of the thermodynamic temperature of the triple point of water.

Interpolating instruments are the vapor pressure thermometer with ^3He or ^4He as the working gas from 0.65 K to 5 K, which is part of the scale's definition as well, an interpolating gas thermometer with the same gases up to 25 K and standard platinum resistance thermometers (SPRTs) above. From the freezing point of silver (1234.93 K) to the highest temperatures to be reached the relative spectral radiance thermometer is used, being calibrated at the Ag, Au or Cu fixed point, respectively. Table 8.4 includes the temperature fixed points and indicates the uncertainty ΔT_{90} of the realization of the ITS-90.

In 2000 the CIPM (Comité International des Poids et Mesures) adopted an extrapolation of the temperature scale to sub-kelvin temperatures. This scale,

called the Provisional Low Temperature Scale of 2000, PLTS-2000, is based on magnetic and superfluid phase transitions in ^3He and the minimum of its melting pressure as fixed points and the ^3He melting curve thermometer as the interpolating instrument.

The national metrological systems, often divided into legal and industrial branches, provide national temperature standards and calibration facilities for science and industry to trace back the readings of thermometers of individual users. The lowest uncertainty is available from those national metrological institutes, which compare their particular representations of ITS-90 from time to time by means of so called key comparisons to guarantee the uniformity of temperature measurements throughout the world. The definition of temperature, the development of temperature scales and the principles of thermometry are extensively explained in the monograph [8.52].

Very recently, efforts have been started by several national metrological institutes to replace the dependence of the kelvin on a material property, namely the already mentioned triple point of water. Instead, it is suggested that the kelvin should be based on a fundamental constant as is done with other SI units, which are already related to a fundamental constant, such as the meter to the speed of light in vacuum, or are in the process of being related, like the kilogram. In the case of the kelvin the appropriate constant would be the Boltzmann

Table 8.4 The defining fixed points of ITS-90 [8.51]

No.	T_{90} (K)	t_{90} ($^{\circ}\text{C}$)	ΔT_{90} (mK)	Substance	State
1	3–5	–270.15 to –268.15	0.1	^3He and ^4He	Vapor pressure
2	13.8033	–259.3467	0.1	e- H_2^{a}	Triple point
3	≈ 17	≈ -256.15	0.2	e- H_2	Vapor pressure ≈ 33.3213 kPa
4	≈ 20.3	≈ -252.85	0.2	e- H_2	Vapor pressure ≈ 101.292 kPa
5	24.5561	–248.5939	0.2	Ne	Triple point
6	54.3584	–218.7916	0.1	O_2	Triple point
7	83.8058	–189.3442	0.1	Ar	Triple point
8	234.3156	–38.8344	0.05	Hg	Triple point
9	273.16	0.01	0.02	H_2O	Triple point
10	302.9146	29.7646	0.05	Ga	Melting point
11	429.7485	156.5985	0.1	In	Freezing point
12	505.078	231.928	0.1	Sn	Freezing point
13	692.677	419.527	0.1	Zn	Freezing point
14	933.473	660.323	0.3	Al	Freezing point
15	1234.93	961.78	1–10	Ag	Freezing point
16	1337.33	1064.18	10	Au	Freezing point
17	1357.77	1084.62	15	Cu	Freezing point

^a e- H_2 is hydrogen at the equilibrium concentration of the ortho and para molecular forms

constant k_B . If its value is determined with sufficient accuracy – about one order of magnitude better than now – and then fixed by definition, temperature could be traced back to the internal energy $k_B T$, the quantity to which it is proportional in the microscopic view, as mentioned at the beginning of this section.

8.5.2 Use of Thermometers

Strictly speaking, a thermometer never measures the temperature of the sample of interest, but always its own. To get an indication of the sample's temperature its temperature and the temperature of the thermometer should agree within the requested uncertainty of the measurement. To meet this requirement within a finite amount of time heat should easily be able to flow between them. If the heat flow has approached zero, so called thermal equilibrium is reached between sample and thermometer, and the thermometer is ready to indicate the sample's temperature. In the case of contact thermometry the thermal resistance between the sample and the thermometer should be low. Thermal conductivity should be high within the sample and within the thermometer to provide thermal equilibrium within both. A small heat capacity of the thermometer is advantageous, since then only a small amount of heat is forced to flow in order to reach thermal equilibrium. Small heat capacity, good thermal contact and large internal thermal conductivity make the thermometer fast.

A thermometer gives an indication of its temperature by measuring some other property that is somehow dependent on temperature. With a constant-volume gas thermometer the pressure is the quantity that measures temperature, with a resistance thermometer it is the electrical resistance of the sensor. Usually some energy is needed to read the thermometer on the display. This energy is fed to the sensor and, in principle, due to the permanent heat flow, keeps the thermometer out of equilibrium. Therefore, the measuring energy must be reduced to a value that does not disturb the result. Since thermal conductivity, thermal contact resistance and heat capacity change with temperature, the measuring energy must also be changed in most cases over the temperature range.

In the following, we will consider some frequently appearing errors in the use of thermometers, which are discussed in [8.53] in great detail.

- *Electromagnetic interference*

Since the energy flowing between sample and thermometer is not limited to the measuring energy, other

energy contributions coupled into the system, such as heat leaks, must be kept under control during the measurement. If electromagnetic energy from radio and television broadcasts irradiates the thermometer and is fed in by the wiring, or if the electromagnetic radiation emitted from hot surfaces nearby is absorbed by the thermometer, the measuring result can be significantly affected. Electromagnetic shielding of the thermometric sensors and electronics, filtering circuits in the sensor wiring and radiation shields are necessary tools when the amount of irradiated external energy can not be tolerated. In extreme situations the whole measurement should be located in an electromagnetically shielded room.

- *Immersion error*

Immersion error is an issue for liquid-in-glass thermometers and others that are usually not fully immersed in the liquid to be measured. In this case, heat is permanently flowing through the stem of the thermometer from the bath to the surrounding air. This is a typical nonequilibrium situation inappropriate for an exact result. As a rule of thumb a thermometer should be immersed into the bath by more than ten diameters of the thermometer (that means 40 mm beyond the sensing element with a sensor diameter of 4 mm) to limit the error to 0.01%.

- *Heat capacity error*

If the heat capacity of the thermometer is not negligible compared to the heat capacity of the sample and the sample is more or less thermally isolated, a certain amount of heat flows between them when the starting temperatures are different. After reaching thermal equilibrium both temperatures have changed to a common value somewhere between their initial temperatures. This means that, if the sample's temperature was, e.g. much hotter than that of the thermometer, the finally indicated temperature of the sample would be less than its value before the measurement. This difference is called the heat capacity error.

- *Time constant*

Even if the sample's heat capacity is large enough to avoid the heat capacity error it may take a significant time to replace the heat in the sample that has flown into the thermometer while thermal equilibrium was established. Therefore, the reading of the thermometer approaches its final value following an exponential trend with a time constant τ_0 . If insufficient time is given to the system, a settling response error is arising. If the temperature of a sample

is changing at a certain rate, and the settling rate of the thermometer is too slow compared to the temperature variation rate, a lag between the real and the measured temperature will develop. This can be avoided either by slowing down the rate of temperature change or by a constructive improvement of the thermal coupling between the parts of the system.

- **Environmental irradiation**

According to the Stefan–Boltzmann law (see Table 8.3) all material surfaces emit electromagnetic radiation proportional to T^4 . Therefore, all radiating sources in the environment should be removed, if possible, or at least shielded, since thermometers should not see surfaces at temperatures very different from their own. In addition, thermometers show significantly different readings up to the order of some kelvin depending on their surface emissivity. This fact recommends proper shielding, as well.

To clarify the different influences on thermometers during the measurement of temperature it is helpful to use *analogue electrical modeling*. Since thermal conductivity can be described in a similar way as its electrical correspondent, one can derive analogue relations. Heat Q corresponds to electrical charge Q_{el} , heat flux q to electrical current I , temperature difference ΔT to voltage V , thermal resistance R_{th} to electrical resistance R_{el} , and heat capacity c_p to electrical capacitance C . Thus, Ohm's law can be applied in analogy to heat flow processes in the following form:

$$\Delta T = T_2 - T_1 = qR_{\text{th}}. \quad (8.24)$$

If the heat flow crosses several materials with different thermal conductivities and thermal contact resistances in between, the thermal resistances can be added like electrical resistances in series. If there are several heat flows from different sources to one thermometer, such as heat conduction from the sample and from the surroundings and thermal radiation from other nearby objects, the inverse of the thermal resistances can be added again. Within this electrical analogue picture one can state that a thermometer measures the correct sample temperature when the thermal resistance between them goes to zero, whereas the thermal resistances to other objects such as the surroundings tend to infinity by screening or shielding measures.

If temperature measurements are performed in a way that excludes all errors, most of which are mentioned above, the result is reliable only with the correct calibration of the instrument. This means, that its indicated result must be traced to the SI unit kelvin by linking it

to the international temperature scale. Furthermore, the uncertainty of the calibration caused by the number of steps or the special way of this trace back must be known or investigated, and the reliability of the instrument over a longer period of time should be proven. The last requirement can be met by repeated calibrations from time to time, depending on the frequency and intensity of the thermometer's use.

8.5.3 Resistance Thermometers

The type of thermometers most frequently found in scientific and technical equipment is the resistance thermometer, since it is easily read by electronics and can simply be used for temperature control cycles. The most widespread type among the resistance thermometers is the platinum resistance thermometer, which at the same time is the interpolating instrument of the ITS-90 at the highest level of accuracy. In the latter case it is called the standard platinum resistance thermometer (SPRT) and is used in different forms between the triple point of hydrogen at 13.8033 K and the freezing point of silver at 1234.93 K.

The electrical resistance of metallic samples comes from the scattering of the conduction electrons at the atoms or molecules of the solid lattice. There is a temperature-dependent part of the resistance R_t due to lattice vibrations, which increases with increasing internal energy, and a temperature-independent part R_0 caused by impurities and by lattice defects. The total sample resistance arises as the sum of both

$$R(T) = R_t(T) + R_0. \quad (8.25)$$

This equation, in the literature called Mathiessens's rule, can be reformulated as

$$R(T) = R(0^\circ\text{C})(1 + \alpha t), \quad (8.26)$$

where α is the temperature coefficient of resistance. Fewer impurities or defects reduce R_0 or R at 0°C and increase α . Therefore, the metals that should be used for resistance thermometers are those that can be purified to the highest values and effectively annealed. High-purity platinum most closely obeys Mathiessen's rule with small deviations found by Callendar and later by van Dusen. Finally, (8.26) is modified to the Callendar–van Dusen equation

$$R(T) = R(0^\circ\text{C}) \left[1 + At + Bt^2 + C(t - 100)t^3 \right], \quad (8.27)$$

with coefficients of the order: $A = 4 \times 10^{-3} ^\circ\text{C}^{-1}$, $B = -6 \times 10^{-7} ^\circ\text{C}^{-2}$, and $C = 4 \times 10^{-12} ^\circ\text{C}^{-3}$.

This ideal behavior of platinum thermometers is only true, if no other effects influence its resistance. Such disturbing effects to be avoided are strain, mechanical shock, vibration, pressure, humidity, and corrosion. Some of them, such as strain, are caused by temperature changes in an uncontrolled manner. Others can be reduced by careful handling. Further ones must be minimized by using a sealed and shielded construction.

Standard platinum resistance thermometers for ITS-90 realization are manufactured in three different types, as listed in Table 8.5.

SPRTs are usually constructed of high-purity coiled platinum wire within a sheath of glass or quartz embedded in a platinum tube. This is a setup free of strain and danger of contamination, but extremely sensitive to shock, vibrations or other mechanical stress. Therefore, SPRTs are, on one hand, temperature standards with high stability and an uncertainty of less than 1 mK, but on the other not suitable for rough industrial environments. To obtain a more robust device, the support of the platinum wire should be improved. This inevitably causes more strain during temperature variations and increases the uncertainty to about 10 mK. A further disadvantage of all wire-made devices is the poor thermal contact only made by the gas in the capsule and the leads, resulting in time constants of several seconds. As an alternative solution, thick-film thermometers are available, which can be glued to the sample of interest and have improved thermal contact and time constant. They mostly have a nominal resistance of 100 Ω and are well suited as sensors for rough environments and temperature control circuits, but they feel much more strain and contamination effects and suffer from a larger uncertainty of about 100 mK. All of these devices are available commercially and should not be fabricated by the user except for very special needs. Some of them are shown in Fig. 8.10.

For the *electronics of resistance thermometers* two different concepts are in use: the potentiometric method and the resistance bridge (Fig. 8.11). The first is the most common concept, especially since precise electronic devices appeared on the market. A reference resistor is placed in series with the temperature sensor and the voltage drop across each of the resistors is determined when a constant current is applied. The voltage drop

Fig. 8.10 (from left to right) three thick-film Pt-100 resistors; Pt-500 chip resistor prepared for SMD mounting; Pt-100 resistor in ceramics; two NTC thermistors in glass; Pt-100 resistor in glass; double Pt-100 resistors in glass; long-stem SPRT (Pt-25); capsule SPRT (Pt-25)

across the known reference resistor R_{ref} yields the current I through the sensor. Using the voltage drop $V(T)$ measured across the sensor, the resistance $R(T)$ can be calculated using Ohm's law again.

The use of bridge circuits is an alternative method. These circuits rely on the principle of the Wheatstone bridge. The design consists of two parallel branches of two resistors in series, e.g. R_1 and the sensor $R(T)$ in one branch and R_2 and R_3 in the other. In the balanced bridge mode, the resistor R_3 is adjusted so that the voltage between the centers of the two branches is zero. This adjustment has to be done for each temperature T . $R(T)$ is then given by

$$R(T) = R_1(R_3/R_2) . \tag{8.28}$$

If this balancing is performed at only one temperature, say T_0 , the bridge output $V_1 - V_2$ differs from zero at other temperatures and is proportional to the measured temperature in the linear range of the bridge around T_0 .

When measuring the temperature sensor's resistance one has to consider that there always is a lead resistance in series. The best method to avoid this error is to measure with a four-lead arrangement, where the two voltage probe leads are fixed as close to the sensor as possible.

Table 8.5 Types of standard platinum resistance thermometers

Type of thermometer	Temperature range	Typical resistance
Capsule thermometers, 50–60 mm long	13.8–430 K	25.5 Ω
Long-stem thermometers, 450 mm long	84–933 K	25.5 Ω
High-temperature long-stem thermometers	0.01–962 °C	0.25 Ω

If the voltmeter's internal resistance is close to infinity, only a negligible current flows through the voltage leads and their voltage drop can be neglected. If four leads are too expensive and less accuracy is sufficient, a two-lead arrangement can be used. For the lead wires, materials with a low temperature coefficient of electrical resistance are preferred. Furthermore, the wiring should be performed such that the temperature along these leads will not change during the measurement to keep their resistance constant. There is also a third method, which is a sort of compromise in expense and accuracy between both methods described: the three-lead concept. Here only one voltage lead is connected close to the sensor. Thus, one can measure the voltage drop across the sensor and one current lead in series and subtract the voltage drop of the other current lead measured separately.

There are further sources of errors not dealt with up to now, the thermoelectric effect at connections of different materials along the leads and the input offset voltage of the voltmeter. By reversing the direction of the measuring current those errors can be averaged out. If this is done systematically by applying alternating current for the measurement, one can remove these errors quantitatively. In addition, the resolution of the measurement can be improved by the application of lock-in techniques.

Electromagnetic interference (EMI) can be a problem in particular with alternating current (AC) measurements, if the filtering of, e.g., the power lines is not adequate in the electronics. In addition, the sensor leads should be protected from extra currents induced by changing external magnetic fields. This could be achieved using the twisted-pair design or by coaxial cable to minimize the loop area between the lead wires. The heating of the sensor by captured radio and television frequencies should be prevented by appropriate shielding of the whole measuring arrangement. Other errors are primarily due to the handling of the measurement and the methods of avoiding these are described in the previous section.

A different type of resistance thermometer is the rhodium-iron thermometer (0.5% Fe in Rh). Its merits are at the low temperature range between 0.5 K and 30 K, where it is more sensitive than the platinum thermometer, but it is still useful up to room temperature. Besides the wire-type device with a resistance in the range 20–50 Ω , thick-film versions are commercially available. For very low temperatures different resistance materials are used and described in the last section.

There are also resistance thermometers made from semiconducting materials, known as negative temperature coefficient (NTC) or positive temperature

Fig. 8.11a,b Resistance measurement circuits (a) potentiometric type. (b) bridge type

coefficient (PTC) thermistors. The temperature dependence of the resistance of NTCs obeys an exponential law

$$R(T) = A \exp(B/T) . \quad (8.29)$$

Compared to platinum resistance thermometers, NTCs show more than 100 times the sensitivity (3–6%/°C) in the temperature range from –100 °C to +150 °C as well as being smaller and faster. Two such devices are shown in Fig. 8.10. However, they are significantly less stable than PRTs and their temperature resistance relation is extremely nonlinear (8.29) and difficult to fit accurately over a wide range. They are ideal for use in control circuits and for differential temperature measurements.

8.5.4 Liquid-in-Glass Thermometers

A liquid-in-glass thermometer, the oldest type of thermometer, is based on the thermal expansion of a liquid as a function of temperature. It consists of a glass bulb connected to a capillary containing the sensing liquid – in most cases mercury or an organic liquid. Attached to it is a scale scratched on a flat glass strip along the capillary or on the capillary itself. The bulb, capillary, and scale are placed in a slightly wider glass tube as a protective container.

In spite of the image of simplicity that liquid-in-glass thermometers have obtained, they are more complicated to understand and to handle than is commonly recognized. Such a thermometer is a system with strong interference between its components. The liquid is the temperature sensor and its indicator at the same time, which means that the volume of the bulb that contains the sensing liquid should be much larger (by a factor of at least 1000) than the volume of the indicating cap-

illary due to the small relative expansion coefficients (mercury: $0.00016^{\circ}\text{C}^{-1}$; ethanol: $0.00104^{\circ}\text{C}^{-1}$). The bulb and capillary are the container for the sensing liquid but, as they have a temperature coefficient different from zero, they are an integral part of the sensor and are the origin of nonlinearities in the reading. Finally, the scale, which is needed for the user to read the indicated temperature by comparison with the liquid level in the capillary, shows a temperature-dependent length dilatation. It can easily be seen, that this complicated temperature dependence causes uncertainties, especially due to the level of immersion of the thermometer in the bath to be measured. Therefore, the depth of immersion during calibration is usually marked on the thermometer and should preferably be used again when measurements are made.

There are other sources of errors, some of which are similar to issues in other thermometers. Thermal contact through the glass walls and the heat capacity of the liquid in the bulb lead to time-constant effects and errors if there is not enough time for the system to equalize. Particular errors of liquid-in-glass thermometers result from pressure effects. High external pressure may change the bulb volume and consequently the level of the liquid in the capillary. The gas in the capillary, which should compensate for the vapor pressure of the liquid at higher temperatures to avoid interruptions of the liquid column and the formation of bubbles, will affect the indication. Linearization of the scale may not be perfect or the scale may be misplaced or misaligned. Also, parallax errors may occur due to refraction by the glass tubes if the reading is not taken exactly perpendicular to the surface.

The advantages of liquid-in-glass thermometers remain their immunity to chemical attack and electromagnetic interference and their low cost. Instruments are available with a maximum error of 0.1°C in the range from the ice point to about 50°C . This error increases to 1°C or 2°C near the limits of the application range at -80°C and 500°C .

8.5.5 Thermocouples

Thermocouples nowadays have the widest field of application of all temperature sensors. They generate an electrical readout similar to resistance thermometers, but the measuring principle is quite different. In resistance thermometers a sensor's property, namely the temperature-dependent resistance of the material, is measured at the location of the sensor. With thermocouples, their basic principle, the Seebeck effect (one of the thermoelectric effects, discovered in 1821), is a property of the whole wiring between the measur-

ing and the reference junction. The principle circuit of a thermocouple is presented in Fig. 8.12.

The Seebeck effect means that within a conducting wire exposed to a temperature gradient a voltage difference is generated between its ends depending on their temperature difference. The simplified picture considering the electrons within the conductor as free particles explains that they tend to move to the low-temperature side because on the high-temperature side the electron gas contains more kinetic energy and expands to the other end of the wire. This expansion causes a negatively charged low-temperature end. The voltage difference generated in this way finally stops the electron motion at an equilibrium state. If the conductor, named A for distinction, is homogeneous along its length with respect to its geometrical cross section, chemical composition, and lack of defects, the Seebeck voltage depends only on the temperature difference between the ends. To measure this voltage one connects a second wire B of a different material to the temperature-measuring end of wire A and leads it, via a contact stabilized to a reference temperature, to the other input terminal of a voltmeter. Due to the fact that disturbing effects can only be excluded from the temperature measurement for homogeneous parts of the circuit, all inhomogeneous parts of the wiring, such as the measuring junction, the reference junction and other contacts within the measuring voltmeter circuit, should be strictly kept isothermal. Consequently, the number of junctions in the wiring should be reduced to an absolute minimum. In addition, current-induced voltage drops along the leads should be excluded by the use of a high-impedance voltmeter.

For the temperature of the reference junction in most cases the ice point is used, since it can be realized simply and provides sufficient temperature stability and homogeneity. Alternatively, an isothermal reference junction at a stabilized temperature different from 0°C can be applied, if its temperature is accurately measured and

Fig. 8.12 Principle design of a thermocouple

Table 8.6 The eight internationally adopted types of thermocouples

Type	Materials	max. Temp. (°C)	Sensitivity ($\mu\text{V}/^\circ\text{C}$) at		
			20 °C	100 °C	500 °C
B	Platinum 30% rhodium/platinum 6% rhodium	1700	0	0.9	5.1
E	Nickel–chromium alloy/copper–nickel alloy	870	60.5	67.5	81.0
J	Iron/another slightly different copper–nickel alloy	760	51.5	54.4	56.0
K	Nickel–chromium alloy/nickel–aluminium alloy	1260	40.3	41.4	42.7
N	Nickel–chromium alloy/nickel–silicon alloy	1300	26.6	29.6	38.3
R	Platinum 13% rhodium/platinum	1400	5.9	7.5	10.9
S	Platinum 10% rhodium/platinum	1400	5.9	7.4	9.9
T	Copper/copper–nickel alloy	370	40.3	46.7	

the Seebeck voltage of the reference-junction temperature read from standard tables (see below) is used for correction.

For different measuring purposes, different materials are used for thermocouples. In Table 8.6 standard commercially available devices are listed including their maximum temperature.

There are mathematical definitions for the response of each leg material or material composition to temperature changes. Manufacturers guarantee tolerance classes 1 to 3 for the agreement of their products with those formula-based tables (class 1: 0.4%; class 2: 0.75%; class 3: 1.5% within certain temperature limits).

Most errors when using thermocouples are similar to those with other thermometers concerning heat capacity, time constants, immersion and radiation. Particular errors due to material properties or construction principles are avoided by obtaining the instrument from a well-known supplier.

The type of thermocouple appropriate for a certain application should be selected first according to the temperature range specified by the manufacturer. For low-accuracy demands in industrial environment uncertainties of 1% are reached with standard devices. For higher demands, rare-metal thermocouples such as type B, R and S should be chosen because of their improved uncertainty of 0.1%.

8.5.6 Radiation Thermometers

Radiation thermometers determine the surface temperature of an object by measuring its temperature-dependent radiation. They are noncontact thermometers and are suitable for remote sensing. This makes them a superior or even only choice, if the objects are far away, moving fast or if they are too hot or dangerous to achieve direct contact, e.g. hot furnaces, the blades of a spinning turbine or the sun and other stars in the universe.

Radiation thermometers rely on fundamental thermodynamic physical laws, e.g. Planck's law, and they can easily be modeled in great detail. A measurement at a certain temperature can be related to the measurement of the temperature of the triple point of water or another temperature fixed point by direct comparison and is, by this means, directly traceable to the ITS-90. The measured radiance has to be corrected, however, due to the quality of the sample's surface, characterized by its spectral emissivity and the stray light reflected into the detector from the surroundings.

A radiation thermometer observes only the temperature of the object's surface, which may even be considered as the sensing element of the method, and not the sample's temperature deep in the bulk. This is a disadvantage for the determination of bulk temperatures, but it turns out to be an exclusive advantage if the surface temperature is the quantity of interest.

The most common type of radiation thermometers are *spectral band radiation thermometers* (for the design principle and a photograph, see Fig. 8.13). The main components are focusing optics with a set of two apertures defining the observed part of the target surface and the field of view. Within the optical path a band filter selects the wavelengths of interest. Finally a radiation detector converts the collected light flux into an electrical current which is amplified and indicated on the display.

Although everything radiates, only for certain geometric configurations can the radiance be calculated ab initio, so that they can be used for calibration of electromagnetic radiation detectors, especially for radiation thermometers. Those calculable sources are blackbodies, which radiate according to Planck's law (Table 8.3), and electron storage rings, which deliver synchrotron radiation at higher energies following the Schwinger formula. Because the wavelengths used in radiation thermometry mainly coincide with the regime of Planck's

Fig. 8.13 Principle design and photograph of a radiation thermometer

law, blackbodies operating at the fixed point temperatures of ITS-90 are the natural devices for temperature calibrations.

The spectral radiance L_{meas} measured by a spectral-band radiation thermometer is given by (8.30) for sample temperatures higher than 200 °C

$$L_{\text{meas}} = \varepsilon(\lambda) L_{\text{bb}}(\lambda, T_s). \quad (8.30)$$

This is the spectral radiance of a blackbody $L_{\text{bb}}(\lambda, T_s)$ at the sample temperature T_s corrected by the emissivity $\varepsilon(\lambda)$ of the sample surface. Applying Wien's radiation law

$$L_{\text{bb}}(\lambda, T) = (c_1/\lambda^5) \exp(-c_2/\lambda T) \quad (8.31)$$

as a valid approximation for the blackbody radiation at the wavelengths shorter than λ_{max} commonly used in radiation thermometry the true temperature of the sample surface T_s can be estimated from the measured radiance temperature T_{meas} according to

$$1/T_s = 1/T_{\text{meas}} + (\lambda/c_2) \ln[\varepsilon(\lambda)]. \quad (8.32)$$

T_{meas} is the temperature derived from the spectral radiance L_{meas} by Wien's law. If the sample temperature

is below 200 °C, the detector's own radiance must be compensated.

Calibration of a radiation thermometer is performed by comparison with a source of known radiance. This can be done by measuring the emission of a tungsten strip lamp or, as mentioned, of a blackbody at a certain temperature known from a calibrated, e.g., platinum thermometer or preferably of a temperature fixed point blackbody. If only an uncalibrated light source is available, one may compare the thermometer under test with a reference radiation thermometer when they both observe the radiance of a light source with stable emission.

There are several other types of radiation thermometers, such as the disappearing-filament thermometer, the ratio thermometer, and the multi-spectral radiation thermometer, which are not described here [8.53]. Based on a different physical law, the Stefan–Boltzmann law (Table 8.3), *total radiation thermometers* measure a signal proportional to T^4 . They often collect the radiation of the target incident on a hemisphere. Therefore, the distance to the object has to be quite short. Further thermometers use optical fibres to conduct the light to their detector. In some cases the other end of the fibre is covered by a sort of small blackbody, the temperature of which is changed by thermal contact with the target. Its temperature is then determined from its spectral radiance as described above.

8.5.7 Cryogenic Temperature Sensors

Temperatures near absolute zero seem to be of interest only to specialists in ultra-low temperature physics. However, a lot of important material properties, which are of increasing interest for technical applications, change with decreasing temperature, superconductivity and superfluidity being the most prominent examples. There are further macroscopic quantum phenomena, such as the Josephson effect, that are essential for the highest sensitivity magnetic-field sensors (superconducting quantum interference devices or **SQUIDS**) or the quantum Hall effect as basis for the international standard for the resistance unit ohm. As a consequence the **CIPM** recently adopted an extension of the international temperature scale from the lower end of ITS-90 near 1 K down to below 1 mK, the Provisional Low Temperature Scale of 2000 (PLTS-2000). It is given by the definition of the relation between pressure and temperature along the melting curve of ^3He . This solid–liquid phase transition can be described by the Clausius–Clapeyron equation in principle. But, since the molar volumes and entropies of the solid and the liquid phase are not known

with sufficient accuracy, a polynomial with internationally agreed coefficients is used [8.54].

Before cooling the sample and the thermometer ^3He is filled from the gas-handling system into the measuring cell (Fig. 8.14) via a capillary. The pressure in the cell at low temperatures varies within the range 2.9–4.0 MPa and is determined capacitively. One of the cell walls is shaped as a membrane and responds to pressure changes by changing the distance between the moving plate glued to it and the fixed counter plate (center plate). The center plate and the reference plate represent a stable reference capacitor at low temperatures. The resolution of the capacitance bridge indicates distance changes between the plates of the order of only fractions of an atomic diameter, which yields a temperature resolution of some μK at 1 mK up to some 100 μK at 1 K.

The temperature values related to the ^3He pressure were determined by primary thermometry based on a noise thermometer with a resistive SQUID as the temperature-sensitive element (Table 8.3). It was cross-checked by several magnetic thermometers described later on. Nuclear orientation thermometry is a further primary method at millikelvin temperatures. It relies on the temperature-dependent ordering of the magnetic moments of radioactive nuclei indicated by the anisotropy of their emitted γ radiation. The problem of this thermometer is its narrow temperature range depending on the activation of the sensor. There is a danger of overheating at low temperatures with high activities, and of insufficient sensitivity at high temperatures with low activities.

For practical temperature measurements, different resistance thermometers are used. The principle of these measurements is described in Sect. 8.5.3. The RhFe re-

sistors mentioned there are suitable for temperatures down to 1 K. Below that, germanium and carbon resistors have been the favourites for a long time. These are semiconducting materials with a temperature-dependent resistance caused by the carriers being frozen with falling temperature. Over recent years further types of resistors have been developed by different manufacturers (carbon–glass resistors, carbon–ceramic resistors, ruthenium-oxide sensors).

Magnetic thermometers show a temperature-dependent magnetization. If the magnetic moments of either the electronic shell of the thermometer's atoms or of their nuclei are exposed to a homogeneous and static magnetic field, they order to a certain extent depending on the lattice or nuclear temperature according to the Boltzmann distribution. The resulting macroscopic magnetization is inversely proportional to temperature (Curie or Curie–Weiss law) and can be probed by susceptibility or magnetic resonance measurements. The first case is realized with the electronic moment of, e.g., cerium magnesium nitrate (CMN), which is a useful thermometric substance and workhorse from above 1 K to about 10 mK. For the measurement of temperatures from about 30 mK down to the μK region pulsed NMR with pure platinum (Pt-NMR) is the standard method. For both thermometers a precise calibration at their high-temperature end is essential, where the signal amplitude unfortunately is low. In addition, both the construction of the device and the purity of the sensing substance should produce a strictly linear behavior, because only extrapolation to their respective lowest temperatures is possible. A detailed description how to generate very low temperatures and how to measure them is given in [8.55] and [8.56].

Electrical Properties

9. Electrical Properties

Electronic materials – conductors, insulators, semiconductors – play an important role in today's technology. They constitute "electrical and electronic devices", such as radio, television, telephone, electric light, electromotors, computers, etc. From a materials science point of view, the electrical properties of materials characterize two basic processes: electrical energy conduction (and dissipation) and electrical energy storage.

- Electrical conductivity describes the ability of a material to transport charge through the process of conduction, normalized by geometry. Electrical dissipation comes as the result of charge transport or conduction. Dissipation or energy loss results from the conversion of electrical energy to thermal energy (Joule heating) through momentum transfer during collisions as the charges move.
- Electrical storage is the result of charge storing energy. This process is dielectric polarization, normalized by geometry to be the material property called dielectric permittivity. As polarization occurs and causes charges to move, the charge motion is also dissipative.

In this chapter, the main methods to characterize the electrical properties of materials are compiled. Sections 9.2 to 9.5 describe the measuring methods under the following headings:

- Electrical conductivity of metallic materials
- Electrolytical conductivity
- Semiconductors
- Dielectrics

As an introductory overview, in Sect. 9.1 the basic categories of electrical materials are outlined in adopting the classification and terminology of chapter the "Electronic Properties of Materials" of "Understanding Materials Science" by Hummel [9.1].

9.1 Electrical Materials

One of the principal characteristics of materials is their ability (or lack of ability) to conduct electrical current. According to their conductivity σ they are divided into conductors, semiconductors, and insulators (dielectrics). The inverse of the conductivity is called resistivity ρ that is $\rho = 1/\sigma$. The resistance R of a piece of conducting material is proportional to its resistivity and to its length L and is inversely proportional to its cross-sectional area A : $R = L\rho/A$. To measure the electrical resistance, a direct current is applied to a slab of the material. The current I through the sample (in amperes), as well as the voltage drop V on two potential probes (in volts) is recorded as depicted in Fig. 9.1.

The resistance (in ohms) can then be calculated by making use of Ohm's law $V = RI$. Another form of Ohm's law $j = \sigma E$ links current density $j = I/A$, that is, the current per unit area (A/cm^2), with the conductivity σ ($\Omega^{-1}\text{cm}^{-1}$ or siemens per cm) and the electric field strength $E = V/L$ (V/cm).

The conductivity σ of different materials at room temperature spans more than 25 orders of magnitude as depicted in Fig. 9.2. Moreover, if one takes the conductivity of superconductors, measured at low temperatures, into consideration, this span extends to 40 orders of magnitude (using an estimated conductivity for superconductors of about $10^{20} \Omega^{-1}\text{cm}^{-1}$). This is the largest known variation in a physical property.

9.1.1 Conductivity and Resistivity of Metals

For metallic materials it is postulated that they contain “free electrons” which are accelerated under the influence of an electric field maintained, for example, by a battery. The drifting electrons can be considered, in a preliminary, classical description, to occasionally collide (that is, electrostatically interact) with certain lattice atoms, thus losing some of their energy. This constitutes the electrical resistance.

Semiconductors or insulators which have only a small number of free electrons (or often none at all) display only very small conductivities. The small number of electrons results from the strong binding forces between electrons and atoms that are common for insulators and semiconductors. Conversely, metals which contain a large number of free electrons have a large conductivity. Further, the conductivity is large when the average time between two collisions τ is large. Obviously, the number of collisions decreases (i. e., τ increases) with

decreasing temperature and decreasing number of imperfections. The simple “free electron model” describes the electrical behavior of many materials reasonably well.

Electron Band Model

Electrons of isolated atoms (for example in a gas) can be considered to orbit at various distances about their nuclei. These orbits constitute different energies. Specifically, the larger the radius of an orbit, the larger the excitation energy of the electron. This fact is often represented in a somewhat different fashion by stating that the electrons are distributed on different energy levels, as schematically shown in Fig. 9.3.

These distinct energy levels, which are characteristic for isolated atoms, widen into energy bands when atoms approach each other and eventually form a solid as depicted on the left-hand side of Fig. 9.3. Quantum mechanics postulates that the electrons can only reside within these bands, but not in the areas outside of them. The allowed energy bands may be noticeably separated from each other. In other cases, depending on the material and the energy, they may partially or completely overlap. In short, each material has its distinct electron energy band structure. Characteristic band structures for the main classes of materials are schematically depicted in Fig. 9.4.

The band structures shown in Fig. 9.4 are somewhat simplified. Specifically, band schemes actually possess a fine structure, that is, the individual energy states (i. e.,

Fig. 9.1 Principle of the measurement of the resistance of a conductor

Fig. 9.2 Conductivity scale of materials

the possibilities for electron occupation) are often denser in the center of a band (Fig. 9.5).

Some of the bands are occupied by electrons while others remain partially or completely unfilled. The degree to which an electron band is filled by electrons is indicated in Fig. 9.4 by shading. The highest level of electron filling within a band is called the Fermi energy E_F . Some materials, such as insulators and semiconductors, have completely filled electron bands. (They differ, however, in their distance to the next higher band.) Metals, on the other hand, are characterized by partially filled electron bands. The amount of filling depends on the material, that is, on the electron concentration and the amount of band overlap.

According to quantum theory, first only those materials that possess partially filled electron bands are capable of conducting an electric current. Electrons can then be lifted slightly above the Fermi energy into an allowed and unfilled energy state. This permits them to be accelerated by an electric field, thus producing a current. Second, only those electrons that are close to the Fermi energy participate in the electric conduction. Third, the number of electrons near the Fermi energy depends on the density of available electron states (Fig. 9.5). The conductivity in quantum mechanical terms yields the following equation: $\sigma = 1/3e^2v_F^2 \tau N(E_F)$, where v_F is the velocity of the electrons at the Fermi energy (called the Fermi velocity) and $\tau N(E_F)$ is the density of filled electron states (called the population density) at the Fermi energy. Monovalent metals (such as copper, silver, and gold) have partially filled bands, as shown in Fig. 9.4. Their electron population density near the Fermi energy is high which results in a large conductivity. Bivalent metals, on the other hand, are distinguished by overlapping upper bands and by a small electron concentration near the bottom of the valence band. As a consequence, the electron population near the Fermi energy is small which leads to a comparatively low conductivity. For alloys, the residual resistivity increases with increasing amount of

Fig. 9.3 Schematic representation of electron energy levels in materials

solute content. Finally, insulators have completely filled (and completely empty) electron bands which results in a virtually zero population density as shown in Fig. 9.4. Thus, the conductivity in insulators is virtually zero.

9.1.2 Superconductivity

The resistivity in superconductors becomes immeasurably small or virtually zero below a critical temperature T_c . About 27 elements, numerous alloys, ceramic materials (containing copper oxide), and organic compounds (based, e.g., on selenium or sulfur) have been found to possess this property (Table 9.1).

It is estimated that the conductivity of superconductors below T_c is about $10^{20} \Omega^{-1}\text{cm}^{-1}$. The transition temperatures where superconductivity starts range from 0.01 K (for tungsten) up to about 125 K (for ceramic superconductors). Of particular interest are materials with T_c above 77 K, that is, the boiling point of liquid nitro-

Fig. 9.4 Electronic energy-band representation

Fig. 9.5 Schematic representation of the density of electrons within an electron energy band

Fig. 9.6 Simplified band diagrams for an intrinsic semiconductor

gen which is more readily available than other coolants. Among the so-called high- T_c superconductors are the 1-2-3 compounds such as $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$, where molar ratios of rare earth to alkaline earth to copper relate as 1:2:3. Their transition temperatures range from 40 K to 134 K. Ceramic superconductors have an orthorhombic, layered, perovskite crystal structure which contains

Table 9.1 Critical temperatures of some superconducting materials (R = Gd, Dy, Ho, Er, Tm, Yb, Lu)

Materials	T_c (K)

$\text{HgBa}_2\text{Ca}_2\text{Cu}_3\text{O}_{8+\delta}$	134

two-dimensional sheets and periodic oxygen vacancies. (The superconductivity exists only parallel to these layers, that is, it is anisotropic.) The first superconducting material was found by H. Kammerlingh Onnes in 1911 in mercury which has a T_c of 4.15 K. Methods to measure superconductivity are described in Sect. 9.2.5.

9.1.3 Semiconductors

The electrical properties of semiconductors are commonly explained by making use of the electron band structure model which is the result of quantum-mechanical considerations. In simple terms, the electrons are depicted to reside in certain allowed energy regions.

Figure 9.6 depicts two electron bands, the lower of which, at 0 K, is completely filled with valence electrons. This band is appropriately called the valence band. It is separated by a small gap (about 1.1 eV for Si) from the conduction band which contains no electrons at 0 K. Further, quantum mechanics stipulates that electrons essentially are not allowed to reside in the gap between these bands (called the forbidden band). Since the filled valence band possesses no allowed empty energy states in which the electrons can be thermally excited (and then accelerated in an electric field), and since the conduction band contains no electrons at all, silicon is an insulator at 0 K. The situation changes decisively once the temperature is raised. In this case, some electrons may be thermally excited across the band gap and thus populate the conduction band (Fig. 9.6). The number of these electrons is extremely small for statistical reasons. Specifically, about one out of every 10^{13} atoms contributes an electron at room temperature. Nevertheless,

this number is large enough to cause some conduction. The number of electrons in the conduction band N_e increases exponentially with temperature T but also depends, of course, on the size of the gap energy. The conductivity depends naturally on the number of these electrons but also on their mobility. The latter is defined to be the velocity v per unit electric field E that is: $\mu = v/E$. All taken, the conductivity is $\sigma = N_e \mu_e e$, where e is the charge of an electron. The mobility of electrons is substantially impaired by interactions with impurity atoms and other lattice imperfections (as well as with vibrating lattice atoms). It is for this reason that silicon has to be extremely pure and free of grain boundaries which requires sophisticated and expensive manufacturing processes called zone refining or Czochralski crucible pulling.

The conductivity for semiconductors increases with rising temperature. This is in marked contrast to metals and alloys, for which the conductivity decreases with temperature. The thermal excitation of some electrons across the band gap has another important consequence. The electrons that have left the valence band leave behind some empty spaces which allow additional conduction to take place in the valence band. The empty spaces are called defect electrons or electron holes. These holes may be considered to be positively charged carriers similarly as electrons are defined to be negatively charged carriers. In essence, at elevated temperatures, the thermal energy causes some electrons to be excited from the valence band into the conduction band. They provide there some conduction. The electron holes which have been left behind in the valence band cause a hole current which is directed in the opposite direction compared to the electron current. The total conductivity, therefore, is a sum of both contributions $\sigma = N_e \mu_e e + N_h \mu_h e$, where the subscripts e and h refer to electrons and holes, respectively. The process is called intrinsic conduction and the material involved is termed an intrinsic semiconductor since no foreign elements are involved. The Fermi energy of intrinsic semiconductors can be considered to be the average of the electron and the hole Fermi energies and is therefore situated near the center of the gap as depicted in Fig. 9.6.

The number of electrons in the conduction band can be considerably increased by adding, for example, to silicon small amounts of Group-V elements called donor atoms. Dopants such as phosphorous or arsenic are commonly utilized which are added in amounts of, for example, 0.0001%. These dopants replace some regular lattice atoms in a substitutional manner (Fig. 9.7). Since phosphorous has five valence electrons, that is,

Fig. 9.7 Two-dimensional representation of a silicon lattice (covalent bonds) with a phosphorus atom substituting a regular lattice atom

one more than silicon, the extra electron called the donor electron is only loosely bound. The binding energy of phosphorous donor electrons in a silicon matrix is about 0.045 eV. Thus, the donor electrons can be disassociated from their nuclei by only a slight increase in thermal energy. At room temperature all donor electrons have already been excited into the conduction band.

Near room temperature, only the majority carriers need to be considered. For example, at room temperature, all donor electrons in an n-type semiconductor have been excited from the donor levels into the conduction band. At higher temperatures, however, intrinsic effects may considerably contribute to the conduction. Compounds made of Group-III and Group-V elements, such as gallium arsenide, have similar semiconducting properties as the Group-IV materials silicon or germanium. GaAs is of some technical interest because of its above-mentioned wider band gap and because of its larger electron mobility which aids in high-speed applications. Further, the ionization energies of donor and acceptor impurities in GaAs are one order of magnitude smaller than in silicon which ensures complete electron (and hole) transfer from the donor (acceptor) levels into the conduction (valence) bands even at relatively low temperatures. However, GaAs is about ten times more expensive than Si and its heat conduction is smaller. Other compound semiconductors include II–VI combinations such as ZnO, ZnS, ZnSe, or CdTe, and IV–VI materials such as PbS, PbSe, or PbTe. Silicon carbide, a IV–IV compound, has a band gap of 3 eV and can thus be used up to 700 °C before intrinsic effects set in. The most important application of compound semiconductors is, however, for optoelectronic purposes (e.g. for light-emitting diodes and lasers).

9.1.4 Conduction in Polymers

Materials that are electrical (and thermal) insulators are of great technical importance and are, therefore, used in large quantities in the electronics industry. Most polymeric materials are insulating and have been used for this purpose for decades. It came, therefore, as a surprise when it was discovered that some polymers and organic substances may have electrical properties which resemble those of conventional semiconductors, metals, or even superconductors. Historically, transoidal polyacetylene (Fig. 9.8) has been used as a conducting polymer.

It represents what is called a conjugated organic polymer, that is, it has alternating single and double bonds between the carbon atoms. It is obtained as a silvery, flexible, and lightweight film which has a conductivity comparable to that of silicon. Its conductivity increases with increasing temperature similarly as in semiconductors. The conductivity of trans-polyacetylene can be made to increase by up to seven orders of magnitude by doping it with arsenic pentafluoride, iodine, or bromine, which yields a p-type semiconductor. Thus, σ approaches the lower end of the conductivity of metals as shown in Fig. 9.9.

Among other dopants are *n*-dodecyl sulfonate (soap). However, the stability of this material is very poor; it deteriorates in hours or days. This very drawback which it shares with many other conducting polymers nevertheless can be profitably utilized in special devices such as remote gas sensors, biosensors, and other remotely readable indicators which detect changes in humidity, radiation dosage, mechanical abuse, or chemical release. Other conducting polymers include polypyrrole and polyaniline. The latter has a reasonably good conductivity and a high environmental stability. It has been used for electronic devices such as field-effect transistors, electrochromic displays, as well as for rechargeable batteries.

In order to better understand the electronic properties of polymers by means of the electron theory and

Fig. 9.8 Transoidal isomer of polyacetylene

the band structure concept, one needs to know the degree of order or the degree of periodicity of the atoms because only ordered and strongly interacting atoms or molecules lead to distinct and wide electron bands. It has been observed that the degree of order in polymers depends on the regularity of the molecular structure. One of the electrons in the double bond of a conjugated polymer can be considered to be only loosely bound to the neighboring carbon atoms. Thus, this electron can be easily disassociated from its carbon atom by a relatively small energy which may be provided by thermal energy. The delocalized electrons behave like free electrons and may be accelerated as usual in an electric field. It should be noted in closing that the interpretation of conducting polymers is still in flux and future research needs to clarify certain points.

9.1.5 Ionic Conductors

Electrical conduction in ionically bonded materials, such as the alkali-halides, is extremely small. The reason for this is that the atoms in these chemical compounds strive to assume the noble gas configuration for maxi-

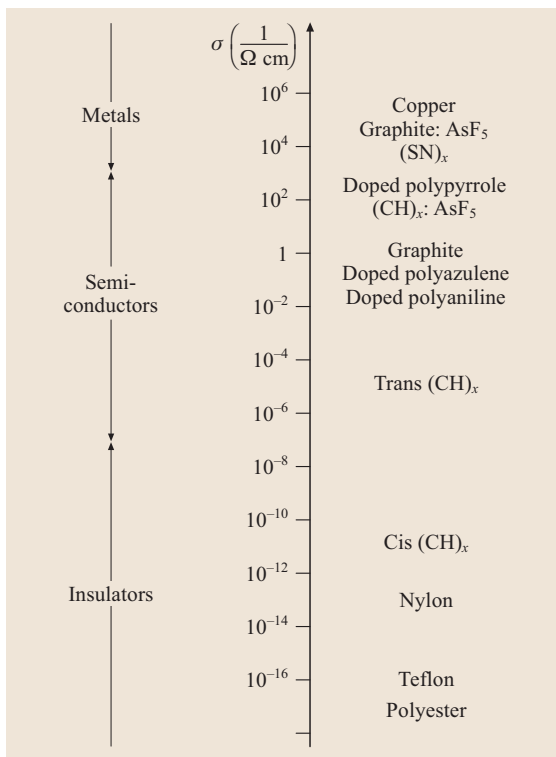

Fig. 9.9 Conductivity of various polymeric materials

mal stability and thus transfer electrons between each other to form positively charged cations and negatively charged anions. The binding forces between the ions are electrostatic in nature, that is, they are very strong. Essentially no free electrons are therefore formed. As a consequence, the room temperature conductivity in ionic crystals is about 22 orders of magnitude smaller than that of typical metallic conductors (Fig. 9.2). The wide band gap in insulators allows only extremely few electrons to become excited from the valence into the conduction band (Fig. 9.4 right).

The main contribution to the electrical conduction in ionic crystals (as little as it may be) is due to ionic conduction. Ionic conduction is caused by the movement of some negatively (or positively) charged ions which “hop from lattice site to lattice site” under the influence of an electric field. The ionic conductivity $\sigma_{\text{ion}} = N_{\text{ion}} e \mu_{\text{ion}}$ is the product of three quantities. In the present case, N_{ion} is the number of ions per unit volume which can change their position under the influence of an electric field whereas μ_{ion} is the mobility of these ions. In order for ions to move through a crystalline solid they must have sufficient energy to pass over an energy barrier. Further, an equivalent lattice site next to a given ion must be empty in order for an ion to be able to change its position. Thus, N_{ion} depends on the vacancy concentration in the crystal (i.e., on the number of Schottky defects).

In short, the theory of ionic conduction contains essential elements of diffusion theory. Diffusion theory links the mobility of the ions with the diffusion coefficient D through the Einstein relation $\mu_{\text{ion}} = De/k_B T$. The diffusion coefficient varies with temperature by an

Arrhenius equation $D = D_0 \exp(-Q/k_B T)$, where Q is the activation energy for the process under consideration and D_0 is a pre-exponential factor which depends on the vibrational frequency of the atoms and some structural parameters. Combining the equations yields $\sigma_{\text{ion}} = (N_{\text{ion}} e^2 D_0 / k_B T) \exp(Q/k_B T)$. This equation is shortened by combining the pre-exponential constants into σ_0 : $\sigma_{\text{ion}} = \sigma_0 \exp(Q/k_B T)$.

In summary, the ionic conduction increases exponentially with increasing temperature (as in semiconductors). Further, σ_{ion} depends on a few other parameters such as the number of ions that can change their position, the vacancy concentration, as well as on an activation energy.

9.1.6 Dielectricity

Dielectric materials, that is, insulators, possess a number of important electrical properties which make them useful in the electronics industry.

When a voltage is momentarily applied to two parallel metal plates which are separated by a distance L as shown in Fig. 9.10, the resulting electric charge essentially remains on these plates even after the voltage has been removed (at least as long as the air is dry).

This ability to store an electric charge is called the capacitance C which is defined to be the charge q per applied voltage V that is $C = q/V$, where C is given in coulombs per volt or farad. The capacitance is higher, the larger the area A of the plates and the smaller the dis-

tance L between them. Further, the capacitance depends on the material that may have been inserted between the plates. The experimental observations lead to $C = \epsilon\epsilon_0 (A/L)$, where $\epsilon = C/C_{\text{vac}}$ determines the magnitude of the added storage capability. It is called the (unitless) dielectric constant (or occasionally the relative permittivity ϵ_r). ϵ_0 is a universal constant having the value of $8.85 \times 10^{-12} \text{ F/m}$ (farad per meter) or A s/V m and is known by the name permittivity of empty space (or of vacuum).

Some values for the dielectric constant are given in Table 9.2. The dielectric constant of empty space is set to be 1 whereas ϵ of air and many other gases is nearly 1.

The capacitance increases when a piece of a dielectric material is inserted between two conductors. Under the influence of an external electric field, the negatively charged electron cloud of an atom becomes displaced with respect to its positively charged core. As a result, a dipole is created which has an electric dipole moment $p = qx$, where x is the separation between the positive and the negative charge. (The dipole moment is generally a vector pointing from the negative to the positive charge.) The process of dipole formation (or alignment of already existing dipoles) under the influence of an external electric field that has an electric field strength E , is called polarization. Dipole formation of all involved atoms within a dielectric material causes a charge redistribution so that the surface which is nearest to the positive capacitor plate is negatively charged. As a consequence, electric field lines within a dielectric are created which are opposite in direction to the external field lines. Effectively, the electric field lines within a dielectric material are weakened due to polarization. The electric field strength $E = V/L = E_{\text{vac}}/\epsilon$ is reduced by inserting a dielectric between two capacitor plates. Within a dielectric material the electric field strength E is replaced by the dielectric displacement D (also called the surface charge density), that is, $D = \epsilon\epsilon_0 E = q/A$. The dielectric displacement is the superposition of two terms: $D = \epsilon_0 E + P$, where P is called the dielectric polarization, that is, the induced electric dipole moment per unit volume. The units for D and P are C/m^2 . The polarization is responsible for the increase in charge density (q/A) above that for vacuum.

The mechanism just described is known as electronic polarization. It occurs in all dielectric materials that are subjected to an electric field. In ionic materials, such as the alkali halides, an additional process may occur which is called ionic polarization. In short, cations and anions are somewhat displaced from their equilib-

rium positions under the influence of an external field and thus give rise to a net dipole moment. Finally, many materials already possess permanent dipoles which can be aligned in an external electric field. Among them are water, oils, organic liquids, waxes, amorphous polymers, polyvinylchloride, and certain ceramics such as barium titanate (BaTiO_3). This mechanism is termed orientation polarization or molecular polarization. All three polarization processes are additive if applicable.

Most capacitors are used in electric circuits involving alternating currents. This requires the dipoles to reorient quickly under a rapidly changing electric field. Not all polarization mechanisms respond equally quick to an alternating electric field. For example, many molecules are relatively sluggish in reorientation. Thus, molecular polarization breaks down already at relatively low frequencies. In contrast, electronic polarization responds quite rapidly to an alternating electric field even at frequencies up to 10^{16} Hz . At certain frequencies a substantial amount of the excitation energy is absorbed and transferred into heat. This process is called dielectric loss. It is imperative to know the frequency for dielectric losses for a given material so that the device is not operated in this range.

9.1.7 Ferroelectricity and Piezoelectricity

Ferroelectricity is the electric analogue to ferromagnetism, see Chap. 10. Ferroelectric materials, such as barium titanate, exhibit spontaneous polarization without the presence of an external electric field. Their dielectric constants are orders of magnitude larger than those of dielectrics (Table 9.2). Thus, they are quite suitable for the manufacturing of small-sized, highly efficient capacitors. Most of all, however, ferroelectric materials retain their state of polarization even after an external electric field has been removed. Specifically, if a ferroelectric is exposed to a strong electric field E , its permanent dipoles become increasingly aligned with the external field direction until eventually all dipoles are parallel to E , and saturation of the polarization P_s has been achieved as depicted in Fig. 9.11.

Once the external field has been withdrawn a remanent polarization P_r remains which can only be removed by inverting the electric field until a coercive field E_c has been reached. By further increasing the reverse electric field, parallel orientation of the dipoles in the opposite direction is achieved. Finally, when reversing the field once more, a complete hysteresis loop is obtained as depicted in Fig. 9.11. Therefore, ferroelectrics can be utilized for memory devices in computers, etc. The area

Fig. 9.11 Schematic representation of a hysteresis loop for a ferroelectric material in an electric field

within a hysteresis loop is proportional to the energy per unit volume that is dissipated once a full field cycle has been completed.

A critical temperature, called the Curie temperature, exists above which the ferroelectric effects are destroyed and the material becomes dielectric. Typical Curie temperatures range from -200°C for strontium titanate to at least 640°C for NaNbO_3 . By heating BaTiO_3 above its Curie temperature (120°C), the tetragonal unit cell transforms to a cubic cell whereby the ions now assume symmetric positions. Thus, no spontaneous

alignment of dipoles remains and BaTiO_3 becomes dielectric.

If pressure is applied to a ferroelectric material such as BaTiO_3 , a change in the polarization may occur which results in a small voltage across the sample. Specifically, the slight change dimensions causes a variation in bond lengths between cations and anions. This effect is called piezoelectricity. It is found in a number of materials such as quartz (however, much weaker than in BaTiO_3), in ZnO , and in complicated ceramic compounds such as PbZrTiO_6 . Piezoelectricity is utilized in devices that are designed to convert mechanical strain into electricity. Those devices are called transducers. Applications include strain gages, microphones, sonar detectors, and phonograph pickups, to mention a few.

The inverse mechanism, in which an electric field produces a change in dimensions in a ferroelectric material, is called electrostriction. An earphone utilizes such a device. Probably the most important application, however, is the quartz crystal resonator which is used in electronic devices as a frequency selective element. Specifically, a periodic strain is exerted to a quartz crystal by an alternating electric field which excites this crystal to vibrations. These vibrations are monitored in turn by piezoelectricity. If the applied frequency coincides with the natural resonance frequency of the molecules, then amplification occurs. In this way, very distinct frequencies are produced which are utilized for clocks or radio frequency signals.

9.2 Electrical Conductivity of Metallic Materials

9.2.1 Scale of Electrical Conductivity; Reference Materials

Precise measurements of the electrical conductivity date back to the end of the 19th century. With the development of the electrical industry it became important to check the quality of the copper used in electrical machines. The Physikalisch-Technische Reichsanstalt in Berlin, Germany, for instance, was strongly supported by Werner von Siemens, head of the Siemens company. Nowadays, copper is still an important part where conductivity measurements are applied. Furthermore, the aircraft manufacturing industry uses conductivity measurements for the quality assurance of aluminium alloys. Recently, it became also important for the coin manufacturing industry. With the introduction of the Euro, these

coins are produced all over Europe, but have to meet strong criteria in conductivity, on the one hand to protect the consumers from fraud, on the other hand for the acceptance of coins in vending machines.

Conductivity is usually measured in the unit MS/m , or $\mu\Omega \text{ m}$. In practice, the values are commonly given in so-called %IACS, which stands for “Percent International Annealed Copper Standard”. This standard is a hypothetical copper bar of 1 m in length and 1 mm^2 in area having a resistance of $1/58 \Omega$.

Typical values for some metals and alloys are listed in Table 9.3. Generally there are three main areas for conductivity measurements, conductors (copper) at 100%IACS, aluminium alloys at 50%IACS and alloys for coins at 10%IACS. Instruments for the measurement of conductivity operate either with direct current methods (DC) or alternating current methods (AC). The DC

Table 9.3 Typical values for the conductivity of metals and alloys

Metal/alloy	Conductivity at 20 °C	
	(MS/m)	(%IACS)
Copper (soft)	59.9	103.3
Copper (annealed)	58	100.0
Aluminium (soft)	35.7	61.6
E-AlMgSi (Aldrey)	30.0	51.7
Brass (CuZn40)	15.0	25.9
Bronze (CuSn6)	9.1	15.7
Titanium	2.4	4.1

methods usually is a voltage-current method, whereas the AC methods make use of the eddy current principle. Details are described in Sect. 9.2.2 and for the calibration of reference standards in Sects. 9.2.3 and 9.2.4.

For precise measurements of conductivity reference materials are needed. Commonly these reference materials are pure metals and alloys of known composition. Due to the size of the material samples, these materials must have a high homogeneity. Another prerequisite for precise measurement of reference standards for conductivity is the precise knowledge of the dimensions as well as the geometry of the material under test. Typical shapes for a reference material are bars or blocks and the dimensions range from 30 mm to 80 mm in width, 200 mm to 800 mm in length, and 3 mm to 10 mm in thickness for bars and 80 mm by 80 mm by 10 mm for blocks. Opposite sides of the blocks and bars have to be parallel and the surface should have mirror finishing. Furthermore, an important issue is the temperature. The resistivity of pure metals strongly depends on temperature. Typical temperature coefficients are of the order of $1 \times 10^{-3} \text{ }^{\circ}\text{C}^{-1}$.

For AC measurements of the electrical conductivity based on the eddy current method it is important that the magnetic susceptibility of the material is less than 1.001. Magnetic impurities in the metal influence the conductivity as well as the accuracy of the measurement.

The following section describes the principal methods for the determination of the electrical conductivity of metals.

9.2.2 Principal Methods

In principal, the measurement methods for electrical conductivity can be divided in to two sections, direct current (DC) and alternating current (AC) measurement methods. Applications are found in several fields of

material testing as there are air craft industry, coin manufacturing, and pure metal manufacturing (e.g. copper, aluminium). A more qualitative aspect of conductivity measurements is the nondestructive material testing. Cracks and voids in the material lead to a local change in conductivity which can be detected by conductivity probes. In contrast to the determination of conductivity, in this case the metals may also be magnetic.

The determination of conductivity with DC is made by measuring the resistance R and the dimensions of the conductor (length l , width w , and thickness d , Fig. 9.12). From these measurements, the conductivity σ is calculated (9.1)

$$\sigma = \frac{l}{Rwd} . \tag{9.1}$$

The resistance R is usually determined by a voltage-current method. A current I of known value is fed into the sample and the voltage U is measured via point or blade contacts. Since the resistance of metals is typically very low, even for currents of 10 A the voltage drop is of the order of some μV up to several mV. This means high sensitive nanovoltmeters have to be used. The resistance is then calculated according to Ohm’s law

$$R = U/I . \tag{9.2}$$

This method can only be applied to materials of particular shape like rods or bars. For more complex geometries,

Fig. 9.12 Principle of conductivity measurements. The sample under test is of bar shape with known cross sectional area. A current is passed through the sample in the direction of its longitudinal axis. The voltage drop is measured with two contacts, either point or blade type, at a known distance

Fig. 9.13 Principle of the van der Pauw measurement. The van der Pauw method requires two measurements. First the current is passed into contacts 1 and 2 and the voltage is measured at contacts 4 and 3, then the current is passed into contacts 1 and 4 and the voltage is measured at contacts 2 and 3. These two voltage–current measurements together with the measurement of the thickness of the device under test allow for the determination of the conductivity

like, for instance, the surface of an aeroplane, other methods have been developed.

A local determination of the DC conductivity can be obtained by the so-called four-point probe. Four-point electrodes are pressed on the material and a special sequence of voltage–current measurements is made. The basic principle of this method is the van der Pauw method (Fig. 9.13) [9.3, 4]. The van der Pauw method consists of two measurements of resistance, R_A and R_B

$$R_A = V_{43}/I_{12}, \quad R_B = V_{23}/I_{14}. \quad (9.3)$$

From these two measurements and the knowledge of the thickness of the sample under test, the conductivity can be determined by the solution of the following equation:

$$e^{-\frac{\pi R_A}{R_S}} + e^{-\frac{\pi R_B}{R_S}} = 1, \quad (9.4)$$

where R_S is the resistance to be determined. If R_A and R_B are similar, (9.3) can be simplified and solved for the conductivity σ as follows:

$$\frac{1}{\sigma} = \frac{\pi d (R_A + R_B)}{\ln 2}, \quad (9.5)$$

where d is the thickness of the sample. The precision of such a van der Pauw measurement depends on the flatness and parallelism of the surfaces of the sample and on the fact that the contacts are point contacts. An error ε caused by non-ideal point contacts can be estimated by

$$\varepsilon = 2.05\lambda^4, \quad (9.6)$$

Fig. 9.14 Cross-conductivity standard [9.2]. Similar as in Fig. 9.13, the current is either fed into pairs of contact A–B and A–D, and the voltages are measured at contact pairs D–C and B–C

where, for a sample with square geometry, λ is the ratio of the width of the contact and the length of one side of the square. Such small contact areas lead to the problem of local heating since the current density in these contacts becomes significantly high. On the other hand a reduction of the current will lead to loss of sensitivity. A different approach to this problem is the so-called cross-conductivity standard. If one considers a perfect square and transforms this via conform transformation into a star shaped sample (Fig. 9.14) [9.2]. The conductivity σ is also calculated by (9.4).

DC measurements require a good contact between material and electrodes. In practice, the surface of a metal is covered by a thin oxide layer. For a correct DC measurement this layer has to be penetrated. This problem can be overcome by the AC measurement method. The basic principle of AC measurement methods makes use of eddy currents. Alternating magnetic fields induce currents in conducting materials. If the alternating magnetic fields are induced by a pair of coils, the second coil in turn picks up the magnetic field produced by the eddy current. A probe of such a construction acts as a mutual inductor. The magnetic field, induced in the second coil is a function of the magnitude of the eddy current which in turn depends on the conductivity of the material.

Making conductivity measurements with this method, the skin effect has to be taken into consideration. The skin effect limits the penetration of the eddy currents into the material. The higher the conductivity of the material the smaller is the penetration depth. The penetration depth δ is approximately

$$\delta = \sqrt{\frac{2}{\omega \sigma \mu_0}}, \quad (9.7)$$

where ω is the angular frequency ($2\pi f$) and μ_0 the vacuum permittivity.

9.2.3 DC Conductivity, Calibration of Reference Materials

The DC conductivity is given by a simple model

$$\sigma = ne\mu, \quad (9.8)$$

where n is the number of electrons, e is the charge of an electron and μ is its mobility. The number of electrons is nearly the same for all metals, e is constant, but the mobility depends on the lattice parameters of the material.

The basic principles and requirements for the measurement of DC conductivity have been laid out in DIN/IEC 768, “Measurement of metallic conductivity” [9.5]. The standard to be measured must fulfil certain criteria regarding its geometry. The length of the sample has to be at least 0.3 m. A DC current is fed in to the end sections and the voltage drop is measured with either sharp point contacts or blade contacts. The distance between these contacts and the current contacts has to be at least 1.5 times the circumference [$2(t + w)$] of the device under test to allow for uniform current distribution between the contact electrodes.

The latest practical approach of this method is shown in Fig. 9.15. The current is fed into the sample via the clamps at the ends and the potential is measured at the knife edge blade contacts. The blades are mounted on a precisely machined stainless steel bar. This method has the advantage that the distance of the blade contacts has only to be determined once and is the same for a whole set of measurements. Also the parallelism of the contacts is assured by this method.

Fig. 9.15 Measurement setup for the determination of the DC conductivity of bar-shaped samples. The potential contacts are of knife edge type

A principal drawback of the DC method is its sensitivity to oxide layers on certain materials (e.g. aluminium). Since a precise knowledge of the thickness of the sample under test is essential, it is practically impossible to gain full knowledge of the thickness of an aluminium sample without knowing the thickness of the oxide layer. A consequence of this problem is the possibility of differences in conductivity values for the same material determined with the DC method compared to that determined with the AC method. This problem was subject of an intensive study [9.6, 7]. Although the relative uncertainties for conductivity calibrations are of the order of 0.5% for the AC method and of the order of 0.1% for the DC method, differences between the values could be up to 1%.

9.2.4 AC Conductivity, Calibration of Reference Materials

In principle, one could think of measuring the AC conductivity in the same way as the DC conductivity. But the problem of current displacement at AC current is much more pronounced. Depending on the conductivity and the measuring frequency, the current flows in a thin layer at the surface of the material. The thickness of this layer can be estimated by (9.5). So it is not possible to exactly determine the AC conductivity by a simple current–voltage measurement since one dimension, the thickness, is not known without knowledge of the conductivity. On the other hand, most commercial conductivity meters measure with an AC method. To meet the demand of AC conductivity calibration, a suitable method has been developed at the National Physics Laboratory Teddington, UK (NPL) [9.8].

Alternating electromagnetic fields can penetrate metallic materials and so generate an eddy current in the material. This effect is used in a way that the material under test is induced into a nearly ideal inductor. Due to the eddy currents, the inductor is no longer ideal but shows magnetic loss. This loss can be measured as the resistive part of the inductor and from that resistance the conductivity can be calculated according to (9.32). From two-dimensional theory this resistance R_m can be deduced which is not a real resistance but a process of energy loss modelled by a resistance

$$\sigma = \frac{2\omega(b+d)^2\mu_0 N^4}{R_m^2 l^2}. \quad (9.9)$$

The measurement system used is the so-called Heydweiller bridge (Fig. 9.16). The bridge consists of the

Fig. 9.16 Heydweiller bridge for measuring NPL primary conductivity standards at frequencies from 10 to 100 kHz. The standard under test is brought into the mutual inductor M . From the change in R_v , necessary to balance the bridge, the conductivity can be calculated (R_v = variable resistor, C = variable capacitor, $R_{21} = R_{22} = 10 \text{ k}\Omega$, $R_1 = 1 \text{ k}\Omega$, $R_4 = 10 \Omega$, M = inductor)

mutual inductor M with N windings, two fixed resistors R_1 and R_4 , and the balancing circuit R_{21} , R_{22} , C , and R_v . The mutual inductor is of toroidal shape. It can be opened and a specimen of annular shape of width $b = 80 \text{ mm}$, thickness $d = 10 \text{ mm}$, and central circumference $l = 320 \pi \text{ mm}$, can be inserted. From the change in resistance R_v necessary to balance the bridge, R_m is determined and the conductivity can be calculated.

Since the annulus is of considerable size (0.4 m in diameter), the conductivity value of a selected segment that represents the average value of conductivity of the specimen is transferred to a block shaped sample of size $80 \text{ mm} \times 80 \text{ mm} \times 10 \text{ mm}$. The system used for this transfer is the same bridge system, the mutual inductor is a coil of approximately 80 mm in diameter which can be placed on the annulus as well as on the block. These blocks then can be used as reference material.

9.2.5 Superconductivity

Some metals, alloys, compounds and ceramic materials lose their resistance, if they are cooled down to very low temperatures of some K [9.9]. The physical principle is that in these materials electrons of opposite spin and of opposite momentum form pairs. As these pairs have no spin, they can occupy the same lowest energy state. This state allows dissipation free transport of electrical energy since the pairs are not scattered by the surrounding

lattice that means an electrical current is carried without measurable resistivity [9.10]. The transition into this state occurs at a critical temperature T_c and varies with the type of material. For so-called low-temperature superconductors (LTS) the critical temperature is in the range up to 30 K, for high-temperature superconductors (HTS) T_c can be even higher than 100 K. LTS are typically pure metals or alloys, like e.g. lead (Pb), niobium (Nb), tin (Sn), or Nb_3Sn . The HTS are perovskite crystals of mixed copper oxides. This class of material has been discovered in the mid 1980, first by *Bednorz* and *Müller* [9.11]. From that time on, various compositions of copper oxides with rare-earth metals have been investigated [9.12]. The first reproducible composite was Barium-Lanthanum-Copper-Oxide (BaLaCuO) which showed a critical temperature of 40 K. For Tellurium-Barium-Calcium-Copper-Oxide (TBCCO) a T_c of as high as 125 K was observed [9.13].

Superconductors of either type are used for several purposes, as there are

- the transport of electrical energy,
- the generation of high magnetic fields,
- sensitive measurements of small magnetic fields with superconducting quantum interference devices (SQUID) [9.14],
- recently quantum computing, based on QUBITs,
- arrays of superconducting contacts are used as voltage standards.

The first two are DC or low-frequency applications, the other applications make use of the so-called Josephson effect (at radio/microwave frequencies) which is described in detail in [9.15, 16].

Superconductors need low temperatures so applications using LTS are typically operated at the temperature of liquid helium (4.2 K), whereas HTS can be operated at the temperature of liquid nitrogen (77 K). The latter is becoming more and more of interest for industrial applications, since on the one hand it is possible to pro-

Table 9.4 Some typical values for superconductors

Metal/alloy/material	T_c (K)	B_c (T) at 4.2 K
Tin (Sn)	3.7	0.03
Lead (Pb)	7.3	0.08
Niobium (Nb)	9.2	0.2
Nb_3Sn	19	24
Nb_3Ge	23	38
YBaCuO	93	55
BSCCO	110	29

Fig. 9.17 Measurement setup for the characterization of superconductors [9.17]. The resistance of the superconductor is determined by a voltage–current measurement. The apparatus allows for the variation of temperature and magnetic field to determine T_c and B_c

duce mechanically stable ceramic components (e.g. of YBaCuO), and on the other hand the effort for cooling and thermal isolation is less than that for LTC.

The use of superconductors for the generation of high magnetic fields requires to pay attention to their behavior in magnetic fields. This behavior can be divided into so-called type-I and type-II superconductors. If a superconductor of type-I is kept at

a temperature $T < T_c$ and the magnetic induction B is increased there is a critical magnetic induction B_c , where the superconductor becomes normal conducting. Below this B_c , screening currents on the surface of the superconductor compensate the magnetic field inside. This means that a type-I superconductor behaves like a perfect diamagnet, $\mu_r = 0$ [9.18]. Since this effect is also observed for a volume surrounded by a superconductor, these type-I superconductors allow perfect shields for magnetic fields at low temperatures.

Superconductors of type-II show a different behavior. With increasing magnetic induction B , the transition from the superconducting state to the normal conducting state occurs continuously with two critical inductions B_{c1} and B_{c2} . Below B_{c1} , a type-II superconductor behaves as one of type-I. At the critical induction B_{c1} , the magnetic field starts to penetrate the conductor creating flux vortices. At the critical induction B_{c2} no more vortices can be created and the magnetic field can completely penetrate the superconductor and it becomes normal conducting. The critical induction B_{c2} is typically much higher than B_{c1} or the B_c of a type-I superconductor. Some properties (T_c and B_c) of typical superconductors are listed in Table 9.4.

The measurement of these parameters are carried out in an apparatus allowing for control of both, temperature and magnetic field by measuring the voltage as a function of current through the superconductor (Fig. 9.17) [9.17].

Similar to the determination of the DC conductivity the voltage drop over a short length of a superconducting strand is measured, passing a DC current I . At constant temperature T and magnetic induction B the current I is varied to determine the critical current density of the material under test. Other possible measurements are the determination of T_c as a function of B or of B_c as a function of T with I kept constant. With these measurements it is possible to characterise a superconductor. Standardized methods for the determination of parameters are described in [9.19].

9.3 Electrolytical Conductivity

The electrolytic conductivity is a measure of the amount of charge transport of ions in solution. Conductivity measurements are non-selective. All ions in the electrolyte are involved, depending on their mobility, charge and concentration.

While the current is carried by electrons in metals in electrolyte solutions, molten salts and ionic solids the charge carriers are ions.

The extent to which current flows through an electrolyte depends on the concentration, charge and

mobility of the ions present. The concentration of the ions depends on the degree of dissociation in the solution while the extent of ionization also depends on the nature of the solvent. Strong electrolytes are completely dissociated whereas weak electrolytes only partly form ions in solution. In view of applications the most interesting electrolytes are aqueous solutions.

9.3.1 Scale of Conductivity

Electrolytic conductivity is a non-specific sum parameter reflecting the concentration and mobility of all ions dissolved in a solution. Since the mobility of the ions is temperature dependent, the conductivity also depends on temperature. Sometimes the specific conductance is used to describe conductivity. Since conductivity is non-specific this expression is misleading and should be avoided. Figure 9.18 shows the electrolytic conductivity of different aqueous media at 25 °C.

The measurement of conductivity ranges from quality control of high purified water to waste water treatment monitoring and process control in chemical industry. Electrolytic conductivity can also be used to determine the relative ionic strength of solutions and as a detection technique in ion chromatography.

Electrolytic conductivity is in fact the most widely used parameter to monitor the overall ionic purity of water and it is considered the major parameter defining and ranking grades of purified water, e.g., in pharmaceutical, semiconductor and power plant industries. Electrolytic conductivity measurements are used for the evaluation of

Fig. 9.18 The scale of conductivity with examples of various aqueous solutions at 25 °C

Fig. 9.19 Ions in solution conduct the electric current. The positive ions (cations) constantly move towards the negative electrode (cathode), while the negative ions (anions) move towards the positive electrode (anode)

water quality under regulations and standard practices, e.g., drinking water and water used in food industry. Important parameters in specific areas as, for instance, the measurement of the amount of total dissolved solids (TDS) and the salinity of sea water are also related to conductivity measurements.

The SI derived unit of conductivity is the siemens per meter (S/m). The symbol for electrolytic conductivity (sometimes also named electric conductivity) is κ in chemistry, σ or γ in solid-state physics. Very low conductivity values are preferably expressed in the unit of resistivity Ohm meter (Ω m).

9.3.2 Basic Methods

The conductivity κ is defined as the ratio of the current density j and the electric field strength E

$$\kappa E = j. \quad (9.10)$$

Figure 9.19 schematically shows the motion of ions in the electric field. Two parallel electrodes are immersed in an electrolyte solution and connected to a voltage source. When the voltage is applied positive ions move constantly towards the cathode, while the negative ions move towards the anode.

For a sample of a constant cross sectional area A , electrode distance l and with a constant electric field of strength E , the voltage U across the sample between the electrodes is given by

$$U = IE. \quad (9.11)$$

The field exerts a force F on the ion of charge ze according to (9.12), where z is the charge number of the ion and e the elementary charge.

$$F = zeE = \frac{zeU}{l}. \quad (9.12)$$

Ion Mobility

This force (9.12) accelerates the cations in the direction of the cathode and anions towards the anode. The ion moving through the solvent experiences also a frictional force F_R proportional to its velocity. Assuming Stoke's law of friction is applicable [9.20], the frictional force is given by (9.13), where r is the radius of the ion (for water as solvent the radius includes the radius of the solvate shell of the ion), η is the viscosity of the solvent and w_i the speed of ion motion

$$F_R = 6\pi r\eta w_i. \quad (9.13)$$

The two forces act in opposite direction. After a short time the speed of ion motion reaches a steady state (9.14) and (9.15):

$$F = -F_R, \quad (9.14)$$

$$w_i = E \frac{|z_i|e}{6\pi\eta}. \quad (9.15)$$

From (9.15) a field independent quantity for the speed of ions, the ion mobility u_i can be derived

$$u_i = \frac{|z_i|e}{6\pi\eta}. \quad (9.16)$$

The speed of motion is proportional to the field strength

$$w_i = Eu_i. \quad (9.17)$$

In Fig. 9.19, a strong electrolyte, i. e. potassium chloride (KCl), $A_{v+}B_{v-}$ of concentration c is dissociate into n_+ cations and n_- anions carrying the charge z_+e and z_-e , respectively. The concentration of cations and anions is therefore nc . The number of cations and anions, respectively, per volume is ncN_a (N_a is Avogadro's constant). In the electric field, cations and anions move with speed w_+ and w_- in opposite direction. During a time period $\Delta t N_a c n_+ |w_+| A \Delta t$ cations and $N_a c n_- |w_-| A \Delta t$ anions pass an area A as shown in Fig. 9.20.

The charge carried per time period through the area A results in the current I_+ and I_- , respectively [9.21]. Inserting the Faraday constant F (9.18) and because of $w = uE$ (9.15) and taking into account $U = IE$ (9.11), I_+ is given by (9.19) and I_- by (9.20)

$$F = N_a e, \quad (9.18)$$

$$I_+ = F(U/l)A c n_+ u_+ z_+, \quad (9.19)$$

$$I_- = F(U/l)A c n_- u_- z_-. \quad (9.20)$$

With Ohm's law (9.21), we find for the conductivity the reciprocal of the resistivity (9.22),

$$I = \frac{U}{R}, \quad (9.21)$$

$$\kappa = \frac{1}{\rho} = \frac{l}{AR}. \quad (9.22)$$

Molar Ionic Conductivity

Combining (9.19–9.22) yields (9.23) for the molar ionic conductivity λ_+ of the cations. The derivation of the molar ionic conductivity λ_- of the anions is similar.

$$\frac{\kappa_+}{n_+ c} = z_+ u_+ F = \lambda_{m+}. \quad (9.23)$$

Since the conductivity depends on concentration of all mobile ions, measured values for different solutions are not directly comparable. For this reason the molar conductivity of electrolytes (9.24) as the sum of the molar ionic conductivities of anions and cations has been introduced. Equations (9.23) and (9.24) applied to the anions and cations in the solution yield (9.25). The molar conductivity is expressed in $\text{mS m}^2 \text{mol}^{-1}$

$$\Lambda_m = n_+ \lambda_{m+} + \lambda_{m-} n_-, \quad (9.24)$$

$$\kappa = c \Lambda_m. \quad (9.25)$$

For strong electrolytes, Kohlrausch's law empirically relates the molar conductivity with concentration according to (9.26) meaning that the molar conductivity decreases only slightly with increasing concentration.

Fig. 9.20 The charge carried per time Δt period through the area A results in the current I_+ and I_- , respectively

Weak electrolytes are dissociated only to a certain degree and the molar conductivity varies nonlinearly with concentration (9.27). The classification into strong and weak electrolytes depends on the kind of ions and on the properties of the solvent

$$\Lambda_m = \Lambda_m^0 - K\sqrt{c}, \quad (9.26)$$

$$\alpha = \frac{\Lambda_m}{\Lambda_m^0}, \quad (9.27)$$

where Λ_m^0 is the limiting molar conductivity of an electrolyte at infinite dilution, K is a constant and depends primarily on the type of electrolyte and on the solvent. The limiting molar conductivity for any electrolytic solution can be expressed similarly to (9.24–9.28), where also the sum of the contributions from anions and cations are present. This relation is known as Kohlrausch's law of the independent motion of ions in solution

$$\Lambda_m^0 = n_+ \lambda_+^0 + n_- \lambda_-^0. \quad (9.28)$$

With increasing concentration, the molar conductivity of an aqueous solution decreases caused by the solvation of the ions. The ion sphere has an electrical charge equal in magnitude but opposite in sign to that of the ion. Two main effects lead to a decrease of the molar conductivity: the relaxation or asymmetry and the electrophoretic effect. The relaxation effect takes into account the influence of the counter ion, while the electrophoretic effect is a result of the ionic sphere. For a detailed description of the classical Debye–Hückel–Onsager theory and further sophisticated quantitative treatment of the concentration dependence of the conductivity, see [9.22, 23].

If the sample contains only the species of interest and if the concentration dependence of this species is known, conductivity measurement can be used to estimate concentration.

Limiting conductivities of cations and anions in various solvents are listed in [9.23]. The ion mobilities and therefore the limiting ionic molar conductivities of the proton and of the hydroxyl ion are much larger than for other ions. The usual explanation is a different transport mechanism. Protons and hydroxyl ions are not transported through the solution but is transferred by a sequential von Grotthuss type proton-hopping mechanism through water bridges [9.24].

9.3.3 The Measurement of the Electrolytic Conductivity

An equipment to measure the electrolytic conductivity consists of a cell mostly with built-in temperature probe

Fig. 9.21 For a standard cell, the volume of the sample solution is the area of the electrode times the distance between the electrodes

and a conductivity meter. The conductivity cannot be measured directly but is evaluated from the measurement of the conductance G or resistance $R = 1/G$ of the sample in a cell according to (9.22).

Analogous to the resistivity, the cell constant K equal to 1.0 cm^{-1} if the current flow contained within 1 cm^3 of sample solution is between the two electrodes of 1 cm^2 area and in a distance of 1 cm . The so-called standard cell is shown in Fig. 9.21.

Only for a cylindrical cell with parallel electrodes, the cell constant K is determined by the effective cross sectional area A and the effective length l of the current path as in (9.29)

$$K = l/A. \quad (9.29)$$

Influences on Conductivity Measurements

In practice, the cell geometries are usually more complex than the defining example and side effects must be taken into account. These effects include ion–ion interactions, the electrode–sample interface (electrical double layer) and the lead influences.

The cell construction and measurement procedures, e.g. the selected frequency range, must thus be optimized to permit minimization of parasitic influences and separate evaluation of the bulk resistance of the sample solution.

The conductivity meter typically applies an AC current to two electrodes at a frequency optimized for the measuring range and measures the voltage given by

$$G = I/U. \quad (9.30)$$

If the cell constant K_{cell} can be determined from the physical dimensions of the cell and if the resistance mea-

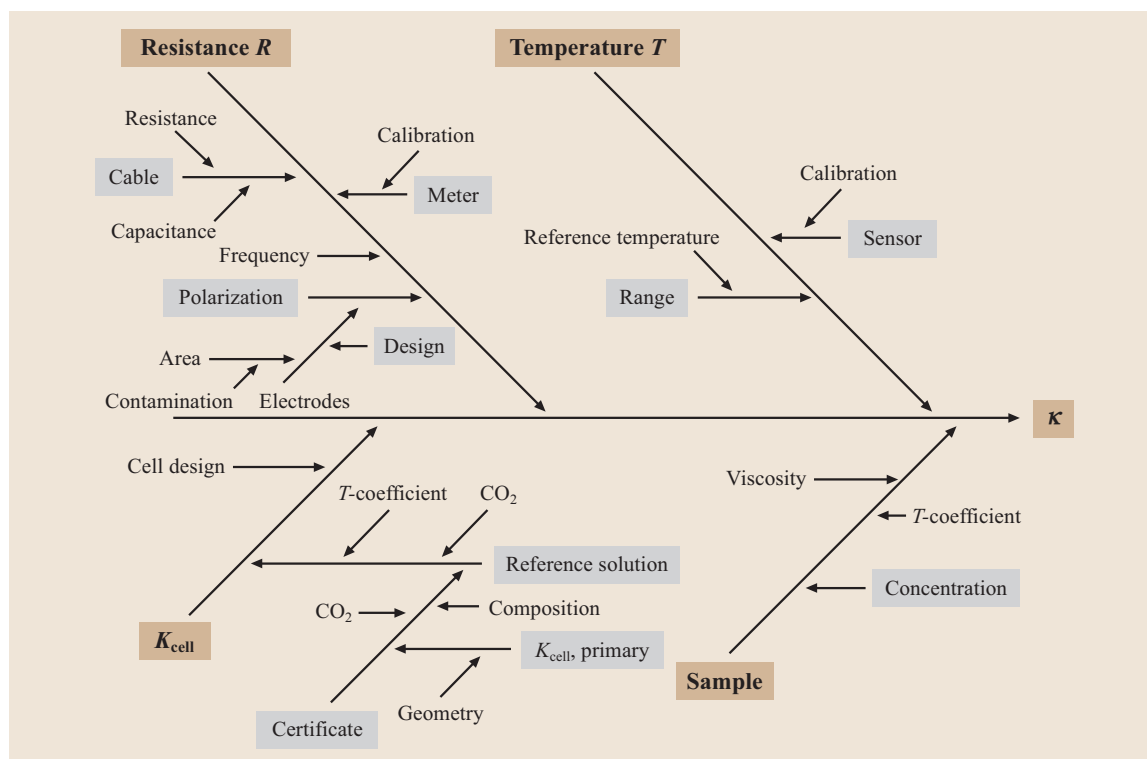

Fig. 9.22 The relevant uncertainty sources and their relationship are shown in a cause and effect diagram (fishbone)

surement is traced back to the SI units, the conductivity of the sample can be also determined by being traced back to the SI unit. Primary cells are used to measure the conductivity of primary reference solutions. Solutions of potassium chloride are usually used for primary reference solutions (primary standards). In a traceability chain, the known electrolytic conductivity of primary standards is used to calibrate conductivity cells of unknown cell constant. These cells are then used together with properly calibrated conductivity meters for routine measurements the results of which are traceable to the SI unit [9.25].

On a worldwide scale the equivalence of the existing national primary measurement standards are ensured by means of international comparisons.

The best way to obtain all information on possible sources of uncertainty on the resulting conductivity of the sample is a cause and effect diagram shown in Fig. 9.22. This fishbone visualizes the relationship of the uncertainty sources. The main sources of uncertainty are the measurement of the resistance of the sample, the sample temperature, the cell constant and the sample itself.

Temperature Influence on Electrolytic Conductivity

The conductivity of the sample depends on temperature and only conductivity values obtained at the same measurement temperature can be compared. The concept of reference temperatures (mostly 25 °C) was introduced to solve this problem. A temperature correction function allows the conductivity meter to convert the actual conductivity to that of the reference temperature.

There are three ways of temperature correction:

- No correction (according to the specification of the United States Pharmacopeia (USP) [9.26]) for water used in pharmaceutical industry, like water for injection (WFI);
- Linear correction function;
- Nonlinear correction function (e.g. for natural waters according to ISO 7888 [9.27]).

The standard uncertainty of the temperature should be $u = 0.1 \text{ K}$ or better. For low uncertainty it is recommended to thermostat the sample so that the same temperature is used for calibration and measurement.

Fig. 9.23 Fringe effects occur on the edge of a two-electrode cell. If the field is not homogeneous it is not possible to determine the cell constant by a geometrical approach

Conductivity Cells

The conductivity cell should be especially designed for the measurement in the conductivity range of interest. The electrolyte solution is filled in or flowing through a vessel containing at least two electrodes.

Primary Cells

The conductivity of primary reference solutions are measured by means of conductivity cells with known cell constant. Various cell types have been tested in the past on their ability to avoid or minimize fringe effects and stray fields typical for two-electrode cells as seen from Fig. 9.22. Two common models are shown in Figs. 9.23 and 9.24.

The cell type schematically shown in Fig. 9.24 was developed at the National Institute of Standards and Technology (NIST, Gaithersburg) [9.28]. The so-called Jones cell [9.29] is based on the principle of a geometrically measured, removable center section. The cell constant is primarily determined by the cross sectional area and length of the glass tube separating the platinum electrodes rather than by the size of the electrodes themselves. In the primary cell the resistance of the solution can be reduced by reducing the distance between the electrodes using a removable center section. The difference in resistance is therefore due to the geometry change of the center section of the cell and the conductivity of the sample.

Fig. 9.24 Jones-type primary cell with removable centre section

The disadvantage of this cell design is that the cell must be disassembled and cleaned between measurements with and without the center section which enhances the risk of contamination. The relatively expanded uncertainty (coverage factor $k = 2$) e.g. for the conductivity of a 0.01 mol/kg potassium chloride solution with nominal conductivity of 1.41 mS/cm (at 25 °C) is of the order of 0.03%.

A different approach of a two-electrode cell with well-known geometry developed at the Physikalisch-Technische Bundesanstalt (PTB, Braunschweig) [9.30] goes back to Jones et al. [9.31] and Saulnier [9.32] designs. For this model, the distance between the two electrodes can be adjusted very precisely without the cell being disassembled.

The cell design is shown in Fig. 9.25. The cross-sectional area is constant and is determined by the internal diameter of the tube. The two electrodes are made of Pt directly vapour deposited onto the electrode bodies [9.33]. If the spacing between the two electrodes is large compared to its change the distribution of the electric field is not influenced by the movement and the reactance terms remain only frequency dependent.

Four-Terminal DC Cell

Measurements for a primary reference solution of the molality 1.0 mol/kg potassium chloride are performed using a four-electrode DC cell [9.34].

Fig. 9.25 Primary differential cell with adjustable electrode distance

At higher conductivity, i. e. at low resistance, this method has advantages [9.25]. The current has to be kept relatively low to avoid heating the solution and electrolysis. Reversible electrodes are required to eliminate any polarization effect. Measurements are affected by the two outer Pt current electrodes and the inner two reversible electrodes as potential electrodes. The traceable value of the cell constant is directly determined through the geometry of a glass tube precisely bored and divided into three pieces. The center section is removable and its internal diameter and length are accurately known.

Fig. 9.26 Classical two-electrode conductivity cell

Commercial Conductivity Cells – Two-Electrode Cell

The two-electrode cell as shown in Fig. 9.26 is the classical conductivity cell sometimes called Kohlrausch cell.

The two-electrode cell consists of two parallel electrodes immersed in the sample solution. An AC current is applied and the resulting voltage is measured. Stray field and polarization effects influence the measurement. These effects must be kept under control in order to measure only the bulk resistance of the sample. Polarization is a side effect of the contact of electronically conducting electrodes with a solution showing ionic conduction. A charge buildup occurs at the electrical double layer at the electrode–solution interface and causes a voltage drop across the electrode surface. As a consequence, the measurements can, in general, not be performed with DC but have to be carried out with AC in the frequency range of typically up to 5 kHz.

The deposition of a platinum black layer on a platinum electrode (platinization) also reduces the polarization effect by increasing the electrode surface and thus reducing the current density [9.35].

It is important to choose the right frequency for the respective application. Low frequencies are applied at low conductivities. In this range the polarization is negligible compared to the bulk resistance of the sample. High frequencies (1 kHz to 5 kHz range) are applied at high conductivities in order to minimize the polarization resistance.

A disadvantage of the two-electrode cells is that any changes of the electrode surface such as corrosion or coatings influence the measurement result. If the electrodes are covered by platinum black any scratch or other damage would change the surface and therefore the cell constant.

Four-Electrode Cell

The four-electrode cell reduces the problem of polarization effects. Changes of the electrode surface like blocking and coating do not influence the measurement

result. A typical four-electrode cell as oversimplified shown in Fig. 9.27 consists of four concentric rings, one outer pair of current electrodes and one inner pair of voltage electrodes. The AC current is applied only to the outer pair of rings. The voltage is measured on the inner rings without polarization effects.

Three-Electrode Cells

The three-electrode cell type is nowadays almost completely replaced by the four-electrode cell. For a three-pole cell the third pole is connected to pole 1. The electrical field is guided and confined in an optimally and stray-field effects are therefore minimized [9.36].

“Electrodeless” Conductivity Measurements – Toroidal “Inductive” Conductivity

In the toroidal conductivity measurement cell as shown in Fig. 9.28, the electrodes are located outside the solution being investigated. An oscillating potential is applied to the first electrode and induced in the second toroidal coil and the conductance of the solution is measured [9.37]. A main field of application is the process control, e.g., in food industry.

Monitoring the Purity of Water

Since electrolytic conductivity is a sensitive measure for the amount of ions dissolved in the solution, a threshold for conductivity is a clear and simple specification for the quality and purity of water in general but also for high-purity water. The relevant measuring range is below 0.1 mS/m (0.06 $\mu\text{S}/\text{cm}$ to 1 $\mu\text{S}/\text{cm}$ at 25°C). The US Pharmacopoeia [9.26] as well as the European one [9.38] have specified the standard for purified water, highly purified water and water for injection for the pharmaceutical industry based on conductivity measurements. Sectors that also use conductivity thresholds for water purity are electrical power plants, food industry, electronic industry and analytical laboratories.

To compensate for the absence of certified reference solutions, a calibration method based on high-purity water as a standard has become widely accepted by the users of low conductivity measuring devices [9.39]. For this purpose it is necessary to determine the conductivity of high-purity water traceable to the SI unit.

Flow-Through Cell for the Low-Conductivity Range

The most common cell design for in-line applications in the high-purity water range is shown in Fig. 9.29. The contamination with atmospheric carbon dioxide from surrounding air is avoided for this type of cell. The concentric design minimizes electromagnetic interfer-

Fig. 9.27 Oversimplified four-electrode cell

Fig. 9.28 Toroidal “inductive” conductivity cell

ence [9.40] and the cell constant can be calculated from the inner and outer diameters and from the length of the cell tube according to (9.31). Due to the unknown fringe effect a at the holes and at the end of the electrodes this concentric cell has also to be calibrated.

$$K = \frac{\ln(D_A/D_I)}{2\pi(l+a)} \quad (9.31)$$

The principle of a new approach based on a primary flow-through cell [9.41] is shown in Fig. 9.30. The cell constant of this primary cell is determined by a geometrical approach where the distance between the concentric electrodes is varied in a controlled and traceable way. The differential cell constant is of the order of 1 m^{-1} with a relative expanded target uncertainty ($k = 2$) smaller than 0.5%. Because cell dimensions, resistance and temperature measurements are known to be traceable to the SI unit, the conductivity of the high-purity water can thus be determined by a primary measurement method. The same water is used as “transient” reference material to calibrate a commercial cell in-line and at the same temperature as the primary cell. The concentric cell consists of two inner electrodes of different length and one outer

Fig. 9.29 Flow-through cell for the low conductivity range. For this closed cell type the influence of air-borne contaminations like carbon dioxide on the measurement result can be avoided

electrode. The gap between the inner electrodes is filled with inert material. Platinum resistance thermometers (RTD) temperature sensors are mounted in each inner electrode.

On the assumption that the fringe effects are of the same order and the length of the inner electrodes are known it is possible to calculate α from the resistance measured in water.

Another promising design of a primary flow-through cell is based on the so-called van der

Fig. 9.30 Primary flow-through cell for in-line conductivity measurements in the high-purity water range. The concentric cell consists of two inner electrodes of different length and one outer electrode. The gap between the inner electrodes is filled with inert material

Pauw principle which is used extensively in solid-state physics to measure surface resistivity. The principle is based on a theorem similar to that of Lambert used for the determination of the capacitance unit. The theorem can be applied to a cell with constant cross section and with four electrodes at the edges [9.42].

9.4 Semiconductors

Semiconductor materials offer a wide range of conductivity according to their free carrier concentration, starting from the intrinsic conductivity (10^{-8} S/cm) up to 10^5 S/cm by controlling the doping concentration from 10^{12} cm $^{-3}$ up to 10^{21} cm $^{-3}$. Thus, the determination of the conductivity, conductivity type (n- or p-doped), and the related majority carrier mobility are the most important characterizations, especially in the case of newly developed materials.

After these majority carrier properties are known, minority carrier properties come into consideration, which are mainly related to lattice defects (vacancies and interstitials), but also to chemical impurities, which produce (deep) electron or hole states within the band gap. The most important parameter is the minority carrier lifetime which is applied to describe leakage currents of p–n junctions, charge storage times in dynamic memory cells or sensitivity of charge-coupled device light sensors.

With respect to high-speed devices, like e.g. bipolar transistors or photodiodes, saturated drift velocity values are needed to estimate the high-speed performance. Many semiconductor devices reach their operating limits with respect to some breakdown mechanisms,

like the onset of tunneling currents or impact ionization.

Table 9.5 gives a selected list on semiconductor properties and related methods to determine their values. The following paragraphs give some guidance to determine the most relevant parameters useful for device simulation, device design, and device analyses.

As all semiconductor devices need a more or less ideal contacting of their active regions via metallization of ohmic contacts, the final section collects measurements methods for specific contact resistances.

9.4.1 Conductivity Measurements

Conductivity measurements on semiconductors are predominantly related to bulk material, e.g. semiconductor wafers and epitaxial layers or layer stacks. The conductivity σ (S/cm) is related to the specific resistance ρ (Ω cm):

$$\sigma = \frac{1}{\rho}. \quad (9.32)$$

The conductivity can be calculated from basic semiconductor properties in case of dominating electron

Table 9.5 Overview on selected semiconductor properties and related characterization methods

Property	Symbol	Characterization method
Specific resistance	ρ	Four-point probe, van der Pauw method
Conductivity type	(n- or p-type)	Thermo probe, Hall effect
Carrier concentration	n, p	Hall effect, capacitance–voltage (C–V)
Carrier mobility	μ_n, μ_p	Hall effect with resistivity
Compensation ratio	$N_A/N_D, N_D/N_A$	Temperature dependence of Hall coefficient
In-depth doping profile	$N(x)$	Capacitance–voltage (C–V), Hall effect with selective layer removal, spreading resistance on beveled samples
Diffusion length	L_n, L_p	Junction photocurrent, electron beam induced currents (EBIC)
Saturated drift velocities	$v_{n,sat}, v_{p,sat}$	I–V analysis (Kelvin method)
Ionization rates by electrons or holes (impact ionization)	α_n, α_h	Temperature resolved I–V analyses
Minority carrier lifetime	τ_n, τ_p	I–V analysis, photoconductivity
Deep states (traps): density, thermal emission rates, capture cross sections, energy level	N_t $e_n, e_p, \sigma_n, \sigma_p$ E_t	Deep level transient spectroscopy (DLTS)

Fig. 9.31 Four-point probe on a semiinfinite semiconductor wafer with specific resistance ρ

conduction.

$$\sigma = q\mu n \quad (9.33)$$

with the elementary charge $q(1.602 \times 10^{-19} \text{ As})$, the carrier mobility μ (unit cm^2/Vs), and the carrier density n (unit cm^{-3}).

If both carrier types (electrons and holes) are concerned, the conductivity is deduced from

$$\sigma = q\mu_n n + q\mu_p p. \quad (9.34)$$

The standard method for measuring the specific resistance of bulk materials and thin layers is the four-point probe [9.43]. This method is well established for silicon and germanium but works as well on GaAs, InP, and other III–V compound materials. By applying the method to beveled surfaces, in-depth resistivity profiles can be deduced (spreading resistance method [9.44]).

The basic measurement setup of the four-point probe (c.f. e.g. DIN Norm 50431) is depicted in Fig. 9.31. A measurement head comprising four spring-loaded needles with equal distances s (e.g. $s = 1 \text{ mm}$), is pressed onto the semiconductor sample with a pressure ensuring good near-ohmic contacts, but soft enough not to

produce visible damage. The measurement current I is fed via the outer needles through the sample. The voltage V is measured between the inner needles. Assuming a constant current source with nearly infinite source impedance and a voltage meter with nearly infinite input resistance, possible contact voltages at the needles due to the current flow can be neglected in this Kelvin-like setup. The specific resistance of the sample is

$$\rho = \frac{V}{I} c \quad (9.35)$$

with c denoting a geometry dependent correction factor, depending on the sample dimensions and the needle distances. The following constraints have to be fulfilled in all sample configurations for accurate measurement within inaccuracies below 1%:

- nearly ohmic contacts between the needles and the semiconductor,
- negligible heating of the sample due to the measurement current I (mA range),
- no excess injection of carriers, which would lead to excess conduction (dark measurement),
- no extreme surface potential induced surface band bendings; otherwise leading to stronger surface accumulation or surface inversion layers which would affect the bulk conduction.

In the following sections the correction factor c is given for different samples geometries.

Conductivity of Thin Layer Samples

The measurement setup of the four-point probe applied to a laterally infinitely extended thin layer of thickness d and specific resistance ρ , grown on a semiinsulating wafer is depicted in Fig. 9.32. The specific resistance (unit $\Omega \text{ cm}$) of the layer can be deduced from the measured voltage V , induced by the current I using

$$\rho = \frac{V}{I} d \frac{\pi}{\ln 2}. \quad (9.36)$$

An error in the evaluation of the specific resistance approaches 1%, if the layer thickness d would be one half of the needle distance s . This error would increase to 8%, if the layer thickness d would equal the needle distance s . Normally, needle distances of 1 mm are used, thus, for layer thickness values in the 1–10 μm range this systematic error can be neglected easily. This solution is also applicable in all cases, where the lateral dimen-

Fig. 9.32 Four-point probe applied to a thin, infinitely extended layer of thickness d and specific resistance ρ ; the measured layer is isolated by a semiinsulating substrate

Fig. 9.33 Four-point probe on a semi-infinitely extended bulk sample with a specific resistance ρ ; the radius of the measured volume is defined roughly by $d > 3.5s$

sions of the sample are much larger than the threefold measurement–tip distance. If the latter condition cannot be met a setup as in Fig. 9.34 has to be used.

Conductivity of Semiinfinite Bulk Samples

The measurement setup of the four-point probe applied to a semiinfinitely extended bulk sample with a specific resistance ρ , is depicted in Fig. 9.33. The specific resistance (unit $\Omega \text{ cm}$) of the semiinfinite bulk sample can be deduced from the measured inner voltage V induced by the outer current I by

$$\rho = \frac{V}{I} s 2\pi. \quad (9.37)$$

This is valid under the assumption, that the radius of the measurement volume $d > 3.5s$, with s denoting the equal spaces s of the needle setup.

Conductivity of Rectangular Shaped Small Samples

In some cases, the samples to be characterized exhibit neither the shape of a semiinfinitely extended bulk sample nor the structure of a laterally infinitely extended thin layer. Thus, a further solution is given for the case of a rectangular shaped sample of finite dimensions a and b , see Fig. 9.34.

The solution of this problem can be obtained by several approaches, like finite difference methods. Here, an analytical approach of Hansen [9.45] may be mentioned which can be easily implemented on desktop computers. The Laplace equation is solved using a separation of variables and applying standard boundary conditions on the doubled sample (see dotted lines in Fig. 9.34) without changing the field and current line conditions in the original sample. A series expansion is developed

Fig. 9.34 Four-point probe on a thin, rectangular shaped layer of dimensions $a \times b \times d$ with a specific resistance ρ ; the measured layer may be isolated by an underlying semiinsulating substrate or a pn-isolation

in [9.45] to deduce the specific resistance ρ from measured I – V values and the sample geometry data a , b , and d as well as the probe head tip distances s :

$$\rho = \frac{V}{I} \left(\frac{s}{bd} + \frac{8}{bd} \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{\cosh \beta \left(l - \frac{3s}{2} \right) \sinh \left(\beta \frac{s}{2} \right)}{(1 + \delta_{0,m}) (1 + \delta_{0,n}) \beta \cosh(\beta l)} \right)^{-1} \quad (9.38)$$

with (m, n) unequal to $(0, 0)$ and

$$\beta = \frac{2\pi}{b} \left[m^2 + \left(\frac{nb}{2d} \right)^2 \right]^{1/2} \quad (9.39)$$

and

$\delta_{r,s}$ = Kronecker's delta

$[\delta_{0,m} = 1 (m = 0) \text{ or } 0 (m > 0)]$.

A general remark for all four-point probe configurations: the four-point probe can be applied to silicon and germanium using pressures of the needles of approximately up to 50 p; in case of more sensitive III–V materials like InP, the pressure of the probe needles has to be reduced to around 5 p.

Conductivity of Isotype 2-Layer Stacks

If there are two adjacent layers (1, 2) with isotype conduction type with individual sheet carrier concentrations $n_{1,2}$ (unit: cm^{-2}) and mobilities $\mu_{1,2}$ (unit: cm^2/Vs), contributing to the total sheet conductance δ_s , the resulting mixed conductance in terms of the effective sheet carrier density n_s and effective mobility μ_s can be

calculated from the conductances of the single layers according to [9.46]

$$n_s = \frac{(\mu_1 n_1 + \mu_2 n_2)^2}{(\mu_1^2 n_1 + \mu_2^2 n_2)}, \quad (9.40)$$

$$\mu_s = \frac{(\mu_1^2 n_1 + \mu_2^2 n_2)}{(\mu_1 n_1 + \mu_2 n_2)}. \quad (9.41)$$

It is assumed that the adjacent isotype layers are grown either on a semiinsulating buffer layer or together being isolated by a pn-junction from the substrate. Thus, the substrate or buffer conductance should be negligible in this two-layer mixed conduction model.

9.4.2 Mobility Measurements

The mobility μ of the majority carriers is extracted by a two-step procedure applying van der Pauw test structures [9.47]. Firstly, the specific resistance ρ is measured, secondly the carrier concentration n is determined. Both measurement setups use the same test structure but apply different schemes for contacting to feed the measurement current into the sample and to measure the resulting voltages. In a final step the mobility is deduced from the equation $\sigma = q\mu n$ solved for μ :

$$\mu = \frac{\sigma}{qn} = \frac{1}{qn\rho}. \quad (9.42)$$

The term $|\frac{1}{qn}|$ is the Hall constant, which is indicative of the carrier concentration n within the test sample. Thus, the mobility can also be written as

$$\mu = \frac{R_H}{\rho} = R_H \sigma. \quad (9.43)$$

Due to the fact that the Hall effect is polarity sensitive with respect to the conduction type, the sign of the Hall constant comprises the information of the dominating carrier type: negative sign–n-type, positive sign–p-type. In the following, the Hall effect is explained in more detail and some van der Pauw test structures will be discussed.

Hall Effect, van der Pauw Structures

The Hall effect after Hall (1879) denotes the onset of a voltage V_H at a long thin sample of length a , where a current I is driven through the long axis and a magnetic field \mathbf{B} is applied perpendicular to the sample (Fig. 9.35). Due to the balance of the Lorentz force $\mathbf{F} = q\mathbf{v} \times \mathbf{B}$ and the electric field force due to E_H of the Hall voltage, the Hall voltage for an n-type sample can be deduced after integrating over the transverse field E_H

$$V_H = -\frac{1}{nq} \frac{1}{d} IB. \quad (9.44)$$

The term $-1/(nq)$ is known as the Hall constant R_H of the sample, the sign of which depends on the carrier type. In case of a p-type sample, the Hall constant has a positive sign.

Thus, the Hall effect can be used to determine the dominant carrier or conduction type of an unknown semiconductor sample.

The Hall voltage of either type can be written as

$$V_H = R_H \frac{1}{d} IB \quad (9.45)$$

with voltage signs $+/- \leftrightarrow$ p/n-type conduction.

When Hall's constant R_H is determined, the carrier concentration can be deduced

$$n, p = \frac{1}{qR_H} \quad (9.46)$$

(with n, p due to a negative, positive sign, respectively)

In principle, the mobility value can now be calculated from (9.43) assuming that the conductivity of the sample was determined by the four-point probe before. This method applying two different test samples would work but it is rather impractical. A more convenient way was published in [9.47], where a disk of arbitrary shape can be used for both types of measurement. In practice, later a rectangular sample is preferred. The original van der Pauw sample type is shown in Fig. 9.36; the sample must not contain any holes. The van der Pauw sample is used in two measurement configurations:

Fig. 9.35 Hall effect at a long sample with dimensions $a \times b \times d$, where a measurement current I is driven along a , and a magnetic field is applied perpendicular to a, b in z -direction

Fig. 9.36 van der Pauw test sample of specific resistance ρ , disc of arbitrary shape of thickness d with infinitesimal small contacts M, N, O, P at its periphery

a. For the measurement of the specific resistance.

The current I is fed into contacts M, N and the voltage V is taken at contacts P, O. This I – V configuration can be cycled around “90°”, and the voltage at M, P taken, too. Thus, two resistances are built: $R_{MN,OP}$ and $R_{NO,PM}$. In [9.47], it is shown by a conformal mapping method that the sample’s specific resistance obeys van der Pauw’s equation

$$e^{\left[-\left(\frac{\pi d}{\rho}\right)R_{MN,OP}\right]} + e^{\left[-\left(\frac{\pi d}{\rho}\right)R_{NO,PM}\right]} = 1. \quad (9.47)$$

The specific resistance can be solved from (9.47) graphically or numerically, e.g. by a Newton method. For the practically preferred rectangular sample geometry the specific resistance can be deduced from

$$\rho = \frac{\pi d}{\ln 2} R_{MN,OP}. \quad (9.48)$$

In this symmetrical case, the I – V configuration can be rotated four times by 90° and the resulting four voltage values can be averaged. Additionally, the current polarity can be reversed and the resulting voltages averaged again. Thus small asymmetries of the sample can be averaged by taking the mean value of eight measurements. More elaborate evaluation procedures in cases of asymmetric I – V measurements in the van der Pauw configuration are given in [9.43].

b. For measurement of the carrier concentration.

For the determination of the carrier concentration from a Hall measurement at the van der Pauw sample, the I – V setup is modified in which the current and voltage contacts are now crossed. The Hall constant is determined in this case by forming the

average out of two measurements

$$R_H = \frac{d}{B} \left(\frac{R_{NP,OM} + R_{OM,PN}}{2} \right). \quad (9.49)$$

This scheme can also be improved by averaging over eight Hall resistance terms, as given in [9.43]. The carrier mobility is now deduced using (9.43), (9.49) together with (9.48).

Van der Pauw Test Structures

It was mentioned before, that a rectangular test sample with quite small contacts at the corners can be used favorably for the van der Pauw measurements (Fig. 9.37). The ideal infinitesimally small contacts can be approached by soldering 500 μm Sn balls into the corners of the sample while using sample sizes of, e.g. $> 5 \times 5 \text{ mm}^2$.

However, real samples suffer from different non-idealities of the sample preparation; the contacts are not small enough compared to the sample’s edge length or the contacts are not correctly deposited at the sample’s corners. Respective correction terms can be found in [9.43]. To overcome the distorting effects of finitely extended contacts, a lot of alternative test samples are in use. Figure 9.38 gives an overview of common van der Pauw test sample geometries [9.43]. Very popular is the clover-leaf structure (e), which can be fabricated by ultrasonic cutting and which does not need further electrical corrections even in the presence of finite contacts. Very precise results can also be obtained

Fig. 9.37 Quadratic van der Pauw test sample with ideal infinitesimally small contacts in the four corners

Fig. 9.38 van der Pauw test samples with nonideal finite contact sizes (after [9.43])

from the greek cross structure (b). Many discussions concerning ease of fabrication, fragility, heat dissipation, and needs of correction factors can be found in [9.43].

Temperature Dependent Carrier Concentration and Compensation

The carrier concentration determined by the standard Hall technique described so far is assumed to represent the value of the dopant concentration as well. This is valid when a complete dopant ionization can be assumed. In practice, at least two additional aspects have to be considered.

Temperature Dependent Carrier Concentration (Dopant Ionization <100%)

The mobile carrier concentration $n(p)$ follows the dopant concentration N_D (N_A) up to concentration values of the order of the effective density of states (N_c or N_v , for n- or p-type conduction, respectively). The effective density of states depends, besides the sample temperature ($\propto T^{3/2}$), on the effective mass of the carrier, e.g. for the conduction band E_c

$$N_c = 2 \left(\frac{2\pi m_0 m_e k_B T}{h^2} \right)^{3/2} \quad (9.50)$$

with m_0 denoting the free electron mass and m_e the effective mass of the electrons; the other constants have their usual meanings. Normally, electron effective masses m_e are smaller than hole effective masses m_h . Thus, the density of states in the conduction band is smaller than in the valance band (for a first very rough orientation take $N_c = 10^{18} \text{ cm}^{-3}$ and $N_v = 10^{19} \text{ cm}^{-3}$ for E_c and E_v , respectively). The free carrier concentration n is regulated by the position of the Fermi level E_F with respect to the band edges E_c and E_v . Although the Fermi distribution [9.48] gives the correct Fermi level and carrier concentration, often Boltzmann's approximation is used for non-degenerate semiconductors ($E_c - E_F > 3 k_B T$), again denoted for the electron concentration: $n = N_c \exp\left(-\frac{E_c - E_F}{k_B T}\right)$ [for holes: $p = N_v \exp\left(\frac{E_v - E_F}{k_B T}\right)$]. The Fermi level E_F adjusts itself in relation to the band edges to provide overall charge neutrality for the sum of fixed and mobile charges, i.e. for the charge sum of ionized impurities and electron and hole densities (for the n-type semiconductor: $N_D^+ = n - p$). The ionized impurity concentration N_D^+ is given by the Fermi

level position with respect to the impurity level energy E_D

$$N_D^+ = N_D \frac{1}{1 + g \exp\left(-\frac{E_D - E_F}{k_B T}\right)} \quad (9.51)$$

with g denoting the ground-state degeneracy of the donor level [$g = 2(4)$ for electrons (holes)], E_D usually is some (ten) meV below the conduction band edge energy. This equation shows that complete ionization can be achieved at Fermi level positions well below E_D , i.e. for doping concentrations below the effective density of states N_c . The charge neutrality equation together with Boltzmann's approximations for the free carrier concentrations and the before mentioned ionization relation for the dopant N_D fixes the Fermi energy and the free carrier concentrations for a given temperature. For incompletely ionized donors, i.e. for lower temperatures (below 100 K) the carrier freeze-out range begins. This means that only a certain percentage of the donor concentration results in free electrons in the conduction band. Thus, also the Hall technique will measure a reduced carrier density towards decreasing temperatures. Fitting the free carrier concentration given by the above equations to a temperature-resolved Hall measurement, e.g. within a range from 77 K up to 400 K, allows the determination of the dopant ionization energy E_D .

Compensation Effects

In semiconductors there may also coexist a smaller amount of the adverse dopant type of opposite charge polarity besides the dominating one which determines the sign of the Hall constant and the conduction type (n- or p-type). This adverse dopant type tends to partially compensate the effectiveness of the major dopant and results in a pronounced temperature behavior of the free charge concentration in excess of that of an uncompensated semiconductor. At normal (room) temperatures, the free carrier concentration is given by $n = N_D - N_A$, while at reduced temperatures, the free carrier concentration diminishes much more pronounced due to the compensation and incomplete ionization of the majority carrier dopant type. The charge neutrality equation is now replaced by $N_D^+ - N_A^- = n - p$. Applying again Boltzmann's approximations for the free carrier concentrations and the noted ionization relation for the dopants N_D and N_A , the free electron concentration in case of a partially compensated n-type semiconductor can be

deduced:

$$\frac{n}{N_D} = -\frac{1}{2} \left(\frac{n_1}{gN_D} + \frac{N_A}{N_D} \right) + \sqrt{\frac{1}{4} \left(\frac{n_1}{gN_D} + \frac{N_A}{N_D} \right)^2 + \frac{1}{g} \left(1 - \frac{N_A}{N_D} \right) \frac{n_1}{N_D}} \quad (9.52)$$

with $n_1 = N_c \exp\left(-\frac{E_c - E_D}{k_B T}\right)$. This equation can be related again to a temperature-resolved Hall measurement $n(T)$. The fit allows to determine, besides the donor ionization energy E_D , also the compensation ratio N_A/N_D . In dominating p-type semiconductors, the compensation ratio is defined as N_D/N_A (< 1).

In all cases of compensated semiconductors, the Hall mobility is more or less lower than in the uncompensated cases because the additional ionized impurity scattering effects at the compensating centers lead to reduced mobility values. This effect can be even more pronounced at low temperatures when carrier scattering effects by lattice vibrations are negligible, i. e. when the Hall mobility is only affected by free carrier or ionized impurity scattering. Thus, the maximum mobility values of low-doped semiconductors achievable at e.g. 77 K give invaluable information on the purity of the material.

Hall Mobility and Drift Mobility

Deducing from the Hall effect, the carrier velocity was orientated solely along the y -direction of the constant current fed through the long test sample. In practice, the electrons (or holes) are moving not with a linear translation but they are moving on cycloid-type paths due to the two forces of the electric field in y -direction and to Lorentz's force in x -direction. These cycloid-type curves are interrupted by scattering events of the carriers at lattice vibrations and (ionized) impurities depending on the impurity density. A result of these combined movements of the carriers in x - and y -directions under the combined electrical (E_y) and magnetic (Hall) field (E_H) forces are trajectories, where the carriers feel the crystallographic properties of the semiconductor crystal in both directions x and y . Consequently, the Hall mobilities $\mu_{H,n,p}$ may deviate from the drift mobilities $\mu_{n,p}$. The newly introduced Hall factor $r_{H,n}$ denotes the ratio of $\mu_{H,n}/\mu_n$; in the case of a p-type semiconductor, $r_{H,p}$ denotes the ratio of $\mu_{H,p}/\mu_p$. The Hall factor modifies the formerly Hall constants for an n-type semiconductor $R_{H,n} = -r_{H,n} \frac{1}{qn}$ and for the p-type semiconductor $R_{H,p} = -r_{H,p} \frac{1}{qp}$. The Hall factors de-

pend slightly on the magnetic field, the crystal structure, and the measurement temperature. For high magnetic fields, the Hall factor tends to unity. In practice, due to often unknown precise values of the Hall factors, a unity value is assumed for material quality comparisons of different epitaxial approaches or annealing conditions.

Field-Effect Mobility (FET Transistor)

In devices like field-effect transistors (FET), the conducting channel is controlled by gate electrode applying an electrical field perpendicular to the current path. The channel can be either located at the surface of the device, like in a MISFET (metal-insulator-semiconductor FET) or the channel may be buried, like in HFET/HEMT (hetero structure / high-electron mobility FET) transistors. For these large variety of devices, the Hall effect can be applied to measure the channel mobility which can be either enhanced by two-dimensional electron gas effects or be reduced due to surface scattering effects between the insulating gate oxide and the surface conducting channel, compared to bulk conduction in thicker epitaxial layers.

9.4.3 Dopant and Carrier Concentration Measurements

The measurement of the dopant and carrier concentration is mainly done by capacitance–voltage (C – V) analyses because this method delivers not only averaged carrier concentrations but provides the in-depth carrier concentration profiles, too. Capacitance–voltage (C – V) analyses are predominantly executed applying LCR-meters, which can measure the sample's AC conductance besides the capacitance. C – V analyses should be evaluated under the assumption that the loss tangent ($G/\omega C$) of the sample does not exceed some percent proving that the capacitance for a given measurement frequency is dominating the conductance contribution. If sufficiently low values of the loss tangent cannot be achieved for a standard frequency of e.g. 1 MHz, then higher frequencies should be chosen in case of parallel conductance leakage, or lower frequencies should be used in cases of high series resistances of the samples under test. A rule of thumb is to choose the measurement frequency according to the minimum of the loss tangent. If stray capacitances in parallel to the sample are present, then those should be determined by applying adequate test structures and subtracting them before conducting further C – V analyses.

The C - V method can be most simply explained applying a Schottky contact, i.e., a metal contact on an n-type semiconductor. Firstly, the doping profile analysis is explained under the assumption of the depletion approximation. Secondly, some limitations of the C - V method with respect to in-depth resolution limitations due to Debye length effects are discussed. Thirdly, correction procedures are explained for the most important cases of near-surface doping profiles in metal–insulator–semiconductor (MIS) structures and in-depth implantation profiles as well as high-low doping profiles.

Capacitance–Voltage (C - V) Analyses

The basic capacitance-voltage (C - V) evaluation with respect to semiconductor in-depth doping profiling is based on the depletion approximation, i.e. on the assumption of an abrupt space charge edge in conjunction with complete dopant ionization. A suitable sample test structure is shown in Fig. 9.39. A Schottky contact metal with defined area A is evaporated on top of the semiconductor, while ohmic metallization is provided at the back side. Due to the work function difference of the metal to the electron affinity of the semiconductor, a space charge region of depth w is formed. The depth of the space charge region can be controlled by a reverse biased voltage applied to the top gate electrode. Within the depletion approximation, the capacitance of the space charge region (neglecting side wall effects and other stray capacitances) is given by the plate capacitor model

$$C_{sc} = \epsilon_0 \epsilon_r \frac{A}{w_0} \quad (9.53)$$

with ϵ_r being the dielectric constant of the semiconductor, ϵ_0 the vacuum permittivity, and w_0 the space charge width at zero bias. Figure 9.40 shows the related band diagram at zero bias. The Schottky barrier height Φ_{Bn} induces a band bending within the semiconductor of qV_{bi} , with V_{bi} being the built-in voltage of the Schottky diode. E_c , E_v and E_F are the conduction, valence band edges, and the Fermi level, respectively. The Fermi level at equilibrium is constant throughout the whole metal–semiconductor structure indicating the absence of current flow at zero bias conditions. If an external reverse voltage is applied to the left-sided metal electrode, the band bending of the semiconductor increases and the width of the space charge region increases, too. Consequently, the resulting capacitance is reduced, according to (9.53). The depletion approximation model can be seen in Fig. 9.41, where the in-depth

Fig. 9.39 Schottky metal contact (area A) on top of an n-type semiconductor with space charge region depth w

Fig. 9.40 Band diagram of a metal–semiconductor Schottky contact in thermal equilibrium at zero bias

free electron concentration $n(x)$ is shown in idealized form compared to an arbitrarily assumed in-depth doping concentration profile $N_D(w)$. In the neutral region, the free carriers (here electrons) compensate the ionized donor atoms [$N_D^+(w) = N_D(w) = n(x)$]. Depletion approximation means that the free carrier concentration at the edge of the space charge region makes an abrupt transition down towards zero concentration

Fig. 9.41 Arbitrary in-depth doping profile $N_D(w)$ and resulting in-depth free electron concentration profile $n(x)$, described according to the depletion approximation

inside the space charge region. This corresponds to a zero Debye length. The Debye length $L_D = \sqrt{\frac{\varepsilon_0 \varepsilon_r k_B T}{q^2 n}}$ denotes a typical screening length depending on the square root of temperature T compensating space charge distortions from thermal equilibrium of the carrier concentration n .

By solving Poisson's equation $\text{div } \mathbf{D} = \rho$ and integrating twice over the space charge region, the total band bending potential V depending on the space charge region depth w , can be deduced: $V = \frac{1}{2} \frac{q N_D w^2}{\varepsilon_0 \varepsilon_r}$ (so far a constant dopant profile N_D is assumed). By combining this equation with the plate capacitor equation, solving for an expression of $1/C^2(V)$ and differentiating $1/C^2(V)$ versus the external voltage, an expression for a nonconstant in-depth carrier concentration profile $n(x)$ [identified equal to $N_D(x)$] due to the depletion approximation can be found:

$$N_D(x) = \frac{1}{q \varepsilon_0 \varepsilon_r} \frac{1}{A^2} \frac{C^3(V)}{\frac{dC(V)}{dV}} \quad (9.54)$$

for an n-type semiconductor,

$$N_A(x) = -\frac{1}{q \varepsilon_0 \varepsilon_r} \frac{1}{A^2} \frac{C^3(V)}{\frac{dC(V)}{dV}} \quad (9.55)$$

for a p-type semiconductor.

In both cases, the depth x is calculated from the plate capacitor model $x = \frac{\varepsilon_0 \varepsilon_r A}{C(V)}$.

The accuracy of the C - V method is mainly determined by the known accuracy of the gate electrode area, e.g. an accuracy of the area A within 1% gives an accuracy of the doping profile of 2%. Further, the spatial variation of the doping profile should be small within a Debye length to assure the validity of local charge neutrality during in-depth profiling.

Limitations on C - V Analyses, Applying the Depletion Approximation

The in-depth resolution of doping profiles determined by the C - V profiling method is limited by the Debye length. The finite Debye length leads to a smear out of the abrupt space charge edge over roughly 2–3 Debye lengths. This phenomenon is shown in Fig. 9.42. Two effects may result: first, in the case of abrupt steps within the doping profile, the equilibrium carrier profile will not follow the doping step with the same abruptness (local neutrality is not fulfilled); second, in the case of near-surface profiling, the free carrier tail of the space charge edge will touch the interface region even if a certain space charge region is still opened. In both cases profiling errors will arise. In the first case, the abruptness of

real doping profiles cannot be measured adequately; in the second case the apparent carrier profile (from which the user concludes the doping profile) will increase artificially towards the interface when the space charge region is smaller than about two Debye lengths.

The Debye length can be reduced by lowering the measurement temperature ($L_D \sim \sqrt{T}$), but for very low temperatures, the dopant ionization is diminished, too. Thus, the measured carrier concentration would underestimate the true dopant concentration and this approach was limited to very shallow donor levels.

These further aspects of finite Debye length problems during doping profiling will be discussed in the next section.

Debye Length Corrections for Near-Surface Doping Profiles in MOS/MIS Structures and for Ion-Implanted In-Depth Profiles

In this section two correction procedures will be described which help to improve approximations of the true doping profiles while the apparent C - V (carrier) profiles are affected by Debye length broadening effects.

Near-Surface Doping Profiles in MOS Structures

MOS (metal–oxide–semiconductor) or **MIS** (metal–insulator–semiconductor) structures play an important role in all CMOS based devices, like CMOS transistors or (B)CCD [(buried) charge-coupled device] focal plane arrays. The surface doping profile, i. e. the doping profile in the direct vicinity of the dielectric–semiconductor interface needs to be known very accurately because the value and homogeneity of the threshold voltage depends on it. **MIS** structures isolate quite well any current flow due to the high specific resistivity of the dielectric/oxide. This allows to solve Poisson's equation while neglecting any current flow and to consider the additional contribution of mobile carriers in the space charge region [9.49]. By applying this analytical approach Ziegler et al. [9.49] extended the range of the depletion approximation till up to the flatband point of **MIS** capacitors which means up to the semiconductor surface. They developed an analytic tabular correction algorithm for the apparent carrier profile, which is calculated from the depletion approximation and they avoid any artificial increase of the apparent carrier profile towards the surface, even when the profiling depth is lower than two Debye lengths. Figure 9.43 shows a typical comparison of uncorrected concentration profiles (dash-dotted lines) with the corrected ones (circles). In both cases of boron and phosphorus doping of the **MIS** capacitor, the correction algorithm delivers relatively flat profiles. Without this

Fig. 9.42 Arbitrary in-depth doping profile $N_D(x)$ and more realistic in-depth free electron concentration profile $n(x)$ in presence of Debye length smearing of the space charge edge

correction pile-up effects of the dopants were assumed due to annealing and segregation effects. The precise determination of the flatband point and the surface inversion point were greatly improved by applying the Ziegler–Klausmann–Kar profile correction [9.49]. The method is applicable for quasi-static RF measured MIS C–V curves as well as to pulsed RF C–V curves which avoid the surface inversion of MIS structures during the short (ms) measurement windows.

Measurement of Ion Implanted Profiles

In-depth profiling of ion implanted semiconductors is a special challenge for the application of the depletion approximation because a Gaussian-like implantation profile has more or less steep edges around the maximum, i.e. around the average projected range of deposited atoms. Furthermore, implantation profiles are used, compared to diffusion doping profiles, to achieve more abrupt doping transitions when scaling devices or to achieve low-ohmic contacts. Thus, the steepness of profile edges may occur easily within a Debye length, especially for lower implantation doses.

The discussed correction algorithm of Ziegler et al. [9.49] cannot be applied for smaller depth than two Debye lengths. For larger depths this algorithm exhibits a smooth transition into the standard depletion approximation. Quite a lot of implanted profiles show their projected ranges are quite deeper than several Debye lengths.

The same problem arises during profiling of high–low or low–high doping transitions of the same doping type, e.g. in varactor diodes. In all these cases, local charge neutrality is not fulfilled, especially in the vicin-

Fig. 9.43 Examples for doping profiles in silicon MIS capacitors. The *steeply uprising curves* show the apparent doping profiles using the uncorrected depletion approximation; the *circles* show the Debye-length corrected measurements (after [9.49])

ity of the steepest doping gradient. This typical situation is explained in Fig. 9.44 using the example of an implantation profile $N_D(x)$ with a Gaussian-like shape of its edges. The mobile carrier concentration $n(x)$ deviates typically from the dopant distribution due to spreading diffusion effects and repelling electrical field forces, i.e. at the maximum, free carriers are missing and in the edges the mobile carriers produce longer tails of the apparent concentration. This can be proved by comparing SIMS (secondary ion mass spectroscopy) measured implantation profiles with their C–V evaluated counterparts. The C–V technique is based on the signal from the mobile carriers ($C = dQ/dV$), thus the apparent doping profile lacks the abruptness of the real profile. Unfortunately SIMS cannot replace the C–V evaluation because SIMS cannot measure the electrically active concentration which is relevant for the device function. It determines only the atom concentration without information with respect to electrical activation. Thus, an effort is needed to improve the C–V evaluation in these

applications. This improvement was done by Kennedy et al. [9.50, 51]. They developed a correction of the apparent depletion approximation profiles assuming that the free carrier concentration is known. Therefore, they solved Poisson's equation considering additionally the charge contributions of the majority carriers and neglecting current flow in the reverse direction of Schottky- or pn-junction contacts. They deduced (9.56) which extracts the dopant profile $N_D(x)$ from the mobile carrier profile $n(x)$:

$$N(x) = n(x) - \frac{\varepsilon_0 \varepsilon_r k T}{q^2} \frac{d}{dx} \left(\frac{1}{n(x)} \frac{dn(x)}{dx} \right) \quad (9.56)$$

where $n(x)$ is obtained by evaluation of the standard depletion approximation (9.54), (9.55) evaluation from a C - V measurement. This extraction is valid if the true mobile carrier profile would be known exactly. Unfortunately, the C - V measurement determines only an approximation to this true mobile carrier profile because the space charge edge is smeared out over about two Debye lengths. Thus, the Kennedy correction [9.50, 51] is a useful improvement to obtain a more realistic shape of implanted profiles but it cannot, in principle, provide the true physical profile again caused by Debye length reasons. A good rule of thumb in case of implanted profiles, not to be affected too much by Debye length distortions (error < 1%), is the relation $\Delta R_p \geq 10L_D$, with ΔR_p being the half width of the implanted profile and L_D the Debye length for a given doping. This means in practice that high-dose implanted profiles suffer much less from Debye length distortions applying the C - V technique.

Applying (9.56) for the improvement of step-like high-low doping profiles, it is recommended (if possible) to provide the depletion from the highly doped side

because the Debye length is shorter at the begin of the measurement which helps the accuracy of the profile reconstruction [9.52].

Electron and Hole Effective Masses

The effective masses of mobile carriers in semiconductors reflect the curvatures of the band structure in the $E(k)$ diagrams. The effective mass is of a tensorial type with components: $\frac{1}{m_{ij}^*} \equiv \frac{1}{(\hbar/2\pi)^2} \frac{\partial^2 E(k)}{\partial k_i \partial k_j}$ with E denoting the band energy and $k (= 2\pi/\lambda)$ the wavevector of the carrier related to its moment $p = (\hbar/2\pi)k$. The band structure of semiconductors is described by Schrodinger's equation which is based on the wave nature of electron propagation in crystals. Tabulated values of effective masses of common semiconductors can be found in [9.48]. Effective masses can be measured by cyclotron resonance and by angle-resolved photoemission spectroscopy (ARPES) [9.53]. III-V semiconductors with their low effective electron masses (≈ 0.07) provide high carrier velocities within short acceleration times and thus a very high speed potential of electronic circuits.

9.4.4 I - V Breakdown Mechanisms

Electrical breakdown in semiconductors is characterized in terms of the electrical field strength (unit kV/cm) in regions of the I - V curve, where the current increases to a much higher extent than for slightly reduced field strength below. Electrical breakdown, indicated by a steep current increase vs. voltage, is mainly related to two mechanisms: impact ionization (avalanche) breakdown and tunneling (internal field emission). Both mechanisms can be distinguished by investigating the temperature behavior of the current-voltage (I - V) curves. For a certain constant voltage in the breakdown region a positive temperature coefficient of the current is indicative for tunneling breakdown, while a negative temperature coefficient indicates impact ionization breakdown. Both mechanisms are discussed in more detail in the following two subsections.

Impact Ionization Breakdown Field Strength

Impact ionization is a bulk controlled current flow mechanism induced by a carrier multiplying band-band process. Carriers are accelerated by an high electrical field, that they can induce electron-hole pair ionization due to their high energy. The resulting additional electrons and holes are accelerated in opposite directions, until they gain and overcome their specific ionizing

Fig. 9.44 In-depth profiles of implanted dopants $N_D(x)$ and free carrier concentration $n(x)$: near the peak is $N_D(x) > n(x)$ and far away from the peak is $n(x) > N_D(x)$

energy ($\gg kT$); thus, the whole process produces an avalanche-like increase of the current after an only small voltage increase. Impact ionization breakdown can be concluded from a negative temperature coefficient of the current at a high fixed reverse voltage. Increasing temperature causes more lattice vibrations, which hinder carriers, to gain directed acceleration; thus higher electrical fields are needed at elevated temperatures, to produce the same current. Small effective masses ease the ionization process due to higher carrier mobility in the accelerating field. Impact ionization is a band-band pair generation process, thus the break down electric field strength increases with increasing bandgap of the semiconductor. The avalanche process is described by the ionization rates α_n and α_h (unit: 1/cm) for electron or hole induced electron-hole pairs, respectively. The ionization rates $\alpha_{n,h}$ depend largely on the electrical field strength E

$$\alpha(E) = \alpha_\infty e^{[-(E_0/E)^m]} \quad (9.57)$$

with α_∞ , E_0 , and m being a temperature dependent material constant. Graphs of ionization rates of several semiconductors can be found in [9.48] ranging up to values of $\alpha_{n,h}$ of $10^5/\text{cm}$.

Tunneling (Internal Field Emission) Breakdown Field Strength

Tunneling or internal field emission is a quantum mechanical process, where carriers penetrate through thin energy barriers when the barrier thicknesses ap-

proach the value of the de Broglie wavelength (a few nm). During the quantum mechanical tunneling process their energy is conserved. Carrier tunneling is a barrier-controlled current flow mechanism. Tunneling is observed in highly doped pn junctions, where narrow barriers are favored by the high doping and the resulting small space charge regions. The de Broglie wavelength $\lambda_{e,h}$ is given by

$$\lambda_{e,h} = \frac{h}{\sqrt{2 * m_{0,e,h} E}} \quad (9.58)$$

with m_0 denoting the free electron mass, $m_{e,h}$ the effective mass of electrons or holes, and E the energy of the carrier. For, e.g. InP with an electron effective mass of 0.07 and an electron energy of kT ($T = 300\text{ K}$) λ_e amounts to 29 nm, while for $E = 1\text{ eV}$, λ_e reduces to 4.64 nm.

The barrier to be penetrated by the carrier should be narrower than de Broglie's wavelength for the relevant carrier's energy. The probability for tunneling increases considerably for electrical field strength in the range of 10^6 V/cm , i.e. $1(\text{eV})/10\text{ nm}$, where the effective barrier width for band-band tunneling is reduced to 10 nm, being in the range of the aforementioned de Broglie wavelength. For this nonthermal process, the thermal energy of the carrier (electron) is most often neglected.

Temperature Dependent Reverse Current I - V Analysis

According to the explanations given in the two sub sections before, the dominating mechanism for breakdown in pn-diodes or transistors can be identified by measuring the reverse I - V characteristics for various temperatures. A recommended temperature range extends, e.g. from 0°C to 80°C in steps of 20°C , which can be controlled by Peltier cooling or heating. Much wider temperature ranges can be achieved in cryostats, where electrical heating in conjunction with liquid nitrogen cooling can provide a temperature range between 77 K and 420 K. Because generation currents in pn-junctions are increasing proportional to the intrinsic concentration n_i , which itself increases exponentially over temperature in half of a given bandgap; an even moderate temperature spacing within a set of I - V curves results in a current spread over about two orders of magnitude in the low-field generation current regime. The current versus voltage in this low-field generation regime increases quite moderately with the square root of the voltage. At the onset of either tunneling or avalanche breakdown a much steeper increase of current is observed. The following two fig-

Fig. 9.45 Dark current of a GaInAs homojunction photodiode [9.54] dominated by tunneling breakdown above 15 V

ures of pn-diodes show typical characteristics of either tunneling or avalanche breakdown.

Figure 9.45 shows for a GaInAs homojunction photodiode the typical band-band tunneling behavior for voltages above of 15 V, where the remaining temperature dependence stems from the decreasing bandgap with increasing temperature. Thus, a positive temperature coefficient of the current for fixed voltage is present in the tunneling region. Typical at the onset of tunneling is a pronounced reduction of the temperature sensitivity at the transition from the generation regime below 15 V to the tunneling regime above 15 V.

Figure 9.46 presents the typical reverse current characteristics of a silicon p^+n diode [9.55] dominated by avalanche breakdown above 27 V. Again, in the lower field regime, the I - V characteristics show typical Shockley-Read-Hall generation behavior exhibiting a pronounced temperature sensitivity according to the higher bandgap of silicon (compared to Fig. 9.45) comprising a GaInAs photodiode. The onset of impact ionization is characterized by a much steeper increase of the current versus voltage compared to the tunneling breakdown in Fig. 9.45. Furthermore, the temperature coefficient is reversed compared to the tunneling case before. In the impact ionization regime, a higher voltage is needed for constant current with higher temperature,

due to increasing lattice vibrations which hinder the electrons from being accelerated due to a higher collision rate. Thus, the I - V characteristics exhibit a typical crossing behavior when the generation regime is taken over by impact ionization.

In conclusion, the temperature resolved I - V characteristics can clearly distinguish between generation, tunneling and impact ionization regimes.

9.4.5 Deep Level Characterization and Minority Carrier Lifetime

Deep levels in semiconductors heavily affect the forward and reverse current curves they increase the noise in photodiodes and transistors, reduce the minority carrier lifetime, or quench the storage time in charge-coupled devices or CMOS focal plane arrays. One of the most sensitive methods to determine a comprehensive set of deep level or trap parameters is the **DLTS** (deep level transient spectroscopy) technique.

Definition and Role of Trap Parameters

There is a common basis for the description of donor or acceptor states and the so called deep levels or traps. Donor or acceptor states are situated very closely to the respective band edges in the band diagram (some tens meV), while deep levels or traps have an energy position more or less close to the midgap band energy, i.e. they are located deeper than 200 meV. The equations for deep and shallow level ionization, which are given in Sect. 9.4.2 are valid for dopants as well as for deep levels or traps. The difference between deep levels and traps is mainly attributed to their different interaction rates with both bands. While deep levels often may interact with the conduction and valence bands with comparable probabilities, traps are exchanging their carriers dominantly on with one band. This behavior is reflected by differences in energetic positions: deep levels are close to the midgap energy while traps are located near to one of the bands, but considerably deeper than shallow donors or acceptors. Thus, deep levels often function as recombination centers to extract electrons and holes from the bands under nonequilibrium excitation conditions, while traps capture carriers from one of the bands within a very short time constant (capture time constant in the ns range) and emit these carriers back to the same band after some delay (emission time constant in the ms range). The temporal change of the total charge (ionized dopants and deep levels) in the depletion region of a Schottky diode affects the space charge capaci-

Fig. 9.46 Reverse current of a silicon p^+n diode [9.55], dominated by avalanche breakdown above 27 V

tance, which can be measured versus time to monitor trap recharging processes. This field is called capacitance spectroscopy [9.56], or more detailed DLTS: deep level transient spectroscopy [9.57].

Figure 9.47 shows the principal possibilities for locating traps in the band diagrams of n- and p-type semiconductors. The thick arrows indicate the dominant interaction paths. If a trap is located much closer to the conduction band than to the valence band (see the electron traps in the upper parts of Fig. 9.47), then their electron emission rates e_n (unit: s^{-1}) are considerably larger than their hole emission rates e_p (unit: s^{-1}). This situation reverses for hole traps located near to the valence band. A trap interacting dominantly with the majority (minority) carrier band is called a majority (minority) carrier trap. A trap interacting dominantly with the conduction (valence) band is called an electron (hole) trap.

Traps are characterized by several parameters. The first is the concentration N_T (unit: cm^{-3}), the second is the energetic distance from the corresponding energy band edge $E_c - E_T$ ($E_T - E_v$) (unit: eV). The capture of carriers represented by the capture rates c_n, c_p (unit: s^{-1}) into traps from the bands is normally a very fast process, the time constant of which is in the ns range:

$$c_n = \sigma_n v_{th} n \quad \text{and} \quad c_p = \sigma_p v_{th} p \quad (9.59)$$

with σ_n, σ_p denoting the capture cross sections (unit: cm^2 , for orientation purposes $10^{-15} cm^2$), v_{th} denoting the carrier thermal velocity ($10^7 cm/s$) and n, p the carrier concentrations in the corresponding bands. After the capture process the subsequent emission rate e_n (unit: s^{-1}) is driven exponentially by the trap activation energy $E_c - E_T$ given here for an electron trap

$$e_n = \sigma_n v_{th} N_c g \exp\left(-\frac{E_c - E_T}{k_B T}\right). \quad (9.60)$$

Equation (9.60) is the basis for the Arrhenius plot which allows the extraction of the trap activation energy by plotting $\log(e_n/T^2)$ versus $1000/T$ (Fig. 9.51). The prefactor T^2 stems from the joined temperature behavior of the effective density of states N_c in conjunction with the thermal velocity v_{th} .

The minority carrier lifetime τ_{eff} (s) can be deduced from the generation rate U ($cm^{-3}s^{-1}$) from the trap parameters according to the theory of Shockley, Read, and Hall [9.58, 59].

$$\tau_{eff} = \frac{n_i}{U} \quad (9.61)$$

Fig. 9.47 Energetic location and main interactions of majority carrier traps and minority carrier traps in n- and p-type semiconductors

with n_i denoting the intrinsic carrier concentration of the semiconductor material [9.48] and

$$U = \frac{\sigma_p \sigma_n v_{th} N_T}{\sigma_n \exp\left(\frac{E_{trap}}{k_B T}\right) + \sigma_p \exp\left(-\frac{E_{trap}}{k_B T}\right)} n_i. \quad (9.62)$$

Here, E_{trap} is the trap energy position with respect to the intrinsic energy E_i ($E_i \approx (E_c + E_v)/2$) of the semiconductor. It can be seen from this equation that deep levels near midgap are most effective for generation and recombination because they lead to the largest generation or recombination rates U and thus give the lowest minority carrier lifetime according to (9.61). Thus, it is an important task of semiconductor materials quality assessment to determine the trap parameters N_T , E_T (respectively E_{trap}), σ_n , and σ_p to deduce all further generation and recombination statistics.

The DLTS Technique

The DLTS technique is based upon repetitive pulsing the bias of a Schottky diode or pn-diode from slight forward bias conditions (short pulse, some μs) into deep depletion for a considerably longer time (ms to s) and observe the resulting capacitance transient which stems from the charging and emptying of traps. During these repetitive measurements which also allow averaging of the mostly relatively small capacitance transients, the measurement temperature of the sample is varied over a large range, e.g. from 77 K to 400 K. The development of this temperature dependent capacitance transient which is directly indicative for trap charging and emission is shown in more detail in this section.

Figure 9.48 shows the typical capacitance transient for the emission phase 3 of a majority carrier trap, i. e.

Fig. 9.48 Transient capacitance during majority carrier emission (3) after trap filling phase (2) of a donor-like trap

a donor-like trap which is neutral in the electron occupied or filled state and positively charged in the empty state.

The process starts after phase (1), the empty (positively charged) state of all traps in reverse bias of the sample (not shown in Fig. 9.48, this corresponds to $C(t) \rightarrow \infty$), with a short filling pulse at $t < 0$, which is in the range of some μs . The time period 2 is long enough so that all majority carrier traps capture electrons from the conduction band because in the forward biased filling phase all traps are pulsed below the Fermi energy E_F . The traps are now neutrally filled at the end of phase (2). The emission phase (3) is started by pulsing the sample into deep depletion and the capacitance drops to a minimum $C(t=0) = C_0$. The resulting space charge depth is given by the bias voltage and the depleted donor charge of the shallow doping level. The traps are neutral at the beginning of the emission phase (3) and thus they do not contribute to the depleted space charge. Due to the high reverse bias V_r in phase (3) all traps are pushed above the Fermi energy and they are switched to emission. The capacitance transient $C(t)$ in the emission phase can be calculated with (9.63)

$$C(t) = A \sqrt{\frac{q\epsilon_0\epsilon_r}{2(V_{bi} + V_r)}} \{N_D^+ + N_T [1 - \exp(-e_n t)]\} \quad (9.63)$$

with A denoting the area of the Schottky diode and V_{bi} representing the built-in voltage of the test diode. Towards the end of the emission phase (3) all traps are empty, i.e. after loosing their electrons to the conduction band, the traps now contribute to the space charge of the shallow donors $N_D^{(+)}$ with concentration $N_T^{(+)}$. The transient capacitance thus changes by an amount $\Delta C_{\text{tot}} = C_\infty - C_0$. From the amplitude ΔC_{tot} of this transient, the trap concentration N_T can be deduced. For large trap concentrations and thus large capacitance transients, it may be practical to fit (9.63) with a transient

capacitance measurement to extract the trap concentration. In practice, this direct way is difficult when the trap concentration falls below the shallow doping level by orders of magnitude. The transient will be buried within the noise of the measurement. In 1974 *Lang* published a procedure to detect very small capacitance transients out of the noise even when the trap concentration falls by 4 to 5 orders of magnitude below the shallow doping level: the **DLTS** technique [9.57].

Two aspects are important. First, according to the **DLTS** technique, the biasing sequence between filling (slight forward direction) and emptying (reverse voltage V_r) of the traps is applied repeatedly to the sample, thus averaging of the transient can be reached. Second, due to (9.60), the emission rate covers a very large range of more than 10 orders of magnitude if all possible trap positions between conduction band and midgap are considered. This implies too much problems for standard electronics in covering this large emission time range to measure the capacitance transient with sufficient resolution. Thus, the capacitance transient is observed by sampling within a given time window called the rate window rw . The measurement temperature is scanned such that the maximum of the transient amplitude can be easily observed for any given rate window rw . Figure 9.49 elucidates the principle of Lang's **DLTS** technique. For deep temperatures, the emission process is very slow, thus the capacitance stays practically constant over the observation time window $t_2 - t_1$. For high temperatures, the transient has occurred completely even before the

Fig. 9.49 Construction of a **DLTS** signal $[C(t_1) - C(t_2)]$ by observing the temperature dependent transient capacitance within an observation time window $(t_2 - t_1)$

first sampling time t_1 , thus the observed capacitance difference over $t_2 - t_1$ is again a constant. For a certain intermediate temperature, where the trap emission rate fits the observation time window, a maximum transient will be measured. The DLTS signal $[C(t_1) - C(t_2)]$ (right) is the difference capacitance over the rate window rw , according to $t_2 - t_1$. If a trap is very shallow, i. e. located energetically near to the band edge, quite deep temperatures are needed to obtain the maximum of the DLTS signal.

The sign of the DLTS signal allows to determine the trap type, $\Delta C_{\text{tot}} > 0$: majority trap and $\Delta C_{\text{tot}} < 0$: minority carrier trap. Minority carrier traps in Schottky diodes can be excited by applying pulsed optical illumination (optical DLTS); in pn-diodes a sufficient forward biasing is necessary to inject minority carrier, to be trapped.

A typical DLTS measurement of the Au donor trap in n-type silicon is shown in Fig. 9.50. The shift of the DLTS peak to higher temperatures with increasing rate window can be observed i. e. the emission rate increases with increasing temperature. The trap concentration can be determined from the amplitude of the DLTS signal. For extracting the trap activation energy, the emission rates need to be plotted in an Arrhenius plot over the inverse of the temperature $1000/T$. From the same plot, the capture cross section for $T \rightarrow \infty$ can be extracted by extrapolating the emission rate for $1000/T \rightarrow 0$.

Fig. 9.50 DLTS measurement of the Au trap in n-type silicon doped with $3.5 \times 10^{17} \text{ cm}^{-3}$, reverse pulse: 13.3 V. The rate windows rw are from left to right: 20/s, 50/s, 80/s, 200/s, 400/s, and 1000/s. The depletion capacitance is 100 pF

A corresponding Arrhenius plot of the measurement in Fig. 9.50 is shown in Fig. 9.51. The measurement of the emission rate, deduced from the DLTS signal maxima for the different rate windows is shown in full line, the dashed lines represent comparison data from a trap library to assess the measured Arrhenius data compared to known data for easier identification. The measured activation energy is 340 meV. The dotted line is used for extrapolation of the capture cross section for $1000/T \rightarrow 0$.

The DLTS method cannot identify the physical nature of a trap or a deep level, e.g. if the level originates from a crystal defect or from an impurity. The big advantage of DLTS is its impressive sensitivity of N_T/N_D down to 10^{-6} , unsurpassed by other physical analyses. Trap concentrations as low as $< 10^{10} \text{ cm}^{-3}$ can be detected, this is 13 orders of magnitude below the crystals atomic concentration. Therefore electronic averaging of the sampled small capacitance transients applying boxcar or lock-in techniques are necessary. DLTS delivers fingerprints of deep levels, which should be compared to trap libraries of known defects, concerning activation energy and capture cross section. DLTS is spectroscopic, because traps with different activation energies appear with their maxima at different temperatures. If the spectra of two traps are overlapping,

Fig. 9.51 Arrhenius plot of the DLTS spectrum in Fig. 9.50 for Au in n-type silicon; the measurement is shown as full line, the dashed lines represent comparison data from a trap library to assess the measured Arrhenius data compared to known data for easier identification. The measured activation energy is 340 meV. The dotted line is used for extrapolation of the capture cross section for $1000/T \rightarrow 0$

subtraction methods can be applied by simulating and approximating the DLTS maxima by Gaussian curves with different slopes and subtracting the leading peak from the rest of the spectrum until all traps have been identified.

A lot of extensions of the DLTS technique have been published. One important evaluation is the determination of the temperature dependence of the capture cross section of a deep level [9.60], having in mind that the standard DLTS technique allows only to measure the extrapolated capture cross section for $T \rightarrow \infty$. The method of Partin et al. is based on varying the width of the filling pulse to very short times until the traps cannot capture anymore carriers in the filling phase.

The Surface Recombination Velocity

Mesa diodes and also planar pn-diodes sometimes suffer from additional leakage currents across the surface or perimeter of the sample. Thus analyses of the bulk currents are impeded by surface currents, which are induced by additional surface recombination. The surface recombination is described by the surface recombination velocity S_0 (cm/s). Surface recombination or generation occurs during nonequilibrium conditions, e.g. under reverse bias of a pn-junction. A surface recombination current j_s (A/cm²) is directed perpendicular to the semiconductor surface

$$j_s = -qS_0\Delta n, \quad (9.64)$$

Δn is the deviation of the carriers from the equilibrium value. The surface recombination velocity S_0 can be expressed by surface state parameters, like the capture cross section of the surface state σ_0 (cm²) and the concentration N_{st} (cm⁻²).

$$S_0 = \sigma_0 v_{th} N_{st}. \quad (9.65)$$

To identify whether a measured current of a test sample is dominated by bulk or by surface conduction, a double logarithmic plot of the current versus the diameter of the samples under test is helpful (Fig. 9.52). If the current increases linearly with the diameter, then surface recombination is dominant. If the current increases quadratically with the diameter, bulk conduction is dominant.

Bulk conduction should be proved before current conduction mechanisms or parameters are extracted from I - V measurements, like Schottky barriers, ideality factors, Shockley-Read-Hall trap parameters, or reverse current analyses are done with respect to tunneling or impact ionization.

Fig. 9.52 Measured current of a test diode in double logarithmic plot versus diode diameter

9.4.6 Contact Resistances of Metal-Semiconductor Contacts

Ohmic contacts at semiconductor devices are mandatory to connect the inner active regions to the outside circuitry or other devices. Ideal ohmic contacts may be described by several views of physicists or engineers on the idealization of the tasks of ohmic contacts, i. e. ohmic contacts should provide:

- a bipolar linear I - V characteristics,
- an unlimited high recombination rate for minority carriers,
- negligible voltage decay compared to that of the active regions,
- no minority carrier injection.

Basic work on the description and technology of ohmic contacts to semiconductors can be found in [9.61, 62]. The main current conduction mechanisms in ohmic contacts are elucidated in Fig. 9.53. A metal is evaporated onto an n-type semiconductor. The work function differ-

Fig. 9.53 Band diagram of a highly doped, degenerated metal-semiconductor contact under forward bias conditions (metal is positive with respect to the grounded n-type semiconductor)

ence to the electron affinity of the n-type semiconductor should be well chosen to induce at best either an accumulation region at the semiconductor side or at least a small barrier height Φ_B . This has to be surmounted or penetrated by electrons from the semiconductor, e.g. here under forward biasing conditions. A more or less small barrier is a usual case for a lot of metals to semiconductors. If the barrier cannot be avoided principally, it should be only a small obstacle to be surmounted or penetrated. Three current conduction mechanisms should be mentioned here which help electrons to cross the interface into the metal.

1. Thermal emission: electrons have to surmount the barrier $V_{bi}(\approx \Phi_B)$ which is only possible for a few electrons with enough energy compared to the thermal energy kT . Consequently, thermal emission results into bad ohmic contacts. Mostly, these contacts exhibit rectifying characteristics at room temperature. Thermal emission is favored exponentially at high temperatures (thermal process).
2. Field emission or tunneling: this quantum mechanical process allows electrons, due to their wave-like nature, to penetrate the barrier without energy loss if the barrier width is small compared to the de Broglie wavelength (9.58). This process is likely at very high degenerate doping levels ($\gg 10^{18} \text{ cm}^{-3}$) which induce very narrow space charge regions ($< 10 \text{ nm}$) and consequently very narrow tunneling barrier widths. This process is nearly temperature independent and useful even at very low temperatures because no thermal activation is needed for quantum mechanical tunneling.
3. Thermal field emission or thermally activated tunneling: A certain part of the electrons are thermally activated to penetrate the barrier at an enhanced energy position by tunneling but below the peak of the barrier. Both current conduction mechanisms 1) and 3) contribute in series to the conduction “over” the barrier. Compared to the aforementioned processes the electrons “see” a smaller and narrower barrier. This mechanism is likely for intermediate doping levels.

Figure 9.54 depicts the behavior of the contact resistance of different metals on n-type silicon versus the silicon doping level [9.62]. The contact resistance ($\Omega \text{ cm}^2$) strongly decreases with increasing doping level when thermionic conduction is taken over by tunneling or field emission.

Technically useful contact resistances should be below $10^{-5} \Omega \text{ cm}^2$. Thus, doping levels in excess of

10^{19} cm^{-3} are needed here to guarantee clear predominance of tunneling over thermionic emission. Values of contact resistances lower than $10^{-7} \Omega \text{ cm}^2$ are achievable today.

The more exactly termed specific contact resistance $R_{c,\text{spec.}}$ ($\Omega \text{ cm}^2$) is solely the contact resistance in the interface between metal and semiconductor, while the (total) contact resistance R_c (Ω) comprises additional contributions of the spreading resistance of the semiconductor which is depending on the current field lines and thus on the geometry of the ohmic contact: distinguish contacts with vertical current spreading (e.g. top contacts to lasers or emitter contacts to bipolar transistors) and contacts with lateral current spreading (e.g. base contacts in bipolar transistors or source/drain contacts to field-effect transistors). The latter contact type exhibits a strong inhomogeneous current density over the contact length compared to the former contact type, which has a better homogeneous current distribution over its contact area.

Measurement techniques for contact resistances may be attributed to the aforementioned contact geometry. They should allow to extract the (low) specific contact resistance from the (somewhat higher) total contact resistance to provide information for optimizing the contact resistance, e.g. by annealing procedures.

Measurements on ohmic contacts should be done applying a Kelvin contact configuration which means to feed a constant current via two terminals (needles) to the pads of the contacts to be characterized and using

Fig. 9.54 Contact resistance of various metals on n-type silicon depending on doping N_D (after [9.17])

Fig. 9.55 Lateral contact of width w and of length d on a thin epitaxial layer of thickness h [9.63]

Fig. 9.56 Equivalent circuit diagram of a lateral ohmic contact according to the current distribution in Fig. 9.55 for the contact resistance of a metal on a thin semiconductor layer

two different terminals (needles) to measure the resulting (small) voltage between the contact pads. In this way, distorting effects of additional contact resistances between the measurement needles and the contact pads can be eliminated.

A method for characterizing contact resistances of contacts with nearly homogeneous current flow into vertical contacts uses contact dots of different diameters on

Fig. 9.57 TLM mask for the determination of the sheet resistance R_s and total contact resistance R_c from which the specific contact resistance ρ_c can be extracted (TLM: transmission line model)

the semiconductor, to distinguish between the specific contact resistance and the spreading resistance contributions. This method by *Cox* and *Strack* is described in [9.64].

A more versatile method which is mainly applied to lateral contacts to thin semiconductor layers with strongly inhomogeneous current flow, is the transmission line method by *Berger* [9.63]. Figure 9.55 shows the current distribution in this lateral contact type. The semiconductor layer is assumed with a specific resistance ρ_s ($\Omega \text{ cm}$) and its sheet resistance R_s (Ω/\square): $R_s = \rho_s/h$. For technically relevant contacts, the semiconductor sheet height h is often quite less than the contact length d . For this configuration, the following equivalent circuit can be derived (Fig. 9.56). The resistance of the epitaxial layer is described by the sum of its differential elements dR_1 .

The specific contact resistance $R_{c,\text{spec.}} (= \rho_c)$ is represented by the distributed vertical elements dR_2 . The total contact resistance R_c is the ratio of the voltage at the left beginning of the contact region and the total constant current I fed into the structure. According to the transmission line nature of such a structure [9.63], the specific contact resistance ρ_c may be extracted from the measurement of the total contact resistance R_c . For that purpose differential equations are formulated [9.63] which can be solved giving a relation between total and specific contact resistance in an implicit equation (9.66)

$$R_c = \frac{1}{w} \sqrt{[R_s (\rho_c + 0.2 R_s h^2)]} \times \coth \left(\sqrt{\frac{R_s}{(\rho_c + 0.2 R_s h^2)}} d \right). \quad (9.66)$$

This implicit equation allows the extraction of ρ_c after R_c has been measured and the geometrical constants w , h , and d of the test structure have been determined. The sheet resistance R_s of the epitaxial layer between two contact stripes has also to be measured before.

The measurement of R_s and R_c can be done with a setup of three contact stripes in a Kelvin contact configuration with two distances l_1 and l_2 between two contacts (Fig. 9.57).

Two measurements need to be taken: first, the current I (mA range) is fed through the epitaxial layer stripe of width w by using the two left-hand contacts 1, 2 with distance l_1 and measuring the voltage V_1 ; second, the two contacts 2, 3 with distance l_2 are used to measure the respective voltage V_2 by driving the same amount of current through the epitaxial layer.

From these two voltage values V_1 and V_2 together with the constant current I the sheet resistance R_s and the total contact resistance R_c under each contact can be calculated by

$$R_s = \frac{V_1 - V_2}{l_1 - l_2} \frac{w}{I},$$

and

$$R_c = \frac{1}{2} \left(\frac{V_1}{I} - l_1 \frac{R_s}{w} \right). \quad (9.67)$$

With these two terms now (9.66) can be used to extract the specific contact resistance ρ_c . The contact distances l_1 and l_2 (1–100 μm) need to be determined with high

precision (sub-micron range) because otherwise larger errors would result for ρ_c , especially when ρ_c falls below $10^{-6} \Omega \text{ cm}^2$.

For electrically long contacts (e.g. $d = 40 \mu\text{m}$) the transfer length L_T is defined as $L_T = \sqrt{\rho_c / R_s}$. The transfer length illustrates the typical length for the current to pass from the epitaxial layer into the metal contact. Practical contacts do not need to be designed longer than about three transfer lengths.

The transfer resistance R_T is defined as $R_T = \sqrt{R_s \rho_c}$ ($\Omega \text{ mm}$). The transfer resistance characterizes the lowest contact resistance which can be achieved for an electrically long contact of a given width w . Transfer resistance values for e.g. FETs should be lower than 0.2 $\Omega \text{ mm}$.

9.5 Measurement of Dielectric Materials Properties

Dielectric materials are the building blocks of functional electronic circuits, capacitors, gate dielectrics, transmission lines are essential as electrical insulators for power distribution. Molecular solids, organic polymer resins, ceramic glasses and composites of organic resins with ceramic fillers represent typical dielectrics. The dielectric properties of materials are used to describe electrical energy storage, dissipation and energy transfer. Electrical storage is the result *dielectric polarization*. Dielectric polarization causes charge displacement or rearrangement of molecular dipoles. Electrical energy dissipation or *loss* results from (1) electrical charge transport or *conduction*, (2) *dielectric relaxation*, (3) *resonant transitions* and (4) *nonlinear dielectric* effects. Energy loss is eventually related to scattering, radiation or conversion of electrical energy into thermal energy (Joule heating). Energy transfer is related to propagation of electromagnetic waves in dielectric media, transmission lines and waveguides, where the dielectric permittivity determines the velocity of wave propagation, attenuation and ultimately the dimensions of the devices.

The most relevant physical processes in dielectric materials from the practical viewpoint are those which result in power loss. It is important to understand the basic characteristics of these processes because they determine the optimal approach to measurement.

Interaction of electromagnetic radiation with materials at frequencies of about 10^{12} Hz and above gives rise to quantized transitions between the electronic, vibrational and rotational molecular energy states, which can be observed by using appropriate quantum spectroscopy techniques. By contrast, the dielectric properties are gov-

erned by reorientational motions of molecular dipoles (dipolar relaxation) and motions of electrical charge carriers (electrical conduction), which leads to continuous dielectric dispersion and absorption that is observed in the frequency range of 10^{-6} Hz to 10^{12} Hz.

The dielectric relaxation [9.65] describes the dispersion of real permittivity ϵ' and the occurrence of dielectric absorption ϵ'' . Permittivity measurements allows for the determination of molecular dipole moments and, subsequently, can link the relaxation process with molecular dynamics and structure. The dielectric absorption (loss) spectra as a function frequency and temperature [9.66, 67], can be used to characterize molecular dynamics in dipolar liquids (polar solvents and solutes), rotator-phase crystals, nonpolar and polar polymers (polyethylene, polyacrylates, epoxy resins, polyimides). Research on dielectric relaxation in molecular liquids and solids was pioneered by Fröhlich [9.68], Hill et al. [9.69], Bottcher and Bordewijk [9.70], and for macromolecules by McCrum et al. [9.71], and Runt and Fitzgerald [9.72]. Selected developments in dielectric and related molecular processes were reviewed by Davies [9.73]. Since 1954, the most widely known and comprehensive work on dielectric materials and corresponding measurements has been that of von Hippel [9.74]. Measurement of RF properties of materials were surveyed by Bussey [9.75]. Broadband waveguiding and free-space measurement methodologies for the agriculture industry were developed by Nelson and co-workers [9.76, 77]. Extensive dielectric data were obtained recently for ferroelectric ceramics (barium

titanate), inorganic and organic semiconductors and photoconductors, for ultra thin dielectrics films, which have important applications in solid-state electronic circuits and devices. Recent advances in the theory of dielectric relaxation and the corresponding experimental methodologies were reviewed by *Kremer and Schönhals* [9.78].

9.5.1 Dielectric Permittivity

The interaction of electromagnetic fields with matter is described by Maxwell's equations [9.79]. The polarization \mathbf{P} describes the dielectric displacement \mathbf{D} which originates from the response of the material to an external electric field \mathbf{E}

$$\mathbf{P} = \mathbf{D} - \varepsilon_0 \mathbf{E} = (\varepsilon_r^* \varepsilon_0 - \varepsilon_0) \mathbf{E}, \quad (9.68)$$

where ε_0 is the dielectric permittivity of free space ($\varepsilon_0 = 8.854 \times 10^{-12}$ F/m), and $\varepsilon^* = \varepsilon_0 \varepsilon_r^* = \varepsilon' - i\varepsilon''$ is the complex permittivity tensor, which depends on temperature, frequency, and in the case of anisotropic materials, on the direction of the electric field vector \mathbf{E} . The frequency dependence of the permittivity is illustrated in Fig. 9.58.

Relative permittivity, ε_r^* , is a dimensionless ratio of complex permittivity to the permittivity of free space,

Fig. 9.58 Frequency dependence of the real ε'_r , and imaginary ε''_r parts of the complex permittivity with a single relaxation process at the relaxation frequency f_r

$\varepsilon_r^* = \varepsilon^* / \varepsilon_0 = \varepsilon'_r - i\varepsilon''_r$. The dielectric constant is the real part of the relative permittivity. The symbol used in this document is ε'_r (Other symbols such as $K, k, K', k', \varepsilon_r$ and ε' are symbols used in the technical literature.). Dielectric loss tangent $\tan(\delta)$ is a dimensionless ratio of the dielectric loss to the dielectric constant, $\tan(\delta) = \varepsilon''_r / \varepsilon'_r$. The real part of dielectric permittivity decreases by $\Delta\varepsilon'_r$ at a certain frequency f_r which gives rise to a corresponding peak of the dielectric loss ε''_r . Such frequency dependence of the complex permittivity indicates a *dielectric relaxation*. A dielectric material may exhibit several dielectric relaxation processes, each associated with its characteristic $\Delta\varepsilon'_r$, ε''_r and f_r depending on the molecular mechanism involved.

The dielectric relaxation should not be confused with resonant transitions between vibrational and electronic states and those that originate from a resonant behavior of the electrical measurement circuit.

Dielectric Relaxation

Unlike *electrical conduction* in which charge carriers (electrons, ions and holes) move physically through the material under the influence of an electric field, the *dielectric relaxation* originates from reorientational responses of electric dipoles to the applied electric field. Materials in which the dipoles are induced only by the application of an electric field are nonpolar materials. Polar materials, on the other hand, have permanent molecular dipoles which may exhibit a number of different relaxation processes, each having a characteristic strength measured by $\Delta\varepsilon'_r$, and a characteristic relaxation frequency f_r . In the simplest case with a single relaxation time τ_r the dielectric relaxation function may be described by Debye's model [9.65], shown by (9.69). Here ε'_u is the dielectric constant at high frequencies, which does not contain a permanent dipole contribution ($\varepsilon'_r = \varepsilon'_u$ when $f \gg f_r$, Fig. 9.58).

$$\varepsilon^* / \varepsilon_0 = \varepsilon'_u + \frac{\Delta\varepsilon_r}{1 + i\omega\tau_r}. \quad (9.69)$$

Cooperative distortional polarization, local rotational polarization and interfacial polarization are the most commonly observed relaxation processes. In a composite material, many or all of these processes may be present and give rise to a very complex relaxation behavior, which can be modeled as a superposition of several relaxations. The Havriliak–Negami (HN) relaxation function, defined below, has often been found to provide a good phenomenological description of dielectric relaxation data in molecular liquids, solids and glass

formers [9.80, 81]

$$\varepsilon^*/\varepsilon_0 = \sum_k \left(\varepsilon'_u + \frac{\Delta\varepsilon_r}{[1 + (i\omega\tau_r)^\alpha]^\gamma} \right),$$

$$k = 1, 2, 3 \dots \quad (9.70)$$

The parameters α and γ describe the extent of symmetric (α) and asymmetric (γ) broadening of the complex dielectric function, where α and γ are ($0 < \alpha \leq 1$ and $0 < \alpha\gamma \leq 1$). Equation (9.70) reduces to the well-known Debye expression when $\alpha = \gamma = 1$. While the HN equation is often referred to as an ‘empirical’ relaxation function, recent modeling has linked the parameters α and γ to the degree of intermittency in molecular movement and long-lived spatial fluctuations in local material properties (‘dynamic heterogeneity’) [9.82], which gives some insight into the meaning of the fitted parameters. In this view, the exponent α is related to the temporal intermittency of molecular displacements while γ corresponds to long-lived ‘dynamic heterogeneities’ (or dynamic clusters). It is beyond the scope of this chapter to explain the theory of these processes and the reader is advised to consult references [9.83–86].

Regardless of the particular molecular mechanism of the dielectric relaxation, the phenomenological dependence of ε_r^* on frequency, as shown in Fig. 9.58, can be used as a guide to select an appropriate measurement method, and then be applied to describe and analyze the dielectric properties of most dielectric materials.

According to Fig. 9.58, the frequency spectrum can be divided into several regions, each corresponding to a characteristic dielectric response.

1. At low frequencies, well below f_r , dipoles easily respond and align with the applied alternating E -field without a time lag. The dielectric loss is negligibly small and the polarization as measured by ε'_r can achieve the maximum value, which depends on the statistical distribution of thermally induced molecular orientations and the amplitude of the applied field. At higher fields, polarization saturation may occur, where all the dipoles are aligned. The E -field induced polarization dominates over the thermal effects, giving rise to a *nonlinear dielectric response*.
2. At frequencies close to f_r , the molecular dipoles are too slow to reorient in phase with the alternating electric field. They lag behind and their contribution to ε'_r is smaller than that at low frequencies. This time lag or phase difference between E and P gives rise to the dielectric loss which peaks at f_r .

3. At frequencies above f_r the particular molecular dipoles cannot follow the electric field and do not contribute to ε'_r and ε''_r , and $\varepsilon'_r = \varepsilon'_u$.

It is important to note that the relaxation process always leads to a decrease of ε'_r with increasing frequency. Dipolar relaxation can be adequately described by an electrical equivalent circuit consisting of a capacitance C_s connected in parallel with resistance R_s which is illustrated in Fig. 9.59. Both, C_s and R_s can be experimentally measured and related to the material's dielectric properties ε'_r and ε''_r .

Resonant Transitions

The rapid oscillations of ε'_r shown in Fig. 9.58 at frequencies above f_r indicate a resonance. Similarly to relaxation, the resonance transitions are associated with the dielectric loss peak. However, the distinguished feature of a resonance transition is a singular behavior of ε'_r at the resonant frequency. From the dielectric metrology viewpoint, the most important resonances are the series resonance and the cavity resonance. These transitions are typically observed in the radio-frequency range and at microwave frequencies, respectively.

Series Inductance–Capacitance Circuit Resonance

Every electrical circuit consists of interconnecting leads that introduce finite residual inductance L_R . Therefore, when measuring a capacitance C_s there will be a certain frequency $f_{LC} = 1/(2\pi\sqrt{L_R C_s})$ at which a series resonance occurs. The equivalent electrical circuit for the series resonance consists of C_s in series with L_R . The residual resistance R_R is due to finite conductivity of the interconnects (Fig. 9.59). Since at f_{LC} the energy is concentrated in the magnetic field (or current) of the inductive component L_R rather than in the electric field in C_s , these resonance conditions generally are not used.

Fig. 9.59 Equivalent electrical circuit of a dielectric material

ful in measurement of the dielectric permittivity. The phenomenon is a common source of systematic errors in dielectric metrology unless the inductance is known or introduced purposely [9.87] to determine the capacitance from the resonant frequency. The characteristic feature of the series resonance is a rapid decrease in the measured complex impedance which reaches the value of R_R when the frequency approaches f_{LC} . The drop in the impedance is associated with an abrupt change of phase angle from $-\varphi$ to φ . The C_s value appears very large near f_{LC} when L_R is neglected in the equivalent circuit (Fig. 9.59), and consequently, it can be incorrectly interpreted as an apparent increase in the dielectric constant (Fig. 9.58).

Dielectric Resonance

When the dimensions (l) of the dielectric specimen are comparable with the guided wavelength $\lambda_g = \lambda_0 / \sqrt{\epsilon'_r}$, a superposition of the transmitted and reflected waves leads to a standing wave called cavity or dielectric resonance. At the resonant frequency, the electromagnetic energy is concentrated in the electric field inside the dielectric. Therefore the measurement techniques that are based on the dielectric resonators are the most accurate methods for determining the dielectric permittivity of low loss materials.

Infrared and Optical Transitions

Interaction of electromagnetic radiation with materials at frequencies of about 10^{12} Hz and above gives rise to quantized resonant transitions between the electronic, vibrational and rotational molecular energy states. These transitions are responsible for a singular behavior of the dielectric permittivity and the corresponding absorption, which can be observed by using appropriate quantum spectroscopy techniques. These quantum spectroscopies form a large part of modern chemistry and physics. At optical frequencies the materials dielectric properties are described by complex optical indices, $n^* = \sqrt{\epsilon^*}$, rather than permittivity.

9.5.2 Measurement of Permittivity

Techniques for complex permittivity measurement may be subdivided into two general categories [9.74]:

1. The frequency range over which the dielectric specimen may be treated as lumped parameter components;
2. The high frequency range where the wavelength of the electric field is comparable to the physi-

cal dimensions of the dielectric specimen and, as a consequence, it is often referred as a distributed parameter system.

Dielectric Measurements Using Lumped Parameter Specimens

In the low frequency range, where the wave propagation effects can be neglected, the equivalent complex impedance Z_s of the relaxation circuit shown in Fig. 9.59 can be measured to determine the capacitance C_s and then the material's relative complex permittivity ϵ_r^* .

When a capacitor is filled with a dielectric material (Sect. 9.1.6) the resulting capacitance is C_s and the dielectric permittivity is defined by (9.71)

$$\epsilon_r^*(\omega) = \epsilon'_r(\omega) - i\epsilon''_r(\omega) = C_s(\omega)/C_0, \quad (9.71)$$

where C_0 is the capacitance of the empty cell and ω is the angular frequency ($\omega = 2\pi f$).

If the sinusoidal electric field $E(\omega) = E_0 \exp(i\omega t)$ is applied to C_s then the dielectric permittivity can be determined by measuring the complex impedance Z_s of the circuit.

$$\frac{1}{Z_s(\omega)} = i\omega C_s, \quad (9.72)$$

$$\epsilon_r^*(\omega) = \frac{1}{i\omega Z_s(\omega)C_0}, \quad (9.73)$$

where $J(\omega)$ is the complex current density. Consistent with the electrical equivalent circuit consisting of the real capacitance C'_s in parallel with a resistance R_s the impedance is given by

$$\frac{1}{Z_s(\omega)} = \frac{1}{R_s} + i\omega C'_s \quad (9.74)$$

and the direct expressions for ϵ'_r and ϵ''_r are

$$\epsilon'_r = \frac{C'_s}{C_0}, \quad (9.75)$$

$$\epsilon''_r = \frac{1}{\omega R_s C_0}. \quad (9.76)$$

The capacitance of the empty cell C_0 (cell constant) is typically determined from the specimen geometry or measurements of standard materials with known dielectric permittivity. Commercially available dielectric test fixtures have the cell constant and error correction formulas provided by their manufacturers [9.88, 89].

Impedance Measurement Using a Four-Terminal Method

In the frequency range of up to about 10^8 Hz, a four terminal (4T) impedance analyzer can be employed to

measure complex impedance of the capacitance C_s and then the permittivity can be calculated from expressions (9.74–9.76). The 4T methodology refers to the direct phase sensitive measurement of the sample's current and voltage. Systems combining Fourier correlation analysis with dielectric converters and impedance analysis have recently become commercially available [9.78]. The recently developed dielectric instrumentation incorporates into one device a digital synthesizer-generator, sine wave correlators and phase sensitive detectors, capable of automatic impedance measurements from 10^{-2} to $10^{13} \Omega$. The broad impedance range also allows a wide capacitance measurement range with resolution approaching 10^{-15} F . The instrumentation should be calibrated against appropriate impedance standards using methods and procedures recommended by their manufacturers.

The dielectric samples typically utilize a parallel-plate or cylindrical capacitor geometry [9.74,90] having capacitances of about 10 pF to several hundred pF. The standard measurement procedures [9.90] recommend a three-terminal (3T) cell configuration with a guard electrode (G), which minimizes the effect of the fringing and stray electric fields on the measurements. The optimal method for connecting a 3T cell to a 4T impedance analyzer is shown in Fig. 9.60.

The “High” current on voltage terminals should be connected via coaxial cables directly to the un-guarded electrode ‘H’, while the “Low” current and voltage should be connected to the electrode that is surrounded by the guard electrode. Note that the return current loop of coaxial shields connections ‘S’ should be short and connected to ‘G’ at a single common point. The return current loop is absolutely necessary for accurate impedance measurements, especially above 1 MHz. In a two terminal configuration (2T) without the guard elec-

trode, the connections ‘S’ should be simply grounded together.

The dielectric constant, dielectric loss and the relaxation frequency are temperature dependent. Therefore, it is essential to measure the specimen temperature and to keep it constant (isothermal conditions) during the measurements.

Impedance Measurements Using Coaxial Line Reflectometry

In the 4T configuration the residual inductance L_R of interconnecting cables contributes to the circuit impedance creating conditions for the series resonance at $f_{LC} \approx 1/(2\pi\sqrt{L_R C_s})$, which limits the usable frequency range. Typically, the series resonance occurs above about 30 MHz. Impedance at higher frequencies may be determined from the reflection coefficient using microwave techniques with precision transmission lines. In these techniques the reference plane can be setup right at the specimen section which largely eliminates propagation delay due to L_R . When a dielectric specimen of impedance Z_s terminates a transmission line that has a known characteristic impedance Z_0 and known wave propagation characteristic, the impedance mismatch between the line and the specimen results in reflection of the incoming wave. The relation between Z_s and complex reflection coefficient Γ is given by (9.77) [9.91,92]

$$\Gamma = \frac{Z_s - Z_0}{Z_s + Z_0} \quad (9.77)$$

It follows from (9.77) that when the line is terminated with a *short* ($Z_{\text{short}} = 0$) then $\Gamma = -1$. For an *open* termination ($Z_{\text{open}} = \infty$) $\Gamma = 1$, while in the case of a matched load, when $Z_s = Z_0$, $\Gamma = 0$, which results in no reflection. These three terminations, i.e. *short*, *load* and *open*, are used as calibration standards for setting-up the reference plane and proper measurement conditions of the reflection coefficient at the specimen section.

Many coaxial line configurations are available in the RF and microwave ranges, each designed for a specific purpose and application. The frequency range is limited by the excitation of the first circular waveguide propagation mode in the coaxial structure [9.91]. Decreasing the diameter of the outer and inner conductors increases the highest usable frequency. The following is a brief review of coaxial line configurations, having Z_0 of 50 Ω , most commonly used for microwave testing and measurements [9.93].

Precision APC-7 mm Configuration

The APC-7 (Amphenol Precision Connector-7 mm) utilizes air as a dielectric medium between the inner and outer conductors. It offers the lowest reflection coefficient and most repeatable measurement from DC to 18 GHz, and is the preferred configuration for the most demanding applications, notably metrology and calibration. The diameter of the inner conductor $d = 3.02$ mm and the diameter of the outer conductor $D = 7.00$ mm (Fig. 9.61) determines the characteristic impedance value of 50Ω [9.91].

Precision APC-3.5 mm Configuration

The 3.5 mm configuration also utilizes air as a dielectric medium between the inner and outer conductors. It is mode free up to 34 GHz.

Precision-2.4 mm Configuration

The 2.4 mm coaxial configuration was developed by Hewlett Packard and Amphenol for use up to 50 GHz. It can mate with the APC 3.5 mm connector through appropriate adapters. The 2.4 mm coaxial line is offered in three quality grades: general purpose, instrument, and metrology. The general purpose grade is intended for economy use on components and cables. Instrument grade is best suited for measurement applications where repeatability and long life are primary considerations. Metrology grade is best suited for calibration applications where the highest performance and repeatability are required.

1.85 mm Coaxial Configuration

The 1.85 mm configuration was developed in the mid-1980s by Hewlett Packard, now Agilent Technologies, for mode-free performance to about 65 GHz. HP of-

fered their design to the public domain in 1988 to encourage standardization of this connector types. Nevertheless, few devices and instrumentation are available today from various manufacturers, mostly for research work. The 1.85 mm connector mates with the 2.4 mm connector.

1.0 mm Coaxial Configuration

Designed to support transmission all the way up to 110 GHz, approaching optical frequencies. This 1.0 mm coaxial configuration, including the matching adapters and connectors, is a significant achievement in precision microwave component manufacturing.

There is a large family of coaxial test fixtures designed for dielectric measurements. *Open-ended coaxial test fixtures* (Fig. 9.61a) are widely used for characterizing thick solid materials and liquids [9.94], and are commercially available (Agilent, Novocontrol Dielectric Probes) [9.95]. The measurements are conveniently performed by contacting one flat surface of the specimen or by immersing the probe in the liquid sample.

Short-terminated probes (Fig. 9.61b) are better suited for thin film specimens. Dielectric materials of precisely known permittivity (air, water) are often used as a reference for correcting systematic errors in measuring Γ that are due to differences between the measurement and the calibration configurations. If the relaxation circuit satisfies the lumped parameters, then ϵ'_r and ϵ''_r can be obtained by combining (9.73) and (9.77) [9.96]:

$$\epsilon'_r = \frac{-2 |\Gamma| \sin \phi}{\omega Z_0 C_0 (1 + 2 \Gamma \cos \phi + |\Gamma|^2)}, \quad (9.78)$$

$$\tan \delta = \frac{\epsilon''_r}{\epsilon'_r} = \frac{1 - |\Gamma|^2}{-2 |\Gamma| \sin \phi}. \quad (9.79)$$

In practice, the conventional lumped parameter formulas (9.78, 9.79) and the corresponding test procedures are accurate up to a frequency at which the impedance of the specimen decreases to about one tenth (0.1) of the characteristic impedance of the coaxial line. Since the standard characteristic impedance of coaxial configuration listed above is 50Ω , the lowest usable impedance value of lumped-parameter circuits is about 5Ω , hence, $f_{\max} \approx 1/(10\pi C'_s)$ [9.97]. Depending on the specimen permittivity and thickness, this upper frequency limit in the APC-7 configuration is typically below 5 GHz. At frequencies $f > f_{\max}$, wave propagation causes a spatial distribution of the electric field inside the specimen section which can no longer be treated as a lumped capacitance and has to be analyzed as a microwave network.

Fig. 9.61 (a) Open-ended, (b) and short terminated coaxial test fixture

Dielectric Measurements Using Microwave Network Analysis

Microwave network analyzer terminology describes measurements of the incident, reflected, and transmitted electromagnetic waves. The reflected wave is measured at the Port 1, and the transmitted wave is measured at Port 2 (Fig. 9.62).

If the amplitude and phase of these waves are known, then it is possible to quantify the reflection and transmission characteristics of a material under test (MUT) with its dielectric permittivity and the dimensions of the test fixture. The reflection and transmission parameters can be expressed as vector (magnitude and phase), scalar (magnitude only), or phase-only quantities. In this notation, impedance and reflection coefficient are vectors. Network characterization at low frequencies is usually based on measurement of complex voltage and current at the input or output ports (terminals) of a device. Since it is difficult to measure total current or voltage at high frequencies, complex scattering parameters, S_{11} , S_{12} , S_{21} and S_{22} are generally measured instead [9.98, 99]. Measurements relative to the incident wave allow to normalize and quantify the reflection and transmission measurements to obtain values that are independent of both, absolute power and variations in source power versus frequency. The scattering parameters (S -parameters) are defined by (9.80) [9.99]

$$\begin{aligned} b_1 &= S_{11}a_1 + S_{12}a_2, \\ b_2 &= S_{21}a_1 + S_{22}a_2. \end{aligned} \quad (9.80)$$

A general signal flow graph of a two-port network with the corresponding scattering parameters is shown in Fig. 9.63a. Here a_1 and a_2 are the complex amplitudes of the waves entering the network, while b_1 and

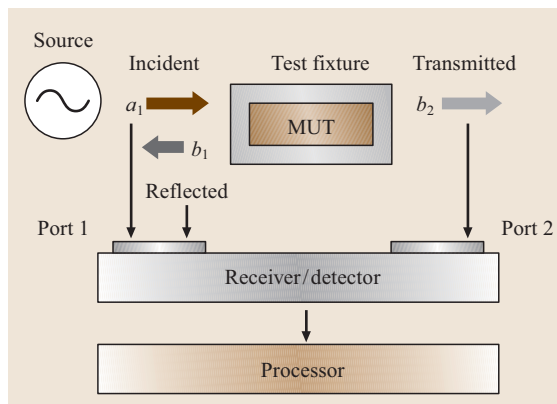

Fig. 9.62 Block diagram of a network analyzer

Fig. 9.63a–d Scattering parameters signal flow diagrams: (a) two-port network, (b) load termination, (c) shunt admittance, (d) transmission line partially filled with a dielectric slab

b_2 are complex amplitudes of the outgoing waves. Figure 9.63b shows a termination or load having reflection coefficient Γ . Since there is no transmitted wave to Port 2, $b_2 = 0$, $\Gamma = b_1/a_1 = S_{11}$.

The number of S -parameters for a given device is equal to the square of the number of ports. For example, a two-Port device has four S -parameters. The numbering convention for S -parameters is that the first number following the S is the Port at which energy emerges, and the second number is the port at which energy enters. So S_{21} is a measure of power emerging from port 2 as a result of applying an RF stimulus to Port 1. When the numbers are the same (e.g. S_{11} , S_{22}), it indicates a reflection measurement. The measured S -parameters of multiple devices can be cascaded to predict performance of more complex networks. Figure 9.63c is a shunt discontinuity, such as the junction of two lines or impedance mismatch where $S_{11} = S_{22} = \Gamma$, while $S_{12} = S_{21} = 1 + \Gamma$. Figure 9.63d shows the flow diagram for a transmission line, which is partially filled with a dielectric material of finite length l [9.100]. This network has a practical application in the dielectric measurements using the reflection-transmission method described in the next chapter.

Two-Port Transmission–Reflection Method

A dielectric specimen partially filling a coaxial air-line (Fig. 9.64) causes impedance mismatch and multiple wave reflections, which can be modeled as a two port network.

The scattering parameters S_{11} and S_{21} at the reference planes A and B for a specimen having the dielectric

Fig. 9.64 Test fixture for dielectric measurement using the reflection-transmission method

permittivity ϵ_r^* can be obtained from the flow graph shown in Fig. 9.63d [9.100, 101]

$$S_{11}(\omega) = \frac{(1 - \tau^2)\Gamma}{1 - \tau^2\Gamma^2}, \quad (9.81)$$

$$S_{21}(\omega) = \frac{(1 - \Gamma^2)\tau}{1 - \tau^2\Gamma^2}, \quad (9.82)$$

$$\Gamma = \frac{Z_s - Z_0}{Z_s + Z_0} = \frac{1 - \sqrt{\epsilon_r^*}}{1 + \sqrt{\epsilon_r^*}}, \quad (9.83)$$

where Γ is the complex reflection coefficient for non-magnetic media, τ is the transmission coefficient

$$\tau = e^{-i\gamma l} \quad (9.84)$$

and γ is the propagation constant, $\gamma = i\omega/c\sqrt{\epsilon_r^*}$.

Using an APC-7 beadless coaxial air line as a sample holder with $d = 3.02$ mm and $D = 7.0$ mm, the dielectric permittivity can be measured up to 18 GHz [9.102].

The dielectric specimen for the transmission-reflection method described above must be machined precisely to fit dimensions of the inner (a) and outer (b) conductors of the coaxial line [9.103].

One-Port Reflection Method

Another important application of network analysis to the high frequency dielectric metrology is the measurement of dielectric permittivity of thin films in a short-terminated coaxial test fixture (Fig. 9.61b).

The scattering parameter of the test specimen treated as a transmission line with capacitance is given by (9.85), while the corresponding expression for impedance is given by (9.86) [9.104, 105]

$$S_{11}(\omega) = \frac{\Gamma + \tau}{1 + \Gamma\tau}, \quad (9.85)$$

$$Z_s = \frac{x \cot(x)}{i\omega C_s} + i\omega L_s, \quad (9.86)$$

where x is the wave propagation parameter

$$x = \omega l \sqrt{\epsilon_r^*}/2c, \quad (9.87)$$

$$L_s = 1.27 \times 10^{-7} \text{ (H/m)} \times d \text{ (m)} \quad (9.88)$$

$$\epsilon_r^* = \frac{x \cot(x)}{i\omega C_0 [Z_0(1 + S_{11})/(1 - S_{11}) - i\omega L_s]}. \quad (9.89)$$

Equations (9.87) and (9.88) have been validated numerically and experimentally up to the first cavity resonance

$$f_{\text{cav}} = \frac{c}{l \text{Re}(\sqrt{\epsilon_r^*})} \approx 121 / [\sqrt{\epsilon_r} \text{ (GHz)}], \quad (9.90)$$

where Re indicates the real part of the square root of complex permittivity and $l = 2.47$ mm, which is the propagation length for the APC-7 test fixture presented in Fig. 9.61b [9.105]. For example, in the case where a specimen has a dielectric constant of 100, f_{cav} is about 12 GHz.

Resonant Cavity Methods

Resonant measurement methods are the most accurate in determining the dielectric permittivity. In order to excite a resonance the materials must have a low dielectric loss ($\epsilon_r'' < 10^{-3}$). The measurements are usually limited to the microwave frequency range. A fairly simple and commonly used resonant method for measurement of microwave permittivity is the resonant cavity perturbation method [9.106]. Figure 9.65 illustrates a cavity test fixture which is a short section of rectangular waveguide. Conducting plates bolted or soldered to the end flanges convert the waveguide into a resonant box. A small iris hole in each end plate feeds microwave energy into and out of the cavity. Clearance holes centered in opposite walls are provided for a dielectric specimen, which

Fig. 9.65a,b Scattering parameter $|S_{21}|$ measured for (a) an empty test fixture and (b) for test fixture with a specimen inserted

is placed into region of maximum electric field. The measurement frequency is limited to few values corresponding to the fundamental mode and few higher order modes. Typically standard rectangular waveguide for the X-band [9.102] is used as a test fixture that covers the frequency range from 8 GHz to 12 GHz. The test specimen may have the shape of a cylindrical rod, sphere or a rectangular bar [9.106].

The test fixture is connected to a network analyzer (Fig. 9.62) by using appropriate adapters and cables. The resonance is indicated by a sharp increase in the magnitude of the $|S_{21}|$ parameter, with a peak value at the resonant frequency. When the dielectric specimen is inserted to the empty (air filled) cavity the resonant frequency decreases from f_c to f_s while the bandwidth Δf at half power, i. e. 3 dB below the $|S_{21}|$ peak, increases from Δf_c to Δf_s (see illustration in Fig. 9.65). A shift in resonant frequency is related to the specimen dielectric constant, while the larger bandwidth corresponds to a smaller quality factor Q , due to dielectric loss. The cavity perturbation method involves measurement of f_c , Δf_c , f_s , Δf_s , and volume of the empty cavity V_c and the specimen volume V_s .

The quality factor for the empty cavity and for the cavity filled with the specimen is given by expression (9.91)

$$Q_c = f_c / \Delta f_c, \quad Q_s = f_s / \Delta f_s. \quad (9.91)$$

The real and imaginary parts of the dielectric constant are given by (9.92) and (9.93), respectively

$$\epsilon'_r = \frac{V_c(f_c - f_s)}{2V_s f_s}, \quad (9.92)$$

$$\epsilon''_r = \frac{V_c}{4V_s} \left(\frac{1}{Q_s} - \frac{1}{Q_c} \right). \quad (9.93)$$

The resonant cavity perturbation method described above requires that the specimen volume be small compared to the volume of the whole cavity ($V_s < 0.1 V_c$), which can lead to decreasing accuracy. Also, the specimen must be positioned symmetrically in the region of maximum electric field. However, compared to other resonant test methods, the resonant cavity perturbation method has several advantages such as overall good accuracy, simple calculations and test specimens that are easy to shape. Moreover, circular rods, rectangular bars or spheres are the basic designs that have been widely used in manufacturing ceramics, ferrites and organic insulating materials for application in the microwave communication and electric power distribution.

There is a large number of other resonant techniques described in the technical and standard literature, each

having a niche in the specific frequency band, field behavior and loss characteristic of materials. Some of these are briefly described below:

Sheet low loss materials can be measured at X-band frequencies by using a split cavity resonator [9.107]. The material is placed between the two sections of the splitable resonator. When the resonant mode is excited the electric field is oriented parallel to the sample plane.

The split-post dielectric resonator technique [9.108] is also suitable for sheet materials. The system is excited in the transfer electromagnetic azimuthal mode. A useful feature of this type of resonant cavity is the ability to operate at lower frequencies without the necessity of using use large specimens.

Parallel-plate resonators [9.109] with conducting surfaces allow measurements at lower frequencies since the guided wavelength λ_g inside the dielectric is smaller than in the air-filled cavities by a factor of approximately $\sqrt{\epsilon'_r}$. The full-sheet resonance technique [9.110] is commonly used to determine the permittivity of copper clad laminates for printed circuit boards.

9.5.3 Uncertainty Considerations

With increasing frequency, the complexity of the dielectric measurement increases considerably. Several uncertainty factors such as instrumentation, dimensional uncertainty of the test specimen geometry, roughness and conductivity of the conduction surfaces contribute to the combined uncertainty of the measurements. The complexity of modeling these factors is considerably higher within the frequency range of the LC resonance. Adequate analysis can be performed, however, by using the partial derivative technique [9.111] and considering the instrumentation and the dimensional errors. Typically, the standard uncertainty of S_{11} can be assumed to be within the manufacturer's specification for the network analyzer, about ± 0.005 dB for the magnitude and $\pm 0.5^\circ$ for the phase. The combined relative standard uncertainty in geometrical capacitance measurements is typically smaller than 5%, where the largest contributing factor is the uncertainty in the film thickness measurements. Equation (9.88), for example, allows evaluation of systematic uncertainty due to residual inductance. It has been validated empirically for specimens $8 \mu\text{m}$ to $300 \mu\text{m}$ thick for measurements in the frequency range of 100 MHz to 12 GHz. These are reproducible with relative combined uncertainty in ϵ'_r and ϵ''_r of better than 8% for specimens having $\epsilon'_r < 80$ and thickness $d < 300 \mu\text{m}$. The resolution in the dielectric loss tangent measurements is < 0.005 . Additional limitations may

arise from the systematic uncertainty of the particular instrumentation, calibration standards and the dimensional imperfections of the implemented test fixture. Furthermore, the results of impedance measurements may not be reliable at frequencies, where $|Z|$ decreases below 0.05Ω .

9.5.4 Conclusion

In summary, one technique alone is typically not sufficient to characterize dielectric materials over the entire frequency and temperature range of interest. The broadband one-port reflection method (9.86–9.89) is most suitable for thin high dielectric constant films that are of

interest to electronics, bio- and nano-technologies. For bulk anisotropic dielectrics, the two-port transmission reflection method (9.81–9.84) is best. These materials must be machined to a toroidal shape to precisely fit the test coaxial test fixture. The resonant cavity method (9.91–9.93) is best for evaluating low-loss solid dielectric materials having the standard shapes used in manufacturing ceramics, ferrites, and organic insulating materials for application in microwave communication and electric power distribution. It is very important to use proper method for a given situation. Therefore measurements of dielectric substrates, films, circuit board materials, ceramics or ferrites always present a metrological challenge.

Magnetic Properties

10. Magnetic Properties

Magnetic materials are one of the most prominent classes of functional materials, as introduced in Chap. 3. They are mostly inorganic, metallic or ceramic in nature and typically multicomponent when used in applications (e.g. alloys or inter-metallic phases). Their structure can be amorphous or crystalline with grain sizes ranging from a few nanometers (as in high-end nanocrystalline soft magnetic materials) to centimeters (as in grain-oriented transformer steels). They are available as powders, cast, sintered or composite materials, ribbons or even thin films and find a huge variety of applications in transformers, motors, generators, medical system sensors, and microelectronic devices.

The aim of this chapter is to give advice as to which methods are most applicable to determine the characteristic magnetic properties of any of the materials mentioned above. Magnetic thin-film structures have recently gained significant scientific and economic importance. Not only can their properties deviate from the respective bulk materials but novel phenomena can also occur, such as giant and tunnel magneto-resistance, which lead to their application in read heads and their likely future application to nonvolatile magnetic solid-state memory (MRAM). Therefore, we have added a section that explains the important peculiarities special to thin films, in which we summarize the most relevant measurement techniques.

Section 10.1 will give a short overview to enable the reader to differentiate between the various manifestations of magnetism, different materials and their related properties. For a deeper understanding, of course, textbooks should be used (see the references given in Sect. 10.2). Section 10.2 covers the standard measurement techniques for soft and hard magnetic materials. The tables at the beginning of Sect. 10.2.1 are a valuable guide to choose the best technique for any given property to be measured. It is anticipated that this chapter will cover the

overwhelming needs for a routine characterization of soft and hard magnetic materials in their various forms. Section 10.3 introduces an elegant, novel and extremely fast technique, the so-called pulse field magnetometer, to measure the hysteresis loop of hard magnetic materials and thereby to determine the remanent magnetization, the anisotropy field and coercivity, respectively. This method has been developed only recently and is not yet comprehensively covered in textbooks. It is therefore described in more detail with a critical discussion of possible measurement errors and calibration requirements. Finally, as mentioned above, Sect. 10.4 addresses features peculiar to magnetic thin films and recommends techniques for their magnetic characterization. It comprises an overview of magneto-resistive effects occurring in magnetic thin films or multilayers where the electrical resistivity depends on external magnetic fields. These devices find important applications as read heads in hard-disc drives and as sensors in the automotive and automation industries. The standard measurement to determine the field response (change in resistance within a given field range) is simply a resistivity measurement, as described in Chap. 9, except that it needs to be done in an external magnetic field. These electrical techniques are therefore not covered in this chapter.

In bulk and thin-film ferromagnets properties such as remanent magnetization and coercivity often depend on the time scale used in the measurement (Sects. 10.1.6, 10.3.3). Time-dependent measurements needed, e.g., to predict the stability of the material in applications are not explicitly described in this chapter since, in principle, any sensitive magnetometer can be used for these measurements. In research, sophisticated methods are used to resolve magnetization dynamics on pico- or even femtosecond time scales. A detailed description of these more specialized methods is beyond the scope of this handbook.

10.1 Magnetic Materials

Empirically, materials are classified according to their response to an applied magnetic field, i. e. the magnetization induced by the external field. A more fundamental understanding results from considering the microscopic mechanisms that determine the behavior of materials in the magnetic field.

10.1.1 Diamagnetism, Paramagnetism, and Ferromagnetism

Diamagnetism is a property of all materials. It results from an additional orbital angular momentum of electrons induced in a magnetic field. In analogy to the induction of eddy currents in a conductor it manifests itself as a magnetization oriented in the opposite direction to the external field; by definition this is equivalent to a negative susceptibility (definitions are given below).

Paramagnetism means a positive magnetic susceptibility, i. e. the induced magnetization is along the direction of the external magnetic field. It is observed in materials which contain atoms with nonzero angular momentum, e.g. transition metals. The susceptibility scales with $1/T$ (Curie's law). Paramagnetism is also found in certain metals (e.g. aluminum) as a consequence of the spin of conduction electrons (Pauli

spin susceptibility). The related susceptibility is essentially independent of temperature. The paramagnetic susceptibility is generally several orders of magnitude larger than the diamagnetic component; therefore, diamagnetism is not observable in the presence of paramagnetism.

Ferromagnetism describes the fact that certain solid materials exhibit a *spontaneous magnetization*, M_S , even in the absence of an external magnetic field. It is a collective phenomenon resulting from the spontaneous ordering of the atomic magnetic moments due to the *exchange interaction* among the electron spins. It is observed in a few transition metals (e.g. 3d, 4f) where itinerant electrons play the essential role for the exchange coupling mechanism, but also in their oxides, halides etc., where the exchange interaction is mediated by localized electrons of oxygen, sulfur etc. atoms located between neighboring metal atoms (*indirect exchange*, *superexchange*).

Many ferromagnetic objects do not show a net magnetization without an external magnetic field. This is a consequence of magnetic domains, which are formed to reduce the energy connected with the dipolar fields (the stray field and demagnetizing field). When an external magnetic field is applied domains gradually vanish due to the motion of domain walls and rotation of the magnetization inside the domains. These processes are

partly reversible and irreversible. In sufficiently high fields *technical saturation* is achieved. The corresponding *saturation magnetization*, however, must not be mistaken for the *spontaneous magnetization*. The reason is that, at any temperature $T > 0$, an external field will increase the magnetization above the spontaneous value inside the domains (i.e. M_S at $H = 0$) by suppression of spin waves (the *para-process*). Hence, the experimental determination of the spontaneous magnetization in general requires a specific extrapolation of high-field data to zero field.

Spin-wave excitations are the reason for the decrease of the spontaneous magnetization with increasing temperature, which in general follows Bloch's law, i.e. the decrease of the spontaneous magnetization from its ground-state value at $T = 0$ is proportional to $T^{3/2}$. The phase transition from long-range ferromagnetic order to the paramagnetic state at a critical temperature (the *Curie temperature*, T_C) is governed by power laws for the spontaneous magnetization, $M_S = A(1 - T/T_C)^\beta$, for the magnetic susceptibility, $\chi = \chi_0(1 - T/T_C)^{-\gamma}$ and for other quantities. The *critical exponents* (β and γ) are of universal character and depend only on the dimensionality of the sample in real space (e.g. 3D for a bulk material, or 2D for ultrathin films) and in spin space (e.g. 3D if all orientations of the magnetization are allowed, 2D if the magnetization vector is confined to a plane, and 1D in the case of extremely strong uniaxial anisotropy).

In general, the magnetization of a ferromagnetic object is preferentially oriented along certain axes that correspond to an *energy minimum*, which are known as *easy axes* of magnetization. The directions of the respective *energy maxima* are called *hard axes* or *hard directions*. This property, *magnetic anisotropy*, is the key to many technical applications of ferromagnetic materials; e.g. a binary memory element requires a *uniaxial anisotropy* characterized by two stable states. The strength of the anisotropy is expressed by anisotropy constants K_i ; it can be measured by the external field required to rotate the magnetization from an easy direction to a hard one. Materials with small/large anisotropy constants are called *magnetically soft/hard*.

Two interactions are responsible for magnetic anisotropies: *dipolar interactions* between atomic moments are directly connected with the shape of a given ferromagnetic body (*shape anisotropy*), while *spin-orbit interaction* is the origin of all other anisotropies: magneto-crystalline, magneto-elastic, surface/interface anisotropies, which are intimately related to the local symmetry of the atomic configuration.

10.1.2 Antiferromagnetism and Ferrimagnetism

In certain materials atomic moments are strictly ordered without showing any resulting magnetization. This happens if neighboring spins are antiparallel to each other due to a *negative exchange interaction*; this phenomenon is called *antiferromagnetism* and is mainly found in transition-metal oxides, halides etc. (MnO , CoO , NiO , $\alpha - \text{Fe}_2\text{O}_3$ etc.), but also in metal alloys such as FeMn or IrMn . Antiferromagnetism vanishes above a critical temperature called the Néel temperature. Due to their zero net magnetic moment, antiferromagnets are hardly affected by external fields. This has recently led to technical applications in so-called *spin-valves* where the antiferromagnet pins the magnetization of an adjacent ferromagnetic layer.

A special form of antiferromagnetism is observed in metallic chromium: the local magnetization varies sinusoidally along certain lattice directions. This is called a *spin-density wave* and is not always commensurate with the crystal lattice.

Ferrimagnetism is a more general version of antiferromagnetism: neighboring moments are antiparallel but of different sizes, resulting in a finite net magnetization. It is found in compounds of 3d transition metals and rare-earth elements (e.g. ferrites, garnets, amorphous 3d–4f alloys and multilayers).

Other forms of magnetic order are found mainly in rare-earth compounds: magnetic moments can form helical structures (*helimagnetism*) and even more complex structures. These result from competing exchange interactions and very strong magnetic anisotropies.

Competing ferromagnetic and antiferromagnetic coupling between neighboring moments in a crystalline lattice or purely antiferromagnetic interactions on a triangular lattice can lead to *frustration*; this means that the individual spins cannot follow the exchange coupling to all neighbors simultaneously. The consequence is a spin configuration similar to a *frozen paramagnet* called a *spin-glass* state. It manifests itself by thermal hysteresis below the freezing temperature and pronounced relaxation effects, indicating the presence of highly degenerate states. Typical materials showing such behavior are dilute alloys of 3d metals (Mn , Fe , Co) in a nonmagnetic matrix (Au , Cu).

10.1.3 Intrinsic and Extrinsic Properties

Intrinsic magnetic properties are those characteristic of a given material (e.g. spontaneous magnetization,

magneto-crystalline anisotropy constant etc.), while extrinsic properties are strongly affected by the specific shape and size of the magnetic object as well as by their microstructure. The most important example is the *magnetic shape anisotropy* caused by the dipolar energy via the demagnetizing field: for a three-dimensional ferromagnetic object characteristic quantities such as the remanent magnetization and saturation field are mainly determined by the shape and much less by the intrinsic magnetic anisotropy.

Another *extrinsic* effect is the role of mechanical strain in a specimen; this may be introduced during the production process. Stress and strain may significantly alter the shape of the magnetization loop via magnetostrictive effects.

10.1.4 Bulk Soft and Hard Materials

The *magnetic softness* or *magnetic hardness* of a material is a key factor for many applications. For instance, *magnetically soft* materials are needed for transformers, motors and sensors, i. e. where the magnetization should fully align with even very small external magnetic fields. This requires very low coercivity and the highest possible susceptibility (or permeability), which is equivalent to weak anisotropy and large magnetization. Also, very low magnetostriction is needed to prevent mechanical strain from building up magneto-elastic anisotropies. As an example, in some specific binary or ternary alloys of 3d metals the magneto-crystalline anisotropy can be very close to zero, making them magnetically very soft. In particular, $\text{Ni}_{81}\text{Fe}_{19}$ ('Permalloy') has nearly zero magneto-crystalline anisotropy and nearly zero magnetostriction. A large number of special alloys of Fe, Co and Ni with the addition of Cr, Mn, Mo, Si and other elements have been developed that allow for a compromise between high permeability (e.g. 78 Permalloy = $\text{Fe}_{21.2}\text{Ni}_{78.5}\text{Mn}_{0.3}$, Supermalloy = $\text{Fe}_{15.7}\text{Ni}_{79}\text{Mn}_{0.3}\text{Mo}_5$, Mu metal = $\text{Fe}_{18}\text{Ni}_{75}\text{Cr}_2\text{Cu}_5$) and high magnetization (e.g. Permen-dur = $\text{Fe}_{49.7}\text{Co}_{50}\text{Mn}_{0.3}$). For all these alloys proper heat treatment is essential for optimum soft magnetic properties.

For high-frequency applications soft magnetic ferrites still play an important role.

Magnetically hard materials, in turn, are needed for permanent magnets, magnetic information-storage media (memories) and other applications. They should possess strong anisotropies and large coercivity so their magnetic state cannot be easily altered by external magnetic fields. Besides high coercivity and large re-

manent magnetization their maximum energy product $(BH)_{\max}$ is a key quantity. While alloys of 3d metals with aluminum dominated the market until 1975 (e.g. Alnico V = $\text{Al}_8\text{Ni}_{14}\text{Co}_{24}\text{Fe}_{51}\text{Cu}_3$) they have gradually been replaced by materials based on intermetallic rare-earth cobalt compounds [e.g. SmCo_5 , $\text{Sm}_2(\text{Co}, \text{Fe})_{17}$] and more recently by $\text{Nd}_2\text{Fe}_{14}\text{B}_1$, which does not contain relatively expensive cobalt. The magnetic properties of these materials critically depend on the metallurgical production process, which affects the granular structure needed for high coercivity and large energy product; the latter has increased by more than an order of magnitude since the development of rare-earth-containing permanent magnets. For less-demanding applications ferrite magnets are still in use.

For magnetic recording media (mainly hard-disk drives) somewhat different requirements have to be met. Here alloys of the type CoCrPt in the form of thin films are mainly used today.

10.1.5 Magnetic Thin Films

For several reasons ferromagnetic thin films constitute a special class of magnetic materials:

1. the reduced dimensionality of a thin film makes the axis perpendicular to the film plane a natural symmetry axis, which gives rise to specific magnetic anisotropies, e.g. the so-called shape anisotropy with an easy plane and a perpendicular hard axis;
2. the reduced dimensionality also causes modifications of fundamental magnetic properties such as the saturation magnetization, its temperature dependence, the Curie temperature and others. These *size effects* become more pronounced with decreasing film thickness;
3. magnetic properties at surfaces and interfaces are generally different from the corresponding bulk properties. These *surface effects* become more influential with decreasing film thickness and may even become dominant for *ultrathin* films, i. e. films of only a few atomic layers. Indeed, new materials with a combination of properties that does not occur in nature can be created in this way, e.g. multilayers or superlattices of a ferromagnetic and a nonmagnetic component;
4. certain magneto-transport phenomena such as the *giant magneto-resistance* (GMR) or *tunnel magneto-resistance* (TMR) effects can best be observed and exploited in very thin films. As these effects find more practical applications (e.g. in hard-disk read

heads) thin and ultrathin magnetic films receive increasing attention.

The growing interest in magnetic films and their technical application naturally increases the demand for methods and instruments to characterize their magnetic properties as completely as possible. Established instruments suitable for the study of bulk magnetic materials are of limited value because of the high sensitivity required for measurements of the small material quantities typical for thin films. Suitable methods will be described in Sect. 10.4.

10.1.6 Time-Dependent Changes in Magnetic Properties

Ferromagnetic materials frequently show a continuous change of their macroscopic magnetization in the course of time even in a constant or zero applied magnetic field. This is usually termed the *magnetic aftereffect* or *magnetic viscosity* and may occur on a time scale of seconds, minutes or even thousands of years. The underlying physical reason is that a ferromagnetic object with a net magnetic moment in the absence of an external magnetic field is generally in a thermodynamically metastable state. This is indicated by the presence of hysteresis. The equilibrium state will be asymptotically approached by domain nucleation and wall motion. Domain-wall motion is a relatively slow process due to the effective mass or inertia that can be attributed to a magnetic wall; since it is thermally activated it, also depends strongly on temperature. For the same reason the coercivity of a sample depends on the measurement time if magnetization reversal occurs via domain walls. This needs to be taken into account when comparing data obtained by quasistatic measurements with those extracted from high-speed measurements (Sect. 10.3.3).

In the absence of domains walls and for a uniformly magnetized sample the magnetization responds to the torque exerted by an external magnetic field by a precession of the magnetization vector around the effective field, which is well described by the Landau–Lifschitz–Gilbert equation. As a consequence, in these cases the maximum rate of change of the magnetization is limited by the precession frequency of the magnetization vector, which for common materials like Fe, Co, Ni and their alloys is between 1 GHz and 20 GHz in moderate applied magnetic fields. It is evident that magnetization dynamics on a timescale of nanoseconds and below is relevant for magnetic devices in high-frequency applications.

10.1.7 Definition of Magnetic Properties and Respective Measurement Methods

The most important magnetic quantities are defined in the following in conjunction with their primary measurement methods.

The *magnetic field* H , or *flux density* B , (which are equivalent in free space) are measured with Hall probes, inductive probes (e.g. flux-gate magnetometers for very low fields) or nuclear magnetic resonance (NMR) probes for very high accuracy.

Magnetic moments are measured by different types of magnetometers

- via the force exerted by a magnetic field gradient [e.g. Faraday balance, or alternating gradient magnetometer (AGM)]
- via the voltage induced in a pick-up coil by the motion of the sample, e.g. the vibrating-sample magnetometer (VSM) is a widely used standard instrument, or a superconducting quantum interference device (SQUID) magnetometer for highest sensitivity

The (average) *magnetization* of a magnetic object is usually determined by dividing the magnetic moment by the volume of the sample. Care must also be taken concerning the vector component of the magnetic moment that is detected. This is crucial in the case of samples with a significant magnetic anisotropy which can even result from the shape of the specimen (see Sect. 10.1.1).

All these instruments need careful calibration. This is important because the effective calibration factors depend more or less on the size and shape of the specimen.

Magnetic moments related to different chemical elements in a specimen can be measured selectively by means of magnetic X-ray circular dichroism (MXCD) using circularly polarized X-rays from a suitable synchrotron radiation source. In principle, this method

Quantity	Symbol	Unit
Magnetic field	H	[A/m]
Magnetic flux density, magnetic induction	B	[T]
Magnetic flux	Φ	[Wb]
Magnetic moment	m	[Am ²]
Magnetization ($= m/V$)	M	[A/m]
Magnetic polarization ($= \mu_0 M$)	J	[T]
Susceptibility ($= M/H$)	χ	[–]

allows the separation of orbital and spin magnetic moments.

If only the a relative value of the magnetization is of interest and not its absolute value, then a number of different methods can be used to measure, for instance, M as a function of temperature or of the applied magnetic field. Such methods include magneto-optic effects [e.g. the magneto-optic Kerr effect (MOKE)] or the magnetic hyperfine field measured by using the Mößbauer

effect, perturbed angular correlations (PAC) of gamma emission, or nuclear magnetic resonance (NMR). While MOKE is widely used for characterizing magnetic materials, nuclear methods due to their relative complexity are restricted to special applications where standard techniques do not provide adequate information.

The methods most commonly used for characterizing different magnetic materials are discussed in the following sections.

10.2 Soft and Hard Magnetic Materials: (Standard) Measurement Techniques for Properties Related to the $B(H)$ Loop

10.2.1 Introduction

During the past 100 years many different methods have been developed for the measurement of magnetic material properties and sophisticated fixtures, yokes and coil systems have been designed. Many of them vanished when new materials required extended measuring conditions. With progress in electronic measuring techniques other instruments were superseded. Fluxmeters and

Hall-effect field-strength meters, for example, replaced ballistic galvanometers and rotating coils. Comprehensive explanations of the older methods can be found in [10.2] and [10.3]. New methods are ready to enter magnetic measuring technique. One new opportunity is for the pulse field magnetometer (PFM), which is discussed in Sect. 10.3. This device can complement the capabilities of a hysteresisgraph for hard magnetic materials, although it should be mentioned that the in-

Table 10.1 Measuring methods for properties of magnetic materials

Measuring method	Soft / Hard	Quantities
Hysteresisgraph for hard magnetic materials	H	$J(H)$, $B(H)$, B_r , H_{cJ} , H_{cB} , $(BH)_{\max}$, μ_{rec}
Vibrating-sample magnetometer (VSM)	H, (S)	J_s , $J(H)$, B_r , H_{cJ} , H_{cB} , $(BH)_{\max}$, μ_{rec} , $J(T)$, T_c
Torque magnetometer	H, (S)	Anisotropy constants
Moment-measuring coil (Helmholtz)	H	J (at working point)
Pulse field magnetometer (PFM) (Sect. 10.4)	H	J_s , $J(H)$, $B(H)$, B_r , H_{cJ} , H_{cB} , $(BH)_{\max}$
DC hysteresisgraph for soft magnetic materials—ring method	S	J_s , $B(H)$, B_r , H_{cB} , $\mu(H)$, μ_i , μ_{\max} , P
DC hysteresisgraph (permeameter) for soft magnetic materials—yoke methods	S	J_s , $J(H)$, $B(H)$, B_r , H_{cJ} , H_{cB} , μ_i , μ_{\max} , P
Coercimeter	S, (H)	H_{cJ}
AC hysteresisgraph—ring method	S	J_s , $B(H)$, B_r , H_{cB} , P_w
Epstein frame	S	P_w , $J(H)$, B_r , H_{cJ}
Single-sheet tester (SST)	S	P_w , $J(H)$, B_r , H_{cJ}
Wattmeter method	S	P_w
Voltmeter-ammeter method	S	P_w , μ_a
Saturation coil	S	J_s , μ_r
Magnetic scales (Faraday, Gouy)	S	$\mu(H)$, μ_i , μ_{\max} , $\chi(H)$, χ_i , χ_{\max} , J_s , T_c
Impedance bridges	S	$\underline{\mu} = \mu' - j\mu''$, Q , $\tan \delta$

$J_s = \mu_0 M_s$ saturation polarization; T_c : Curie temperature; $B_r = J_r$: remanence; H_{cJ} : coercivity (coercive field strength) for $J(H)$ hysteresis loop; H_{cB} : coercivity (coercive field strength) for $B(H)$ hysteresis loop; $(BH)_{\max}$: maximum energy product; $\mu = \mu_0 \mu_r$: permeability; $\chi = \mu - 1$: susceptibility; μ_r : relative permeability; μ_i , χ_i : initial permeability/susceptibility; μ_{\max} , χ_{\max} : maximum permeability/susceptibility; μ_{rec} : recoil permeability; μ_a : amplitude permeability; $\underline{\mu} = \mu' - j\mu''$: complex permeability; P : hysteresis loss; P_w : total loss; Q : Q -factor, quality factor; δ : loss angle

Table 10.2 Characteristics of measuring methods for magnetic materials

Measurement principle	Measurement range (limiting quantities)	Measurement sensitivity	Measurement reproducibility range (%)	Materials specimen type	Specimen geometry, dimensions	Methods merit	Methods demerit
Hysteresisgraph for hard magnetic materials	H_{\max} : 1.6–2.4 MA/m J_{\max} : 1.2–1.5 T	H : 0.1 kA/m J : 1 mT	H : 1–3 J : 0.5–2	Bulk permanent magnets	Cylinders, blocks, segments, (large) rings	Many quantities, standardized, easy operation	Restricted for non-plane-parallel specimens
Vibrating-sample magnetometer (VSM)	H_{\max} : 1.2–4 MA/m m_{\max} : 1 Am ² j_{\max} : 10 ^{−6} Vsm	H : 0.1 kA/m m : 10 ^{−9} Am ² , j : 10 ^{−15} Vsm	H, J : 1–3	Ferro- and paramagnetic material, amorphous or nanocrystalline alloys	Powders, thin films, ribbons, small massive samples	High sensitivity, wide specimen temperature range	Demagnetization factor to be considered
Torque magnetometer	H_{\max} : 0.8–10 MA/m L : 10 ^{−4} –10 ^{−2} Nm	1) L : 10 ^{−9} –10 ^{−7} Nm	1) L : 1–5	Ferro- and paramagnetic material	Discs, spheres, small particles, films, single crystals	High sensitivity, low temperatures possible	Restricted specimen shape, sometimes delicate instrumentation
Moment-measuring coil	j_{\max} : 10 ^{−4} –10 ^{−2} Vsm	j : 10 ^{−10} Vsm	j : 0.5–1	Bulk permanent magnets	Cylinders, blocks, rings, segments	Fast and accurate, standardized	Only for two pole magnets, one quantity
Pulse field magnetometer (PFM)	H_{\max} : 4–8 MA/m	H : 1 kA/m J : 1 mT	H, J : 1–3	Bulk permanent magnets	Cylinders, blocks, segments	High field strength, fast	Demagnetization factor, eddy currents to be considered
DC hysteresisgraph – ring method	H_{\max} : 10–20 kA/m	H : 0.01 A/m	H : 1 J : 1–2	Ferromagnetic, sintered or powder compacted rings, wound ring cores	Rings (geometries with closed magnetic path), stamped stacks of sheet	Many quantities, very low field strength possible, standardized	Requires specimen winding
DC hysteresisgraph – yoke methods	H_{\max} : 50–200 kA/m	H : 1 A/m	H : 2–3 J : 1–2	Ferromagnetic steel	Bars, strips of sheet	Many quantities, standardized	Restricted specimen dimensions and shapes
Coercimeter	H_{\max} : 20–200 kA/m	H : 0.5–1 A/m	H_c : 2–5	Ferromagnetic steel	Components of various shapes	Various specimen shapes, standardized	Only one quantity (H_c)
AC hysteresisgraph – ring method	f : 10 Hz–300 kHz	H : 0.01 A/m	J : 1–10 H : 1–2	Ferromagnetic materials	Rings (geometries with closed magnetic path), stamped stacks of sheet	Many quantities, standardized	Restricted specimen shape, requires specimen winding

Table 10.2 (cont.)

Epstein frame	$f: \leq 400 \text{ Hz}$ $\hat{J}_{\text{max}}: 1.5\text{--}1.7 \text{ T}$	$J: 1 \text{ mT}$	$J: 2\text{--}3$ $P_w: 2\text{--}7$	Ferromagnetic (electric) steel	Strips of sheet	Standardized, widespread method	Demanding specimen preparation, systematic error
Single-sheet tester (SST)	$f: 50\text{--}400 \text{ Hz}$ $\hat{H}_{\text{max}}: 1\text{--}10 \text{ kA/m}$ $\hat{J}_{\text{max}}: 0.8\text{--}1.8 \text{ T}$	$J: 1 \text{ mT}$	$J, H: 2\text{--}3$ $P_w: 1\text{--}2$	Ferromagnetic (electric) steel	Sheet	Standardized, simple specimen preparation	Large specimens in standardized version
Wattmeter method	$\hat{H}_{\text{max}}: 1\text{--}10 \text{ kA/m}$	2)	2)	Ferromagnetic (electric) steel	Rings, sheet using fixtures	Standardized method	Few quantities
Voltmeter–ammeter method	$\hat{H}_{\text{max}}: 1\text{--}10 \text{ kA/m}$	2)	2)	Ferromagnetic (electric) steel	Rings, sheet using fixtures	Fast, standardized method, common instrumentation	Few quantities
Saturation coil	$H: 100\text{--}900 \text{ kA/m}$ $j_{\text{max}}: 10^{-4}\text{--}10^{-2} \text{ Vsm}$	$j: 10^{-10} \text{ Vsm}$	$j: 1\text{--}2$	Nickel, Ni alloys, Co content in hard metals	Discs, wire, cylinders, small components	Fast, standardized method	Only one quantity, J_s limit depends on shape
Faraday scale	$H: 800\text{--}1600 \text{ kA/m}$	1)	1)	Ferro-, para- and diamagnetic materials	Small massive samples, powders, films	High sensitivity, wide temperature range, small samples	Delicate, costly instrumentation
Gouy scale	$H: 800\text{--}2400 \text{ kA/m}$	1)	1)	Para- and diamagnetic materials	Bars, vessels with liquids or gasses	High sensitivity, wide temperature range	Often delicate instrumentation, large specimen volume
Impedance bridges	$f: 1 \text{ Hz}\text{--}100 \text{ MHz}$	2)	2)	Ferro- and ferri-magnetic materials	Rings, components	Component testing close to electrical application	Requires specimen winding
